2. With normal monobasic fatty acids,⁴ one diffraction peak alters its angular position with the number of carbon atoms in the chain in such a manner that the corresponding lengths (computed by Bragg's diffraction law) vary linearly with the carbon content. This is precisely what has been found⁵ with the same fatty acids in solid form and the distances and rate of change are approximately the same in the solids and liquids. Similar causes are presumably operating in the two cases. If the solid is crystalline, the liquid has molecular groups.

3. Comparisons between the solid and liquid diffraction curves show a clear similarity. Of course the diffraction peaks are diffuse as compared with the lines with crystals. But the prominent maxima are similarly located. Krishnamurti⁶ has published comparisons of eight substances. There have also been published lauryl alcohol⁷ and capric acid⁸ diffraction curves. Triphenylmethane shows a like result. The chief maxima of intensity occur apparently at nearly the same angles of diffraction.

4. Binary solutions, where the components are miscible, show not the diffraction intensity maxima of both components, but a modification as of a single liquid. This is analogous to the case of a solid solution,⁹ and can readily be explained by the molecules of the solute participating in the molecular groups of the solvent. This is a reasonable picture of the nature of a solution.

5. The area occupied by the cross-section of a molecule of normal monobasic acids in a surface film on water¹⁰ is the area as computed by measurements within such a liquid assuming the group theory.¹¹ It is also the area computed from similar measurements on primary n-alcohols.¹² The grouping

¹¹ Morrow, reference 4.

¹² Stewart and Morrow, reference 7.

of the molecules in such a surface film is acknowledged. Similar dimensions obtained on the interior argues strongly for molecular groups.

6. The group theory leads to simultaneous measurements of two and occasionally three distances. These are in striking consistency and difficult of explanation otherwise. For example, the molecular "diameters" remain constant with increase in the length of the chain.^{11,12} Again, di-n-propyl carbinol gives three distances,¹³ of which two, 4.85 and 4.5 A.U., are consistent with the interpretation that the former is a measurement of the diameter in the direction of the branch and the latter the diameter of the chain perpendicular thereto, or the diameter of the primary n-alcohol.

7. Assuming the group theory, isomers of primary n-alcohols have been measured¹² and these have been found consistent with the usual chemical views as to structure.

8. The effect of temperature on the diffraction in liquids is, in general, similar to that in crystal powders, i.e., a shifting of the maxima to smaller angles, an increase in diffuseness and a decrease in intensity.¹⁴

9. There are two peaks with the primary n-alcohols¹² and only one with n-paraffins.¹⁵ This is in harmony with the group theory. Each series has parallel chains, but the polar molecules produce a longitudinal orderly arrangement that makes possible the second spacing of diffraction centers as found by x-rays.

10. The relative magnitude of the two diffraction peaks in case of the n-alcohols and the saturated normal fatty acids indicate that the intensity obtained by the diffraction from the parallel planes containing the lengths of the chains is much greater than from the parallel planes passing across these chains. Consideration of the structure factor in these two cases shows that a relative magnitude of this order should be anticipated if the group interpretation is correct. The quantitative details of these considerations are not yet published.

11. Quantitatively the dimensions determined by some of the diffraction maxima are much too long to refer to parts of the same molecule and must refer to intermolecular spacing.

12. The integrated intensity in the region of the chief diffraction maximum for solid (powdered crystal) and liquid triphenylmethane (results unpublished), show approximately equal values. It is difficult to see how such coherence could be obtained from a liquid without groups.

These are the more conspicuous lines of argument. But even aside from the evidence, a moment's general consideration indicates the reasonableness of the cybotactic theory. For the molecular forces are evidenced in surface tension, where there is an orderly arrangement, and, with the closeness of approach of molecules in the liquid, these forces must everywhere be of importance. These force fields introduce potentials. From Boltzmann's statistical distribution law the largest number of molecules must be at the

¹⁵ Stewart, *Phys. Rev.* **31**, 174 (1928).

least potential. It is then merely a question as to what the possible potentials are. Will the least potential be an orderly periodic arrangement or not? *A priori*, one cannot say, but such considerations would cause one to be ready to adopt the answer favored by experiments. From this view point the above twelve items of evidence seem to lead to the adoption of the cybotactic conception as the best description of the condition of least potential.

X-RAY DIFFRACTION IN OCTYL ALCOHOLS

The present contribution was made possible by Professor E. Emmet Reid of Johns Hopkins University who kindly lent samples of the twenty-

Fig. 1. X-ray diffraction; relative ionization currents of octyl alcohols.

fraction, is used. The circle containing a cross is the length of the molecule estimated from the *n*-paraffin chain dimensions obtained in an earlier article.¹⁷

Fig. 3. X-ray diffraction; relative ionization currents of octyl alcohols.

Fig. 4. Effective diameters and comparison of molecular lengths with separation of second set of diffraction planes.

CONCLUSIONS

1. *Molecular diameters.* The effective molecular diameter of octanol-1 is about 4.55×10^{-8} cm (or A.U., indicated merely by A, for the sake of brevity). This is more accurately the mean separation of planes containing parallel

¹⁷ Stewart, Phys. Rev. 32, 153 (1928). The length of a normal paraffin molecule is $1.24n + 2.70$ where *n* is the number of carbons and 2.70 is the length estimated for the two terminal hydrogen atoms. The formula is used for the alcohol molecules, save that *n* does not include the carbon atom in a branch.

molecules and, assuming a square array of the chains in a plane perpendicular thereto, this distance may be interpreted as the effective molecular diameter. It is to be noted that (1) with the group OH in a branch the diameter is not materially increased, (2) with CH₃ in a branch the diameter is increased by approximately 0.24Å for 2-methyl-, 3 methyl- and 6 methyl-heptanol 1, (3) by 0.75Å for 4-methyl-heptanol and (4) by 0.47Å for 5-methyl heptanol. Items (1), (3) and (4) are closely in accord with previous findings on isomers of primary n-alcohols,¹⁸ but the increases noted in (2) are approximately one-half as great. Also, as before, the effect on the diameter of the attachment of OH and CH₃ to the same C atom is not noticeable. The measurements are not in error by more than 0.05Å, but there are other factors to consider. For example the compounds are doubtless not of the highest practicable purity. Also, we are interpreting the grouping in the simplest possible manner, and this picture of the grouping may be only approximately true. Again, the position of the peak in the curve is a statistical result and is not obtained with a *fixed* grouping of molecules.

2. *Association of molecules.* As shown in earlier articles¹⁹ the distance computed from the position of the smaller peak depends upon the length of the molecule but cannot represent the molecular length or an integral value of it because the association produces effective diffraction centers that lie in planes not perpendicular to the molecular lengths. For the primary normal alcohols and the saturated normal fatty acids the distance between the planes was more than the length of the molecule and less than twice this distance. The interpretation was made that two polar groups were associated so that their molecules were placed end to end in the same line. Consequently the effective longitudinal diffraction centers occurred every two molecules. But the planes containing them were not perpendicular to the molecules. Thus the planar distance became less than twice the length of a molecule. In Fig. 4 of this contribution it is noticed that the determination of all the secondary peaks was not possible. But of those obtained, the computed planar distances represented in Fig. 4 convey an interesting result. All the molecules having OH at the end of the molecule or attached to the second C atom, show a distance between planes considerably greater than the computed molecular length and yet clearly less than twice this length. On the other hand when OH is attached elsewhere, the planar distance is approximately the computed molecular length. We hence have here *two different types of association. When the polar group OH is at 1 or 2, the association arranges the molecules end to end in the same line with two polar groups adjoining. When the OH is elsewhere, the associated molecules lie side by side.* This generalization is further verified by the cases of diethyl carbinol and di-n-propylcarbinol.²⁰ The computed molecular length of the former, using the same figures for distance occupied by atoms as described above, is 8.9Å, and the latter 11.38Å, whereas the distances between planes are 8.9Å and 10.5Å, respectively. Considering the

²⁰ Stewart and Skinner, reference 18.

inaccuracy of the length computed from atomic dimensions in the molecule, this is clearly an agreement.

3. *Variation in magnitude of secondary peaks.* An interesting variation in relative heights of the secondary maxima can be seen in Figs. 1 to 3. This secondary diffraction peak is the most prominent in the cases of octanol-4, 2-methyl-heptanol-4, 3-methyl-heptanol-4, 4-methyl-heptanol-4; or, in other words, given the position of the methyl group, the secondary diffraction peak is always the greatest with the OH group on the fourth carbon atom. In fact, there is a variation in magnitude through any such set. These are significant facts but their interpretation is not altogether clear. In the first place one must expect the arrangement of atoms to affect the intensity of diffraction (through the much used structure factor, F). As to the major peak, the intensity of diffraction for all is sensibly the same. The experiments required the use of very thin cylindrical glass receptacles, one for each compound. Differences in these and in the sensitivity of the ionization chamber (which is refilled only once in several months), were not large and the results for the magnitude of the diffraction intensity at the major peaks, even including these unavoidable changes mentioned agreed for all the liquids with an average deviation of 17 percent and a maximum deviation from the mean of 30 percent. And this is what should be expected for the changes in structure of these molecules would result in but little change in the structure factor when the molecular length lies in the diffracting planes. Since, then, the magnitude of intensity of the major peaks is of the same order, comparison may be made of the secondary peaks as plotted in Figs. 1, 2, and 3, assuming the major peaks the same magnitude. The difference in secondary peaks is relatively very great. The structure factor for diffracting planes perpendicular to the molecular length, or at any considerable angle, would vary greatly also. Hence this may be in part the explanation of the experimental results. But the second possible explanation is that, although the molecules may lie with lengths parallel, and give well-marked diffraction planes containing these lengths, yet the molecules may not be so regularly arranged for the other set of planes mentioned. The space arrangement longitudinally may not be so perfect. One need not choose between these two factors, for both doubtless exist in important degrees. Computations are at present being made of the probable variation in structure factor, though of course there is much conjecture involved. As to the perfection of the grouping, there now appears some enlightenment through the study of the viscosity of these liquids. In fact, the viscosity is greatest where the secondary peak is greatest. This correlation is doubtless important and will be discussed in a future article by Dr. R. L. Edwards and the author. In the foregoing it must be understood that the cybotactic condition is not one in which the "groups" are definite, having constantly the same constituents, or the same dimensions or spacing. There must be groupings to give the diffraction effects at any instant, but the effect on the ionization chamber is a statistical one.

To Professor E. Emmet Reid for the use of the octyl alcohols and to Mr. H. A. Zahl, research assistant, who is responsible for the data described herein, I wish to express my thanks.

BARKHAUSEN EFFECT II. DETERMINATION OF THE AVERAGE SIZE OF THE DISCONTINUITIES IN MAGNETIZATION

BY RICHARD M. BOZORTH AND JOY F. DILLINGER
BELL TELEPHONE LABORATORIES, NEW YORK, N. Y.

(Received February 12, 1930)

ABSTRACT

When the magnetic field-strength acting on a ferromagnetic material is changed, the magnetization changes discontinuously (Barkhausen effect). These discontinuous changes have been examined in 1 mm wires; an expression is derived and experimental arrangements are described for determining their average size for a given material in a given state of magnetization.

Experimental determinations of the average size have been made for iron (including a single crystal and a hard-drawn wire), nickel, and several iron-nickel alloys (permalloys). The average size is greatest on or near the steepest part of the hysteresis loop. The greatest average size, expressed as the volume of material the magnetization of which must be changed from saturation in one sense to saturation in the opposite sense to produce the same change in magnetization, is much the same for all of the materials examined, the extremes being 1.2×10^{-9} cm³ for annealed iron and 45×10^{-9} cm³ for 50 percent nickel permalloy. This shows that the sizes of the discontinuities do not depend to any considerable extent on the size or kind of crystals.

Criticism is made of previous work on the size of the coherence region, the region within which the change in magnetization is confined. Although the effect of a single discontinuity in magnetization may be detected as far as 10 cm from its source because of the eddy-currents induced, the experimental evidence is consistent with the view that the permanent change in magnetization is confined to the volume in terms of which the size of the discontinuity is measured as stated above, always less than 10^{-6} cm³.

INTRODUCTION

IT IS a well-established fact that when a continuously-varying magnetic field is applied to a ferromagnetic substance, the induction varies not smoothly, but by sharp sudden jumps or "discontinuities." One may interpret it by supposing that the substance is made up of very small regions or "units," each of which is always magnetized to saturation, and that during the magnetization of the sample, the magnetic axes of half of these are reversed, one after another. The volume v of each unit may then be computed from the amount of the corresponding discontinuity. Of course, it may be that the change in the magnetic moment of a unit is less drastic than a complete reversal of all the atomic magnets; in that case, the value of v computed by our formula will be proportionately smaller than the actual volume of the region. However, it is simpler, and we believe also that for discontinuities on the steeper parts of the hysteresis loops it is correct, to interpret v in the first-mentioned manner.

We wish to know the average sizes of these units for as many ferromagnetic materials and as many parts of the magnetization curve as possible. Especially we wish to compare it with the sizes of the crystals on one hand, of the smallest magnetizable atom-groups on the other. For instance, one of us¹ has shown, for a variety of materials, that on the steeper parts of the hysteresis loop nearly all the discontinuities correspond to units larger than 10^{-13} cm³, comprising more than 10^{10} atoms.

In the present work we have obtained data relevant to these questions by determining the average amount of the discontinuities on various segments of the hysteresis-loops of several substances: iron, nickel, several permalloys both annealed and hard-worked, and a single crystal of iron.

THEORY

In our apparatus a slowly and uniformly changing magnetic field acts on the cylindrical specimen *P*, Fig. 1. When a sudden change, characteristic of the Barkhausen effect, occurs in the induction *B* in the sample, an e.m.f.

Fig. 1. Diagram of the apparatus.

is induced in one of the search coils *S* which are connected in series opposition to the input of an amplifier. At any instant the e.m.f. impressed on the amplifier is equal to the algebraic sum of the separate e.m.f.'s induced in the two coils. The e.m.f. in each coil is proportional to the dB/dt in the material inside of that coil, consequently when the coils are connected in opposition the e.m.f. acting on the amplifier, and the output current, i , are proportional to the difference between the values of dB/dt within the two coils. Considering dB/dt in one coil to be positive and that in the other to be negative, the difference is $(dB/dt)_1 + (dB/dt)_2$, and the mean value of this sum, or $\overline{dB/dt}$ for the combination, is zero. The thermocouple *T* measures $\overline{i^2}$ (the mean value of i^2) which is then proportional to $\overline{(dB/dt)^2}$. We can now use a statistical relation derived by T. C. Fry,² provided the following assumptions are valid:

(1) The law of superposition holds; that is, the e.m.f. impressed on the amplifier at any time is the algebraic sum of the separate e.m.f.'s induced by separate sudden changes in induction.

(2) The discontinuities are random in character both as to magnitude and time; that is, the magnitude and exact time of beginning of any sudden change in induction is independent of previous changes.

¹ R. M. Bozorth, Phys. Rev. **34**, 772-784 (1929). See also an abstract of the present paper, Phys. Rev. **33**, 1071 (1929).

² T. C. Fry, J. Frank. Inst. **199**, 203-220 (1925).

(3) The form of the induction-vs-time relation is the same for all the impulses produced by the various discontinuities; that is, any impulse is identical with the product of any other by some constant factor.

(4) The time required for the thermocouple reading to reach a steady value is large compared to the duration of a single current impulse but small compared to the gross changes in the output of the amplifier, corresponding to what may be considered changes in the magnetic state of the material.

These assumptions are valid except in relatively minor details. Assumption (2) is not exactly true unless the material inside one search coil has exactly the same magnetic characteristics as that inside the other. In reality materials are not quite homogeneous. Assumption (3) implies that the magnetization in a small volume changes very suddenly but that the e.m.f. induced in the search coil is influenced by the rate of decay of the eddy-currents set up by the change in magnetization. If these small volumes are located at different distances from the axis of the sample, the eddy-currents will decay at slightly different rates and assumption (3) is not strictly correct.

The equation derived by Fry is

$$S = \bar{\nu} \bar{w}, \quad (1)$$

where S is the power expended in the thermocouple, $\bar{\nu}$ the mean number of separate impulses occurring per second, and \bar{w} is the average energy expended in the thermocouple by a single impulse. Obviously,

$$S = \bar{i}^2 R, \quad (2)$$

where R is the resistance of the thermocouple and \bar{i}^2 is the mean square current through it. The mean frequency of the impulses, $\bar{\nu}$, may be expressed in terms of the average volume of material, \bar{v} , the magnetization of which is assumed to change from saturation in one direction to saturation in the other:

$$dB/dt = 8\pi I_s \bar{\nu} \bar{v} / V, \quad (3)$$

where I_s is the saturation value of magnetization and V is the total volume of the sample in which magnetic discontinuities affect the search coils.³ The energy w for one discontinuity is

$$w = \int_0^\infty i_1^2 R dt, \quad (4)$$

where i_1 is the current (a function of time) which would flow in the thermocouple if a single isolated discontinuity occurred in the sample. This current is proportional to the rate of change of induction during this single event,

$$i_1 = A \pi r^2 dB_1 / dt, \quad (5)$$

³ B is used here as an approximation for $B-H$, since in these experiments H is always small compared with B . The apparatus measures changes in $B-H$ rather than in B .

where A is a constant determined by calibrating the apparatus and r is the radius of the sample. Also, for a single impulse the induction will be a function of time,

$$B_1 = \frac{8\pi I_s v}{V} f(\tau), \quad (6)$$

where $f(\tau)$ is the same function of time for all impulses (assumption 3) and is determined by the decay of eddy-currents, and v is the volume which changes in magnetization.

Combining Eqs. (4), (5) and (6), and taking the mean value,

$$\overline{w} = 64\pi^4 A^2 R I_s^2 r^4 (\overline{v^2}/V^2) \int_0^\infty [f'(\tau)]^2 d\tau.$$

Using also Eqs. (1), (2) and (3), and putting $V/\pi r^2 = l$, the length of the specimen which affects the search coils, we have the result

$$\frac{\overline{v^2}}{\overline{v}} = \frac{l \overline{v^2}}{8\pi^2 A^2 I_s r^2 dB/dt \int_0^\infty [f'(\tau)]^2 d\tau}. \quad (7)$$

The function $f(\tau)$ is subject to the condition that $f(\infty) = 1$. Its time derivative, $f'(\tau)$, characterizing the decay of eddy-currents, might be determined experimentally as a function of μ , ρ and r by using a suitable oscillograph to record the wave-form of the current impulses, caused by single Barkhausen discontinuities, which pass through the thermocouple heater. Since the recording of these wave-forms puts a very severe requirement on the oscillograph, and since it is a laborious undertaking in any case to determine $f'(\tau)$ completely in terms of μ , ρ and r , we have used the expression derived by Wwedensky⁴ and supported by experiment. For a spontaneous change in magnetization, we find

$$\int_0^\infty [f'(\tau)]^2 d\tau = \frac{2(10)^9 \rho}{\pi r^2 \mu}, \quad (8)$$

where ρ is the resistivity in ohm-cm, and μ is the permeability which controls the rate of decay of eddy-currents, in this case the reversible permeability or permeability for small alternating fields. Substituting Eq. (8) in Eq. (7),

$$\frac{\overline{v^2}}{\overline{v}} = \frac{l \mu \overline{v^2}}{16\pi(10)^9 A^2 I_s \rho dB/dt}. \quad (9)$$

Wwedensky's expression was derived for a long cylinder the magnetization of which is uniform, consequently Eq. (8) is not strictly applicable to the present problem and must be considered as an approximation. Even if the

⁴ B. Wwedensky, Ann. d. Physik **64**, 609-620 (1921).

sudden change in magnetization occurs entirely within a volume small compared to the cube of the radius of the specimen, the disturbance will spread along the axis of the wire to an extent depending on the permeability, resistivity, and diameter of the wire. The extent of the disturbance, necessary for choosing the proper value of l to be used in equation (9), can be determined as described in the next section.

The ratio \bar{v}^2/\bar{v}^2 is very near unity for most distribution functions, but may in certain cases be very large. One of us¹ has shown that there are very few discontinuities corresponding to volumes several orders of magnitude smaller than the average. Taking this into consideration, we may with reasonable safety extrapolate to the origin the size distribution curve determined by Tyndall⁵ for silicon steel. For the curve so extrapolated we find that $\bar{v}^2/\bar{v}^2 = 0.7$, a value sufficiently close to unity to make \bar{v}^2/\bar{v} , as given by Eq. (9), a reasonably good approximation to \bar{v} , the average volume in which we are interested.

All of the quantities on the right-hand side of Eq. (9) can be determined experimentally without unusual difficulties, as described below.

APPLICATION TO EXPERIMENT

Fig. 1 shows the experimental arrangement for measuring \bar{v}^2 of Eq. (9). The magnetizing coil, M , is 60 cm long; each search coil is 3.8 cm long, 1.7 cm outside diameter, 0.4 cm inside diameter, and is wound with 10,000 turns of No. 40 B.E.S.S. copper wire. The samples are 60 cm long and 1 mm in diameter. The magnetizing coil is supported on rubber bands in a permalloy shield 5 mm thick to protect it from mechanical and magnetic disturbances. The arrangement for changing the magnetic field slowly and uniformly is that described previously.¹ The amplifier is resistance-capacity coupled with resistances of 70,000 ohms and capacities of one microfarad. For the first stage a screened grid vacuum tube is used (Western Electric 246-A), for the next five stages 239-A tubes, and for the last stage a 104-D tube. The amplification may be varied by using different taps on the input resistance of the second stage. The space current of the last tube passes through the primary of a transformer the secondary of which is connected to the heater of a thermocouple. The impedances of the transformer match respectively the impedances of the vacuum tube in the last stage of the amplifier and the heating element of the thermocouple. The thermocouple is connected to a critically damped Moll galvanometer, G , the deflections of which are recorded on photographic paper mounted on a rotating drum. With this arrangement the deflection δ of the galvanometer, as measured on the paper, is proportional to the mean value of the power expended in the thermocouple heating element, i.e., $\delta \propto \bar{v}^2$.

The mean rate of change of induction, dB/dt , is determined by observing dB/dH and dH/dt separately. To determine dB/dH , the two search coils are connected in series aiding to the Moll galvanometer and the field is changed at a uniform rate. The galvanometer deflection, proportional to

⁵ E. P. T. Tyndall, Phys. Rev. 24, 439-451 (1924).

dB/dH , is recorded photographically as before. The calibration is made by integrating the dB/dH -vs.- H curve and comparing it with the total change in B as determined in the usual way with a ballistic galvanometer. Lines indicating predetermined values of H are marked on the paper by flashing a light when the field-strength passes through these values.

The rate of change of field-strength, dH/dt , is determined by noting with a stop-watch the times at which the needle of the milliammeter in the magnetizing circuit passes through chosen positions.

The reversible permeability μ is determined by subjecting the sample to the small sinusoidal field created in a small single-layer "calibrating coil" inside the search coils and magnetizing coil. A measured current, i_s , of frequency 5 cycles/sec is passed through the calibrating coil, the search coils are connected to the amplifier in series aiding and the deflection of the galvanometer, δ_s , noted for a given value of H , the strength of the steady field produced by the magnetizing coil. The calibration for determining μ is made by removing the sample and observing the deflection δ_c , when a larger current, i_c , of the same frequency passes through the calibrating coil. The permeability may then be calculated as follows. The root mean square current passing through the heater of the thermocouple is proportional to the root mean square rate of change of flux threading the search coils. Since δ is proportional to the square of the current,

$$\delta_s^{1/2} = K i_s (\mu A_s + A_c - A_s),$$

and

$$\delta_c^{1/2} = K i_c A_c,$$

where A_s is the cross-sectional area of the sample, A_c that of the calibrating coil, and K a proportionality constant. The permeability is then given by:

$$\mu = \frac{A_c i_c \delta_s^{1/2}}{A_s i_s \delta_c^{1/2}} - \frac{A_c - A_s}{A_s}$$

and must be determined for various values of H . For the coil and samples used, $A_c = 0.083 \text{ cm}^2$ and $A_s = 0.0081 \text{ cm}^2$ so that

$$\mu = \frac{10.2 i_c \delta_s^{1/2}}{i_s \delta_c^{1/2}} - 9.2.$$

The maximum value of the alternating field-strength, calculated from i_s and the number of turns per unit length of the calibrating coil, was kept as low as 0.001 gauss for the more permeable materials.

The values of μ so determined were checked in several cases with those determined with a ballistic galvanometer by measuring ΔB for a change ΔH after several reversals of the field-strength between H and $H + \Delta H$, and extrapolating for the value of $\Delta B/\Delta H$ at $\Delta H = 0$.

The factor A in Eqs. (5) and (9) is the ratio of the current in the thermocouple heater to the rate of change of flux inside the search coils. This is determined by producing a known sinusoidal rate of change of flux in the

calibrating coil and measuring the amplifier output i at the same time. If i_c is the root mean square current in milliamperes through the calibrating coil, f the frequency of the current, n the number of turns of wire per cm, and A_c the cross-sectional area, the root mean square value of the rate of change of flux is

$$(d\phi/dt)_c = 8\pi^2 n A_c f i_c (10)^{-4}$$

and therefore

$$A = \frac{i}{d\phi/dt} = \frac{10^4 i'}{8\pi^2 n A_c f i_c},$$

where i' is the root mean square value of i measured at the same time as i_c . Since i' is proportional to $\delta'^{1/2}$ and i is similarly proportional to $\delta^{1/2}$, we may rewrite Eq. (9) as

$$\frac{\bar{v}^2}{\bar{v}} = \frac{l\mu\delta}{16\pi(10)^9 C^2 I_s \rho dB/dt} \quad (10)$$

where

$$C = \frac{(10)^4 \delta'^{1/2}}{8\pi^2 n A_c f i_c} \quad (11)$$

The calibrating deflection δ' is recorded on the same paper as the deflections δ caused by the Barkhausen discontinuities. Since the value of \bar{C} depends on f directly as expressed by Eq. (11) and indirectly through the frequency

Fig. 2. Frequency characteristics of the apparatus (amplifier, transformer, thermocouple and galvanometer).

characteristics of the apparatus, the amplification was measured for a series of frequencies. At each frequency 0.7 milliampere was passed through a fixed resistance of 0.1 ohm connected to the input of the amplifier in parallel with the search coils, and the deflection of the galvanometer noted. The results are shown in Fig. 2. The range of frequencies shown is sufficient to record accurately the Barkhausen impulses in the materials examined. Calibration was made at the frequency of 60 cycles/sec., and the value of C^2 so obtained has been multiplied by 2 to take account of the lower amplification at this frequency, compared with that in the range of 300 to 5000 cycles.

To determine the length of the sample, l , in which discontinuities will affect the search coils, it is necessary to know how the intensity of a magnetic disturbance decreases with the distance from its source. This was determined experimentally for a disturbance produced by a sinusoidal current flowing in a few turns of fine wire wound directly on a specimen. The law of decay of intensity with distance once determined, it was assumed that the magnetic disturbance caused by a discontinuity in magnetization started at a point and spread along the wire according to this same law. On the basis of this assumption a calculation was made of the change in the observed Barkhausen effect, as measured by the galvanometer deflection δ , when the two search coils (connected in series opposing) were brought closer and closer together,

Fig. 3. Decay of magnetic disturbance with distance along wires of different permeabilities.

and this calculation was compared with observation. Ten turns of No. 40 wire were wound closely around the middle of a piece of annealed permalloy containing 81 percent Ni, and a current of 0.5 milliamperes of frequency 35 cycles/sec. was passed through it. Two search coils of 0.15 cm inside diameter and 1.3 cm length were placed at equal distances on each side of the 10-turn coil and the deflection δ_1 of the galvanometer noted for various distances x_1 between the small coil and the centers of the search coils. The results (Fig. 3) show that $\delta_1 = C_1 e^{-ax_1}$, where C_1 and a are constants. Assuming that the rate of change of magnetic flux, $d\phi/dt$, at each point along the sample follows this exponential law, and remembering that $d\phi/dt$ is proportional to $\delta^{1/2}$, we have

$$d(\delta)^{1/2} = C_2 e^{-ax/2} dx \quad (12)$$

for each point along the wire. Since the total effect is obtained by adding the value of $\delta^{1/2}$ contributed by each element along the wire, in a search coil of length l_1 we have

$$\delta_1^{1/2} = \int_{x_1-l_1/2}^{x_1+l_1/2} C_2 e^{-ax/2} dx \quad (13)$$

or

$$\delta_1 = \frac{4C_2}{a^2} (e^{al/4} - e^{-al/4})^2 e^{-ax_1},$$

agreeing with the experimentally determined relation in that $d \ln \delta_1 / dx_1 = -a$. For the sample described above, $a = 0.60$.

Applying Eq. (12) to the Barkhausen effect, we get Eq. (13) for each discontinuity in magnetization which starts at a point in the sample outside of the search coil. For points inside of the search coil,

$$\delta_1^{1/2} = \int_0^{x_1+l_1/2} C_2 e^{-ax/2} dx + \int_0^{x_1+l_1/2} C_2 e^{-ax/2} dx,$$

and integrating for all points on the sample the galvanometer deflection δ is given by

$$\delta^{1/2} = 2 \int_{l_1/2}^{\infty} \delta_1^{1/2} dx_1 + 2 \int_0^{l_1/2} \delta_1^{1/2} dx_1,$$

or,

$$\delta = 16C_2^2 l_1^2 / a^2. \quad (14)$$

To determine the equivalent length l of Eq. (10), used when two search coils are connected in series opposing, δ is recalculated assuming that all impulses originating at points within a length $l/2$ of the specimen affect all turns of one search coil as much as a real impulse occurring within a search coil affects the turns immediately adjacent. This substitutes for Eq. (12),

$$d(\delta)^{1/2} = C_2 dx, \quad (12')$$

for Eq. (13)

$$\delta_1^{1/2} = \int_{x_1-l/2}^{x_1+l/2} C_2 dx = C_2 l, \quad (13')$$

and for Eq. (14)

$$\delta^{1/2} = \int_0^{l/2} \delta_1^{1/2} dx_1 = C_2 l l / 2,$$

or,

$$\delta = C_2^2 l_1^2 l^2 / 4. \quad (14')$$

Comparison with (14) shows that $l = 8/a$ independent of l_1 , the length of each search coil. The value of a is determined experimentally as described above. The data are shown graphically in Fig. 3. A variation in the frequency of the alternating current used in this experiment between 10 and 1000 cycles per

second showed only a slight change in a with frequency. The same experiment was repeated using a hard-drawn wire of the same composition and diameter and a for this sample was found to be 3.22. The ratio of the values of a for these two samples is 5.4, nearly equal to the inverse ratio of the square-roots of their permeabilities, namely $(2510/75)^{1/2} = 5.8$. It is concluded that l is proportional to $\mu^{1/2}$, when the resistivity is constant. If the resistivity ρ varies, l must be proportional to $(\mu/\rho)^{1/2}$ since it is only in the ratio μ/ρ that μ and ρ appear in Maxwell's equations. Using the directly determined value of a for the sample with $\mu = 2510$ and $\rho = 15(10)^{-6}$ ohm-cm, we can therefore finally put

$$l = 1.03(10)^{-3}(\mu/\rho)^{1/2}. \quad (15)$$

A more extensive analysis of the dependence of δ on the distance, y , between the two search coils used in measuring the Barkhausen effect, shows that a may also be determined from the relation between δ and y . Such a determination has been made for one sample and found to agree with the determination as described above.

Combining Eq. (14) with Eq. (10) and designating the ratio \bar{v}^2/\bar{v} by v , we have

$$v = \frac{2.0(10)^{-14}\mu^{3/2}\delta}{C^2 I_s \rho^{3/2} (dB/dH) (dH/dt)} \quad (16)$$

in which all of the quantities are already known or can be determined as described in this section.

THE EXPERIMENTAL RESULTS

The following materials were examined in the form of wires 60 cm long and 0.1 cm in diameter:

Armco iron, hard drawn.

Armco iron, vacuum annealed 2 hrs. at 1000°C, cooled 300°/hr.

Large crystals of Fe⁶.

Nickel, vacuum annealed 2 hrs. at 1100°C, cooled 300°/hr.

Permalloy, 80.5 percent Ni, vacuum annealed 1 hr. at 1200°C, 2 min. at 830°C, cooled about 1000°/min.

Permalloy, 78.1 percent Ni, vacuum annealed 1 hr. at 1100°C, cooled about 1000°/hr.

Permalloy, 50 percent Ni, vacuum annealed 2 hrs. at 1100°C, cooled 300°/hr.

Figs. 4 to 6 show the photographically registered curves dB/dH — $vs.$ — H for annealed iron, permalloy with 80.5 percent Ni, and permalloy with 50 percent Ni. In taking the photographs, as described in the previous section, the field-strength was varied slowly enough to enable the galvanometer to follow the gross changes in dB/dH , but not slowly enough to record the

⁶ We are indebted to Dr. D. Foster of these Laboratories for these crystals. For their preparation and properties, see Phys. Rev. 33, 1071 (1929).

individual discontinuities. It will be noticed that when the Barkhausen effect is large the curve is relatively irregular. Two photographs of each curve are reproduced to show that some irregularities are due to chance and are different in each run, and that some are permanent characteristics of the material and are reproduced during each magnetic cycle. Irregularities of both kinds are present but difficult to detect when hysteresis

Fig. 4. Galvanometer record of dB/dH for annealed iron.

loops are determined in the usual way with a ballistic galvanometer, small variations from a smooth curve being generally indistinguishable from experimental errors.

The regular procedure was modified slightly for measurements on the large crystals. From a 1 mm wire composed entirely of long crystals, two segments were cut, each 14 cm in length, one containing a single crystal

Fig. 5. Galvanometer record of dB/dH for permalloy containing 80.5 percent nickel and 19.5 percent iron.

Fig. 6. Galvanometer record of dB/dH for permalloy containing 50 percent nickel and 50 percent iron.

7.2 cm long and the other a single crystal 8.6 cm long, each single crystal occupying the central portion of its segment. The remainder of the two pieces consisted of only four separate crystals, one at each end of the two longest crystals. One search coil was placed around the middle of each of the two segments, the nearest ends of which were 3 cm apart, and measurements of dB/dH , δ , and μ made without moving the specimens of coils.

Fig. 13. The v -curve for nickel, and the data from which it was calculated.

runs for annealed iron and permalloy containing 80.5 percent nickel indicate how well the data can be repeated.

According to Eq. (16) the galvanometer deflection δ should be proportional to the rate of change of magnetic field-strength, dH/dt , when the other variables are fixed. Fig. 10(a) shows that this relation was observed, and for

Fig. 14. The v -curve for permalloy containing 80.5 percent nickel and 19.5 percent iron, and the data from which it was calculated.

comparison Fig. 10(b) shows the linear relation between the calibrating current, i_c , and the corresponding deflection δ' , which appears in Eq. (11).

Fig. 11 shows an example of a μ -vs.- H curve determined with alternating current of frequency 5 cycles/sec, and for comparison several points determined with a ballistic galvanometer.

Fig. 16. The v -curve for permalloy containing 50 percent nickel and 50 percent iron, and the data from which it was calculated.

The average volume, v , of the discontinuities in magnetization was calculated in accordance with Eq. (16) for all of the materials. The curves showing v as dependent upon field-strength are shown in Figs. 12 to 18, together with the curves from which the calculations were made. In making

these calculations, small irregularities in the original dB/dH and δ curves were smoothed out, as can be seen for example by comparing Figs. 4, 7, and 12. Finally, Figs. 19 to 25 show how the v -vs.- H curves are placed with respect to the hysteresis loops.

Fig. 17. The v -curve for hard iron, and the data from which it was calculated.

Fig. 18. The v -curve for two single crystals of iron.

DISCUSSION OF THE RESULTS

Figs. 12 to 18, as well as Figs. 19 to 25, show how the average size of the discontinuities varies from one part of the hysteresis loop to another with

Fig. 19. Hysteresis loop and v -curve for annealed iron.

different materials. The data for annealed iron are more extensive than for the other materials and have been taken over the whole hysteresis loop,

between -10 and $+10$ gauss. When the slope of the hysteresis curve is relatively small, there is some question as to whether the discontinuous changes in magnetization are due to complete magnetic reversals of small

Fig. 20. Hysteresis loop and v -curve for nickel.

parts of the material or whether the reversals are only partially complete, as mentioned in the introduction. Although for this reason the determination of the mean volume of the discontinuities in this case may not be accurate,

Fig. 21. Hysteresis loop and v -curve for permalloy containing 80.5 percent nickel and 19.5 percent iron.

the data do show, contrary to previous reports, that discontinuities are present throughout the whole cycle. Fig. 26 is a reproduction of the galvanometer record of the Barkhausen effect at the very beginning of the hysteresis

loop for iron, and has been included to show that with sufficiently high amplification the effect is measurable even though dB/dH is as small as 40. It seems possible that the magnetization changes discontinuously in all cases, even

Fig. 22. Hysteresis loop and ν -curve for permalloy containing 78 percent nickel and 22 percent iron.

though the material is nearly saturated, and that the discontinuities have been detected only on the steeper parts of the curve because the amplification available has not been sufficient to detect them on the parts less steep.

Fig. 23. Hysteresis loop and ν -curve for permalloy containing 50 percent nickel and 50 percent iron.

The average volume of material in which the magnetization changes as a unit is found to have a maximum value of the order of $(10)^{-8}$ or $(10)^{-9}$ cm^3 for the materials examined. The maximum values vary only from 1.2

$(10)^{-9}$ cm³ for iron to $45 (10)^{-9}$ cm³ for permalloy containing 50 percent Ni. These volumes are entirely different in order of magnitude from the volume occupied by the crystals in the "single" crystal specimen, which is much

Fig. 24. Hysteresis loop and v -curve for hard drawn iron.

greater; from that occupied by the separate crystals in the hard-worked sample of iron, which is vastly smaller; and also from the volume occupied by a single atom or even by a group of atoms known to be large enough to

Fig. 25. Hysteresis loop and v -curve for two single crystals of iron.

be oriented by an applied magnetic field, which is very much smaller yet. We regard as a mere coincidence the fact that it is of the same order as the volume occupied by the separate crystals in many well annealed materials.

We conclude that the sizes of the Barkhausen discontinuities are independent of crystal size, and of the nature of the grouping of the atoms of ferromagnetic materials both in respect to the type of lattice upon which the crystal is built, and to the distribution of the different kinds of atoms in alloys.

It is rather surprising at first glance that the computed volumes of the groups should have so nearly the same average value for substances so different. One might expect that, if the magnetization of a group is initiated by the reversal of a single atomic magnet the energy so liberated will aid other magnets to reverse to an extent depending both upon the amount of energy liberated (proportional to the coercive force) and upon the number of other magnets which are about to reverse (proportional to dB/dH). If the coercive force is small and the sides of the hysteresis loop are steep, the initial energy liberated will be small, but there will be a comparatively

Fig. 26. Barkhausen effect at the beginning of the hysteresis loop for iron, using high amplification

large number of magnets that need but a small disturbance to turn them. If the coercive force is large, the sides of the hysteresis loop are generally less steep. We imagine that these two factors compensate each other, resulting in a relatively constant size of discontinuities in different materials.

The position of the maxima of the v -vs.- H curves for hard and annealed iron and for nickel are near the coercive force, but for the three alloys are definitely displaced to higher values of H . It may be that the positions of these maxima correspond in each case to those for the thermal cooling attending magnetization, observed by Ellwood⁷ for steel at magnetizations near the knee of the hysteresis loop.

Our experiments show that the number and size of the discontinuities do not depend on the rate of change of field-strength. As Fig. 10 shows, δ is accurately proportional to dH/dt and this relation implies that the number and size remain constant. For the same total discontinuous change in B , an increase in the average size of the discontinuities and a consequent decrease in their number would be attended by an increase in the ratio of

⁷ W. B. Ellwood, *Nature* **123**, 797-798 (1929).

δ to dH/dt , in contradiction to our findings. Although this linear relation has been found to hold for all of the specimens we have examined, it may not of course hold for the fine wires examined by Heaps and Taylor⁸, where the linear extent of the discontinuity is comparable with the diameter of the wire.

Pfaffenberger⁹ has reported that the length of the coherence region, within which the discontinuous change is confined, is 3 mm in a steel wire 0.5 mm in diameter. The implication is that during a single discontinuous change in magnetization elementary magnets scattered throughout a volume of about 1 mm^3 are permanently reversed, but that these elementary magnets, if placed next to each other, would occupy a small part, perhaps 10^{-3} , of this volume, corresponding to our volume v . In view of the experiments on the determination of l , described above, we conclude that this 3 mm length is the extent of the region in which the eddy-currents are produced in this sample of steel by the sudden change in magnetization. If Eq. (15) holds for wires 0.5 mm in diameter, we find for Pfaffenberger's sample, using $l/2=0.3$, that $\mu=2.3$. Since Eq. (15) has been established only for wires of radius 0.5 mm, it may be that the more general equation will include some function of the radius. If, for example, the equation is

$$l = 1.03(10)^{-3}(\mu/\rho)^{1/2}r^2/(0.05)^2 \quad (15')$$

we deduce from Pfaffenberger's data that $\mu=10$, a not unreasonable figure for some kinds of steel.

The experiments described above confirm the earlier experiments¹ in showing that for the steeper parts of the hysteresis loop the volume associated with the average discontinuity is very large compared with the dimensions of the atom and seldom involves less than 10^{10} atoms. In annealed materials the average size is comparable with the size of the crystals, but this is regarded merely as a coincidence because the same sized discontinuities are found in hard-worked materials and in a single crystal. The average size is greatest at or near the steepest part of the hysteresis loop and diminishes rapidly as the ends of the loop are approached. The maximum value of the average size (the average size at or near the steepest part of the loop) is about $(10)^{-8} \text{ cm}^3$, corresponding to $(10)^{15}$ atoms, and is much the same in the different materials examined.¹⁰

⁹ J. Pfaffenberger, *Ann. d. Physik* **87**, 737-768 (1928).

¹⁰ An interesting paper by F. Preisach, *Ann. d. Physik* **3**, 737-799 (Dec. 1929) has just come to our attention. His experiments support the previous report by one of us¹ that on the steeper parts of the hysteresis loop almost all of the change in magnetization is discontinuous. Our results disagree in one important respect: Preisach states that when the magnetization diminishes from its greatest value (near to saturation) at one end of the loop, no Barkhausen effect is detectable (with a three stage voice-frequency amplifier) and the change is continuous; we have shown that with sufficiently high amplification (seven stages, wide frequency range) the effect is pronounced, as shown in Fig. 26 above. Preisach has shown that the sizes of the discontinuities in fine wires can be markedly changed by straining them, and that in some cases a single discontinuity corresponds to almost the whole possible change in magnetization of the material. We have also observed such discontinuities in fine unstrained wires of permalloy containing 78 percent nickel and 22 percent iron.

MEASUREMENT OF THE INTENSITY OF HIGH
FREQUENCY MAGNETIC FIELDS

BY ROY H. MORTIMORE

DEPARTMENT OF PHYSICS, UNIVERSITY OF IOWA

(Received January 20, 1930)

ABSTRACT

Two methods are developed for the measurement of the intensity of magnetic fields produced by currents of frequencies from 10 to 25 megacycles.

By the first method, the current in a coil is computed from vacuum tube voltmeter readings of potential drop across a standard inductance. The values for current thus obtained are compared with readings of thermo-ammeters in the range for which they are calibrated. For larger currents, the instruments are shunted and calibrated for particular wave-lengths by the standard inductance method. From these known values of current the intensities of the fields which they produce are computed.

By the second method, the e.m.f. induced in a single turn coil placed in the field to be measured is indicated by a vacuum tube voltmeter. The field intensity necessary to induce the observed e.m.f. is computed. Good agreement is found between the results obtained by the two methods.

Improvements are made in vacuum tube voltmeter design which make possible their use in voltage measurements at frequencies as high as 25 megacycles.

Information regarding current distribution in a coil is obtained.

INTRODUCTION

CERTAIN aspects of measuring the intensity of magnetic fields at radio frequency are discussed by a number of investigators. The present work is different from these in that it involves measurements of field intensities in the immediate vicinity of the coil carrying the current and that it includes frequencies as high as 25 megacycles.

Since the audibility of signals in a radio receiving system is a function of the electric and magnetic fields in the vicinity of the receiving antenna, a number of methods of measuring their intensities have been developed. By the use of the siphon recorder, De Groot¹ compared the intensity of static impulses with the intensity of telegraph signals. During the years 1920 and 1921 the Bureau of Standards in an extended series of investigations relative to signal fading used the judgments of 253 observers as to the audibility of the signals in a receiving set as a measure of the intensity of the radiated fields.²

Englund and Friis³ reduced the errors in judging audibility by comparing the intensity of sounds in a receiving set due to the radiated signal with that due to a locally induced e.m.f. of known intensity. Recently, Parlin⁴

has published the results of measurements of the relative intensity and state of polarization of radiated fields at distances of 40 to 100 meters from the oscillator. One important difference between this work and that of earlier investigators is that the intensity is measured by direct galvanometer deflection instead of indirect judgments.

In all the above investigations, the measurements involve the radiated fields some distance from the oscillator rather than in the immediate vicinity of a coil carrying the current.

In dealing with the variation with frequency of the magnetic permeability of certain iron specimens, Wait⁵ had occasion to measure the intensity of magnetic fields at the center of a solenoid in the range of wave-lengths from 80 to 1700 meters (more recently⁶ in the range from 70 to 120 meters). In this work he used the standard formula $H = 4\pi nb / (b^2 + a^2)^{1/2}$ for the field intensity at the center of a solenoid of radius a and length $2b$. In the development of this formula it is assumed that the current is uniformly distributed in a cylinder whose length and radius correspond to those of the solenoid and whose thickness is vanishingly small. For the present work this formula does not hold since the dimensions of the coils used depart too far from those assumed.

I. THEORY

Computation of field intensity from current. The computation of the intensity of the field about a coil due to a high frequency a.c. in the coil as is done in the case of direct current, is complicated by two factors. First, no instruments are available which will accurately measure high frequency currents of any considerable magnitude; second, the distributed capacity of the coil causes a non-uniformity in the current distribution throughout the coil.

In meeting these difficulties, the measurement of current is accomplished in two ways; first, Weston thermoammeters and thermo-milliammeters with shunts to cover the desired range of current are calibrated at particular frequencies; second, vacuum tube voltmeter readings of the potential drop across standard inductances are taken and from these currents are computed. To eliminate the second complication, a Helmholtz coil of one turn in each section is constructed in which the distributed capacity is sufficiently small that the use of the standard formula⁷ for direct current is permissible.

$$H = 32\pi ni / 5^{3/2} a$$

where n is the number of turns in each section; a is the radius and i is the current in c.g.s. e.m.u.

Computation of field intensity necessary to induce observed e.m.f. in search coil. Since the e.m.f. in a single turn of wire is equal to the rate of change of magnetic flux through the area enclosed by the wire and since the flux is known to vary sinusoidally, the field intensity can be computed if the

⁵ Wait, Phys. Rev. 29, 566 (1927).

⁶ Wait, Phys. Rev. 32, 967 (1928).

⁷ S. G. Starling, Elec. & Mag. p. 57.

induced e.m.f. is known. It is obvious then, that vacuum tube voltmeter readings for e.m.f. induced in a single turn coil substituted in the formula developed below yield values for field intensity. The assumption is made that the intensity is uniform throughout the area enclosed by the coil. Such uniformity is available within a Helmholtz coil.

$$e = d\phi/dt$$

where e is the induced e.m.f. and ϕ the flux through enclosed area. Since a sinusoidal field is assumed ϕ may be written $\phi_0 \sin \omega t$ and

$$e_{\max} = \phi_0 \omega = 2\pi\nu\phi_0$$

But $\phi_0 = H_0 A$

Then $e_{\max} = 2\pi H_{\max} \nu A$ (Or r.m.s. value may be used for e and H)

$H = e/2\pi A \nu$ if e.m.u. are used

$H = E \times 10^8 / 2\pi A \nu$ using volts, gauss and cm^2

Thus we have a formula for H in terms of measurable quantities.

II. APPARATUS

Oscillator. The oscillator which proved most satisfactory includes two triodes in push-pull arrangement. The circuit diagram is shown in Fig. 1. The symmetrical feed-in to the main oscillatory circuit $C_1 L_1$ through C_2 and C_3 produced a comparatively pure sine wave current in L_1 .

Fig. 1. Oscillator circuit diagram.

The intensity of the output at the first and second harmonics was tested by comparing the readings of the galvanometer of a wave meter tuned to the fundamental with those tuned to the harmonics. The oscillator output was adjusted for full scale deflection of the galvanometer of the wave meter when it was placed several feet from the oscillator. In no case was a deflection of more than a small part of one division (1/100 part of the full scale) noted when the wave meter was tuned to the harmonic frequency and placed one fifth of the above distance from the oscillator.

This circuit is used for three hook-ups. The first, employing seven and one half watt tubes is supplied with seven coils of different numbers of

turns so that a range in wave-length from 5 to 130 meters may be produced. The second, employing fifty watt tubes, covers the range from 5 to 30 meters. The third, employing two hundred fifty watt tubes covers a limited range of 12 to 20 meters.

Pick-up system. The pick-up system in which the current is brought under control is inductively coupled to the oscillator as shown in Fig. 2. L_4 is a one turn coil closely coupled to the output inductance of the oscillator. C_2 and L_5 tune the circuit in which the current is controlled. C_3 and C_1 control the position of the voltage node in circuit C_2L_5 . A_1 and A_3 are thermo-ammeter positions. The position A_2 is used variously to meet different demands. In one Helmholtz coil it serves as a thermo-ammeter position. In another Helmholtz coil and in a 5 turn helix it is supplied with gaps for the plug-in standard inductances.

Fig. 2. Pick-up system.

Wave meter. A wave meter including a variable air condenser, an inductance and a Weston thermo-galvanometer to indicate resonance is calibrated by the Lecher wires direct measurement method.⁸ It is provided with different size coils to cover the range in wave-length from 5.7 to 32 meters. It is carefully calibrated throughout this range.

Vacuum tube voltmeter. From the large number of vacuum tube voltmeter circuits which are described in the literature⁹ the three which gave greatest promise of applicability to measurements at high frequencies were selected for investigation. The first circuit tried out is the vacuum tube multiplier described by M. Y. Colby.¹⁰ The attractive features of this circuit are its flexibility, sensitivity and small power absorption. Several calibration curves run at a frequency of 60 cycles gave satisfactory results in the neighborhood of 100 meters. For wave-lengths much shorter than 100 meters difficulties were encountered and below 20 meters the circuit was found unsatisfactory.

The circuit described by James Taylor¹¹ gave promise of satisfactory performance. Many calibration curves run at a frequency of 60 cycles were applied in the range of wave-lengths from 30 to 100 meters. Below 30 meters, however the circuit was not satisfactory since the galvanometer and filament leads are directly connected to the high frequency source.

¹¹ James Taylor, Jour. Sci. Inst. 3, 113 (1929).

The circuit, Fig. 3, which was selected as the most satisfactory for the present work is not found in the literature but has been in use in this laboratory for some time. The deflection of the Leeds and Northrup Galvanometer, G , caused by the d.c. leak off the grid and plate of the vacuum tube is proportional to the charge accumulated thereon. The capacity of C_1 and the resistance of R_1 are not critical but must be sufficiently large as to provide a time constant for the circuit large in comparison with the period of the lowest frequency used. For frequencies greater than 10 megacycles it was found necessary to insert a resistance R_2 to keep the high frequency currents out of the filament battery leads. Since R_2 holds the potential of the galvanometer and filament at the average value of that applied at T_1 (i.e., zero since the applied potential is sinusoidal), the charge on the plate and grid is proportional to the peak value of the potential variation of T_2 rather than the peak value of the potential difference between T_1 and T_2 . This requires that T_1 be attached at or near the voltage node of the circuit containing the

Fig. 3. Vacuum tube voltmeter circuit.

piece of apparatus across which the potential drop is being measured. Fig. 4 shows a typical calibration curve.

From the circuit diagram, Fig. 3, and from the photograph of the instrument, Fig. 5, it is readily seen that an instrument of this type may be designed whose fundamental wave-length is low and which is therefore readily adaptable to high frequency measurements. The total length of wire from T_2 to the grid is 15 cm and the capacity of the vacuum tube is reduced to a minimum by the removal of the base and separation of the leads. To test for the fundamental wave-length of the circuit a thermo-galvanometer was connected across the terminals T , R_2 was shunted by a good conductor and the instrument closely coupled to an oscillator whose output wave-length was varied from 12 to 5.7 meters. No deflection was observed. Similar tests on other instruments whose leads were longer and not so well arranged showed distinct resonance points corresponding to 9 and 16 meters. Thus, it was shown that the natural wave-length of this instrument is somewhat below 5.7 meters.

Helmholtz coils. Two Helmholtz coils were constructed to produce the uniform fields necessary for the search coil method of measurement. The

two differ only in that one is provided with a gap between the turns so that an ammeter may be inserted. The radius of each turn and the distance between the two turns is 8 cm. Substituting these dimensions in the formula (1) for field intensity at the center we get 0.1125 gauss per ampere.

Fig. 4. Vacuum tube voltmeter calibration curve.

Standard inductances. The standard inductances are made from two brass cylinders of different diameters a and b arranged coaxially. One end of each is soldered to the adjacent end of the other by means of a brass disk. To the opposite ends of the two cylinders are attached terminals for plugging

Fig. 5. Vacuum tube voltmeter.

the inductances into the circuit. The numerical value for the inductance was computed from the theory developed in standard texts.¹²

$L = 2 \log_e b/a$ absolute units of inductance per centimeter. Three inductances L_1 , L_2 , and L_3 were constructed; L_1 is 5 cm long, L_2 is 10 cm, L_3 is 15

¹² Starling, Elec. and Mag. p. 308.

cm. In all three b is 1'' and a is 11/32''. The combination L_3 and L_1 providing a length of 10 cm was most often used.

$$L = 10 \times 4.60568 \times 10^3 \log_{10} 1/(11/32) = 0.02137 \text{ henries.}$$

III. PROCEDURE

Measurement of current by potential drop across a standard inductance.

The operation of measuring current by the standard inductance method is carried out as follows: Two standard inductances L_1 and L_3 (previously described) are plugged into the center turn of a five turn helix. A vacuum tube voltmeter is connected across L_1 . The reading, R_1 , of the galvanometer of the vacuum tube voltmeter is taken. L_1 and L_3 are interchanged and the vacuum tube voltmeter reading, R_3 , is taken across L_3 . $R_3 - R_1$ gives the $I\omega L$ drop across a standard inductance whose length is equal to the difference in length of L_3 and L_1 . This subtraction eliminates the end effects, potential variation at T_1 due to improper location of voltage node, pick up by the lead-ins and stray pick up by the vacuum tube voltmeter. From the equation $V = I\omega L$ the corresponding value for current is computed.

Since the standard inductance is essentially a resistance and an inductance in parallel with a capacitance, the potential drop across it is given by the formula:

$$V = I / \{ (r^2 / \omega^4 L^4) + [(1/\omega L) - \omega C]^2 \}^{1/2}$$

For $\lambda = 10$ meters $1/\omega L = 0.247$ and

$\omega C = 0.000981$ which is 0.4% of $1/\omega L$

For $\lambda = 20$ meters $1/\omega L = 0.494$ and

$\omega C = 0.000491$ which is 0.1% of $1/\omega L$

From the equation $r^2 + 4.05^2 = 4.05^2 (1.01)^2$ we get the value 0.57 ohms which resistance added to WL would increase the impedance by 1 percent. This value is very much greater than the resistance of the standard inductance. We may then drop r and ωC from formula (1) which becomes $V = I\omega L$ as it is used in the preceding paragraph.

Ammeter calibration. Since the use of direct reading instruments is more convenient than the use of the vacuum tube voltmeter with standard inductances, the problem of calibrating thermoammeters was considered. This investigation demanded a solution of the problem of current distribution in the coil since it is not safe to conclude that the current passing through one instrument is the same as that passing through another in a different part of the circuit.

The current distribution throughout the Helmholtz coil was first considered. Three Weston milliammeters, all alike, were placed at the positions A_1 , A_2 and A_3 in the pick-up circuit, (see Fig. 2). The oscillator was tuned to different frequencies and the circuit $C_2 L_5$ tuned to resonance with it. Readings were taken at six different wave-lengths from 10 to 30 meters. In all cases when C_1 was larger than C_3 , A_1 read smaller than A_3 and the voltage node in the circuit $C_2 L_5$ was nearer C_3 than C_1 . Greater differences between C_1 and C_3 always resulted in greater difference between A_1 and A_3 and greater shifting of the voltage node. When C_1 was made smaller than

C_3 the reverse changes were observed. These effects both increased with frequency.

When the five turn helix was substituted for the Helmholtz coil the results were similar but slightly more pronounced. A typical set of data is shown here: C_1 , C_2 and C_3 are condenser dial readings in degrees and are essentially proportional to capacities. A_1 , A_2 and A_3 are milliamperere readings.

TABLE I

C_1	C_2	C_3	A_1	A_2	A_3	Voltage node
41	37	10	84	100.1	115.0	Near A_3
21.4	37	20	103	110.2	115.0	
16.8	37	30	112.6	115.0	115.0	
15.5	37	35	113.1	115.0	113.1	At A_2
14.6	37	40	114.3	115.0	113.1	
13.4	37	50	115.0	114.3	110.2	
12.5	37	60	115.0	113.1	107.0	Near A_1
12.0	37	70	115.0	112.6	106.0	
11.6	37	80	115.0	112.0	105.0	

The above investigation brought out clearly the fact that for instrument calibration the unequal current distribution must be allowed for, the position of the voltage node is a very important factor in current distribution and that the voltage node may be shifted as desired by adjusting C_1 and C_3 .

The next step in current measurement was the comparison of current readings by a Weston 115 milliamperere thermo-galvanometer with currents computed from vacuum tube voltmeter readings for potential drop across standard inductances.

Thermo-galvanometers were placed at A_1 and A_3 , the standard inductances L_1 and L_3 were placed at A_2 with the vacuum tube voltmeter across L_1 . When the oscillator had been tuned to the desired wave-length and the pick-up circuit, with the 5 turn helix for L_5 , had been tuned to resonance with it, C_1 and C_2 were adjusted so that the voltage node in L_5 was at the filament lead of the vacuum tube voltmeter. This adjustment also made A_1 read the same as A_3 . By varying the output of the oscillator, A_1 ($=A_3$) was made to read 115 milliamperes. The reading across L_1 was then taken. L_1 and L_3 were interchanged and the voltage across L_3 was read. Let V_i be the difference between these two readings. Let V_i be the values for voltage across L_3-L_2 computed from the formula $V=I\omega L$ assuming $I=0.115$ amps. From the above operations the following data were obtained:

TABLE II.

λ	V_i	V_i	Diff.
30	0.152	0.155	1.9%
28	0.164	0.166	1.2%
26	0.178	0.179	0.5%
24	0.196	0.194	1.0%
22	0.216	0.212	1.9%
20	0.245	0.233	5.1%
18	0.258	0.258	0.0%
16	0.298	0.291	2.3%
14	0.338	0.333	1.5%

The essential agreement of the above and similar data was interpreted to mean that the thermo-galvanometers are reliable for wave-lengths of fourteen meters and larger.

The precision of Weston thermo-ammeters designed for measurement of larger currents when used for high frequencies may be decreased by either of two factors. First, the capacity between the leads and the instrument case may by-pass a certain amount of current and consequently make the instrument read low. Second, the resistance of the heating element does, no doubt, increase with frequency. Since the deflection is proportional to the power (I^2R) consumed in the heating element any increase in R would make the deflection too large for a given current.

The first effect was easily isolated by comparing readings of a given current with the case on with those after the case had been removed. No effect was observed in the range from 10 to 30 meters except for two instruments designed for mounting with their bases flush with the panel. In these instruments the readings were approximately two percent lower at ten meters with cases on than off. These by-passed currents also expressed themselves in form of heat in the cases when the instruments were shunted and large currents passed through them.

The second effect should be more pronounced in instruments designed for larger currents since their heating elements are made of larger wire. In order to test this factor the 115 milliamper meter was compared with the 250; the 250 with the 500 and the 500 with the one ampere. Then instruments were shunted and calibrated at wave-lengths 12, 20 and 26 meters by comparison with the one ampere instruments. In turn these instruments were compared with a 4 ampere Weston thermo-ammeter. It was found to read slightly high at twenty meters seeming to indicate that the second effect was expressing itself.

The final step in instrument calibration was the comparison of the calibrated instruments against standard inductance values. Table III shows the results.

TABLE III.

λ	I_a	I_L	Diff.
26	1 amp.	0.976	0.024
26	2	2.001	0.001
26	3.5	3.58	0.08

Measurement of field intensity by electromotive force induced in search coil. For this set of measurements the pick-up circuit (Fig. 2) was used with the Helmholtz coil at L_s and calibrated ammeters at A_1 and A_3 . A single turn coil 2.5 centimeters in radius made of fine wire was provided with terminals for plugging it into the vacuum tube voltmeter leads. A short piece of wire just long enough to shunt the leads of the voltmeter thus completing the circle was also provided with plug-in terminals. Reading R_1 was taken with the search coil placed coaxially with the Helmholtz coil and at its center. R_2 was taken with the shunt across the voltmeter leads. The differ-

ence $R_1 - R_2$ gave the e.m.f. induced in a coil of one turn and radius 2.5 centimeters. This value substituted in the formula $H = (E \times 10^8) / \omega A$ gave the values of the field intensity in gauss. Values obtained in this way are listed under H_e in Table IV. Simultaneously with the reading of R_1 and R_2 the current in the Helmholtz coil was read from the calibrated ammeters A_1 and A_2 . This reading substituted in the formula $H = 32\pi ni / 5^{3/2} a$ also gave values for field intensity at the center of the Helmholtz coil. Values obtained from this substitution are listed under H_a in Table IV.

TABLE IV.

λ	I (amps.)	H_a (gauss)	H_e	Diff.
100	1.0	0.1125	0.1145	1.8%
90	1.0	.1125	.1116	0.8%
80	.96	.1078	.1074	0.4%
70	.93	.1048	.1046	0.2%
60	.88	.0990	.1033	4.1%
50	.79	.0894	.0885	1.0%
40	.66	.0746	.0732	1.8%
30	.115	.0089	.0092	3.3%
20	2.00	.225	.220	2.1%
20	3.00	.337	.330	2.0%
16	2.00	.225	.225	0.0%
16	3.00	.337	.346	2.6%
12	2.00	.225	.217	3.5%

The measurements in the range from 30 to 120 meters were made before the method of controlling the position of the voltage node and the current distribution had been developed. The same refinement and precautions used in the range below 30 meters applied to this range would have given better agreement.

The essential agreement in the values for field intensity obtained by the two methods provides good evidence of the accuracy of both.

IV. CONCLUSIONS

1. The vacuum tube voltmeter herein described was applied successfully to the measurement of alternating potentials of frequency as high as 25 megacycles.
2. The standard inductance method provides a satisfactory means of measuring alternating currents of frequencies as high as 22 megacycles.
3. Definite information regarding the distribution of current in a coil was obtained.
4. A comparison of thermo-ammeter readings for high-frequency currents with values obtained by the standard inductance method and with readings of similar instruments made possible their calibration for any desired wave-length above 10 meters.
5. The intensity of a magnetic field within a Helmholtz coil may be computed from known currents in the coil.
6. The intensity of a magnetic field may be computed from the vacuum tube voltmeter measure of e.m.f. induced in a single turn search coil placed in the field.

ON THE FUNDAMENTAL CONSTITUTIVE EQUATIONS IN ELECTROMAGNETIC THEORY

BY C. KAPLAN AND F. D. MURNAGHAN
THE JOHNS HOPKINS UNIVERSITY, BALTIMORE

(Received February 14, 1930)

ABSTRACT

The purpose of this paper is to investigate the absolute significance of the well-known constitutive relations in electromagnetic theory, and to see what simplifications are introduced by various assumptions as to the isotropic character of the space-time continuum. The "linear vector function" expressing the linear relationship between the two fundamental electromagnetic tensors $a_{rs} (\equiv \mathbf{B}, c\mathbf{E})$ and $b_{rs} (\equiv -\mathbf{D}, c\mathbf{H})$ is a tensor c_{rs}^{pq} of rank 4 which is covariant and contravariant of rank 2 respectively and is named the "structure-tensor." In order to express mathematically what is meant by the isotropic character of a medium, the notion of orthogonal ennuples is introduced (an orthogonal ennuple defined at a point in space-time enables us to turn the medium in the neighborhood of that point). A tensor is then determined by its invariants with respect to an orthogonal ennuple at the point at which the tensor is taken, rather than by its covariant or contravariant components with respect to the coordinate system of the manifold. The effect of various assumptions as to the isotropic character of space-time on the invariants of the "structure-tensor" c_{rs}^{pq} is investigated and it is found that if space is completely isotropic in the neighborhood of a point P in space-time, then the simple constitutive relations $\mathbf{B} = \mu\mathbf{H}$ and $\mathbf{D} = \epsilon\mathbf{E}$ (with μ and ϵ independent of one another) hold; and that to an observer in space-time this fact is indicated by a time-direction 4-vector issuing from P . Since μ and ϵ are distinct only in places where matter is present we can say that the distribution of matter in space-time is affected by the distribution of these time-direction vectors in space-time. The corresponding constitutive relations $\mathbf{B} = \mu\mathbf{H}$ and $\mathbf{D} = \epsilon\mathbf{E}$ for empty space (where $\mu\epsilon = 1$; Maxwell's relations) are found to hold in the neighborhood of points where these time-direction vectors are absent; i.e. such points are simply geometrical points. The analysis, as introduced in this paper, is a general one and is applied to elasticity theory. Thus the number of distinct coefficients of elasticity appearing in Hooke's law for a transversely-isotropic medium is found to be six instead of five, the reason for this disagreement being that the assumption as to the existence of an energy-density of deformation reduces the number from six to five.

AS IS well known¹ Maxwell's fundamental equations of electromagnetic theory can be very conveniently written in terms of two alternating covariant tensors of rank two (or six-vectors) in space of four dimensions. The first of these, a_{rs} consists of the magnetic induction vector \mathbf{B} and the electric intensity vector \mathbf{E} in such a way that

$$a_{23} = B_x; a_{31} = B_y; a_{12} = B_z; a_{14} = cE_x; a_{24} = cE_y; a_{34} = cE_z \quad (1.0)$$

(c denoting the velocity of light in vacuo) and one set of Maxwell's equations merely expresses the fact that the flux or surface integral of the six-vector

¹A. Sommerfeld, Ann. d. Physik **32**, 749 (1910); **33** 649 (1910.) H. Bateman, Proc. London Math. Soc. **8**, 223 (1910); F. D. Murnaghan, Phys. Rev **17**, 74 (1921).

a_{rs} across any closed spread of two dimensions, imbedded in the given space-time of four dimensions (x, y, z, t) , is zero. The second fundamental six-vector b_{rs} , consists of the electric displacement (or induction) vector D and the magnetic intensity vector H in such a way that

$$b_{23} = -D_x; b_{31} = -D_y; b_{12} = -D_z; b_{14} = cH_x; b_{24} = cH_y; b_{34} = cH_z \quad (1.1)$$

and the second set of Maxwell's equations states that the flux of this six-vector across any closed spread of two dimensions in the given space-time continuum is equal to the volume integral over the space of three dimensions (bounded by the spread of two dimensions) of the current-charge density four-vector. Now, in addition to Maxwell's equations (and quite distinct from them) are certain relations, connecting the four fundamental vectors, B, E, D, H which are known as the constitutive equations. In space free from matter Maxwell made the hypothesis that these constitutive equations were

$$B = H; D = E \quad (1.2)$$

whilst in a material medium these equations were replaced by

$$B = \mu H; D = \epsilon E \quad (1.3)$$

where if the medium is isotropic μ and ϵ are two constants characteristic of the medium and known respectively, as its permeability and specific inductive capacity. If the medium is not isotropic μ and ϵ are linear vector functions so that the equation $B = \mu H$ for instance, is merely an abbreviation for three equations of the form

$$B_x = \mu_{11}H_x + \mu_{12}H_y + \mu_{13}H_z.$$

It is the purpose of the present paper to investigate the general linear relation connecting the two alternating covariant tensors a_{rs} and b_{rs} and to see what simplifications are introduced by various assumptions as to the isotropic character of the space-time continuum. The "linear vector function" expressing this relationship will be a tensor c_{rs}^{pq} of rank four which is covariant of rank two and contravariant of rank two and which may be assumed without any lack of generality, to be alternating in the contravariant and covariant labels separately. Thus we may write

$$b_{rs} = C_{rs}^{\alpha\beta} a_{\alpha\beta} \quad (1.4)$$

where the Greek labels α, β are summation labels and it is supposed that the summation runs over the six pairs 23, 31, 12, 14, 24, 34 formed from the four numbers 1, 2, 3, 4, ($x = x^1, y = x^2, z = x^3, t = x^4$). The most general situation would involve, then, $6 \times 6 = 36$ coefficients c_{rs}^{pq} . The tensor c_{rs}^{pq} which is the analogue of the linear vector function of elementary vector analysis will be called the structure-tensor.

In the section of our paper devoted to the investigation of the effect upon the structure-tensor of various assumptions as to the isotropic charac-

ter of space or space-time, we shall disregard the fact that in the application of our analysis with which we are primarily concerned, i.e., the electromagnetic theory, the tensors a_{rs} and b_{rs} are alternating. The reason for so doing is that a similar analysis is useful in other departments of theoretical physics, e.g. elasticity theory, where the tensors involved are not alternating. In elasticity theory they are symmetric, but it will be convenient not to make any special assumption as to the nature of these tensors until later. The structure-tensor c_{rs}^{pq} will accordingly involve $256 (=16 \times 16)!$ components and the Greek labels in the fundamental relation

$$b_{rs} = c_{rs}^{\alpha\beta} a_{\alpha\beta}$$

are supposed to run, independently, over the values 1, 2, 3, 4.

MATHEMATICAL DESCRIPTION OF ISOTROPY²

In order to express most conveniently what is meant by the isotropic character of a medium we shall suppose an orthogonal ennuple³ (ennuple = n^{ple} ; $n=4$) attached to each point of space-time. Denoting the four vectors of this ennuple by ${}_1\lambda, {}_2\lambda, {}_3\lambda, {}_4\lambda$ any one, ${}_r\lambda$ say, of these will be a contravariant vector whose components are ${}_r\lambda^p$ ($p=1, 2, 3, 4$) and we shall denote the covariant representation of this vector by ${}_r\lambda_p$. Hence we have the relations defining orthogonality

$${}_r\lambda^{\alpha s} \lambda_{\alpha} = \epsilon_r^s \quad (1.5)$$

where the ϵ_r^s are a set of invariants or scalar quantities having the values of the components of the unit tensor δ_r^s ; i.e. $\epsilon_r^s = 0$ if $s \neq r$ and 1 if $s = r$. By means of the tensors ${}_r\lambda$ and ${}_r\lambda$ any tensor may be described in terms of its invariants relative to the ennuple.⁴ For a tensor $A_{s_1 \dots s_k}^{r_1 \dots r_j}$ these are

² T. Levi-Civita, "Absolute Calculus" Ch. 10 sec. 2.

³ By an orthogonal ennuple we mean a pyramid (a generalization of the notion of the trihedron) whose edges are mutually orthogonal. The purpose of fixing a set of four mutually orthogonal directions at every point of our space-time is to provide a mechanism for turning space. Turning the coordinate system simply changes the numbers, for example, which determine a point in space-time.

When we say that any one of the edges of an orthogonal ennuple, the r th say, is presented by a contravariant tensor of rank one ${}_r\lambda$ ($p=1, 2, 3, 4$), we may consider these four components to be the direction cosines of the r th direction with respect to the coordinate system (x) of the space-time continuum. Thus, for example, let us consider a space of three dimensions in which everything is referred to a set of rectangular Cartesian axes and suppose that at any point P a rectangular frame is formed by the tangents (directed in the sense of increasing variables) to the space-polar coordinate curves r = variable, θ = variable and ϕ = variable passing through P . Then the tangent line to the θ = variable curve, for example, is described in the Cartesian coordinate system of our space by three components:

$${}_0\lambda^1 = \cos \theta \cdot \cos \phi; \quad {}_0\lambda^2 = \cos \theta \cdot \sin \phi; \quad {}_0\lambda^3 = -\sin \theta.$$

⁴ For example suppose a space-polar trihedron to be fixed at a point P of space and a vector R determined at this point. Let us suppose that the vector R represents a generalized force. Then this force may be determined by its covariant components ($-\partial\psi/\partial r$, $-\partial\psi/\partial\theta$, $-\partial\psi/\partial\phi$) or by its projections on the directions belonging to the space-polar trihedron at P ,

$$i_{s_1 \dots s_k}^{r_1 \dots r_j} = A_{\sigma_1 \dots \sigma_k}^{\rho_1 \dots \rho_j} i_{\rho_1 \dots \rho_k} \lambda_{\sigma_1}^{r_1} \dots \lambda_{\sigma_k}^{r_j} \quad (1.6)$$

from which it immediately follows that

$$A_{n_1 \dots n_k}^{m_1 \dots m_j} = i_{\beta_1 \dots \beta_k}^{\alpha_1 \dots \alpha_j} \lambda_{\alpha_1}^{m_1} \dots \lambda_{\alpha_j}^{m_j} i_{\beta_1}^{n_1} \dots i_{\beta_k}^{n_k} \quad (1.7)$$

(In deriving which, one uses the elementary theorem of algebra that since the two sets ${}^r\lambda^s$ and ${}^p\lambda_q$ are reciprocal; i.e. ${}^r\lambda^{\alpha s} \lambda_{\alpha}^p = \delta_r^p$, it follows that ${}_{\alpha} \lambda^r \lambda_s^{\alpha} = \delta_s^r$). It follows without difficulty that the tensor relation

$$b_{rs} = c_{rs}^{\alpha\beta} a_{\alpha\beta}$$

is equivalent to a similar relation

$$j_{rs} = K_{rs}^{\alpha\beta} i_{\alpha\beta} \quad (1.8)$$

between the univariants of the tensors involved and it is in terms of the invariants K_{rs}^{pq} of the structure-tensor c_{rs}^{pq} that we shall find it convenient to express the conditions of isotropy.

Suppose now, that at any point of our space-time we have a second ennuple ${}_1\mu, {}_2\mu, {}_3\mu, {}_4\mu$ whose direction-vectors are connected with those of the first set by the relations

$${}^r\mu^p = s_q^{\alpha} \lambda^p \quad (1.9)$$

where the scalar coefficients s_q^p are the elements of an orthogonal matrix. We shall say that the ennuple μ is derived from the ennuple λ by a *rotation* if the determinant of the matrix of the s_q^p is 1 and by a *reflexion* if the determinant of this matrix is -1 . In fact the covariant presentations of the two ennuples are connected by the relation

$$i_{\mu k} = s'^{\alpha} i_{\lambda k} \quad (2.0)$$

where s' is the conjugate matrix to $s (s'^p_q = s^p_q)$ so that for the μ -ennuple to be also orthogonal it is necessary and sufficient that the product of the matrix s by its conjugate s' should be the unit matrix and this is the definition of an orthogonal matrix.

The relation between the invariants of any tensor relative to the λ and μ ennuples follows at once. Thus if we distinguish the invariants of a tensor relative to the μ ennuple from those relative to the λ ennuple by a superposed bar, we have, taking a covariant tensor a_{rs} of rank two as an illustration.

$$\bar{i}_{rs} = a_{\alpha\beta} {}^r\mu^{\alpha} {}^s\mu^{\beta} = a_{\alpha\beta} s_r^{\rho} s_s^{\sigma} \lambda^{\alpha} \lambda^{\beta} = i_{\rho\sigma} s_r^{\rho} s_s^{\sigma}. \quad (2.1)$$

We are primarily interested in the structure-tensor c_{rs}^{pq} and the relation between its invariants relative to the two ennuples is

$$\bar{K}_{rs}^{pq} = K_{\alpha\beta\gamma\delta}^{\epsilon\zeta\eta\theta} s_r^{\epsilon} s_s^{\zeta} s^{\eta} s^{\theta} \lambda^{\alpha} \lambda^{\beta} \lambda^{\gamma} \lambda^{\delta} \quad (2.2)$$

i.e. $(-\partial\psi/\partial r, -(1/r)(\partial\psi/\partial\theta), -(1/r \sin \theta)(\partial\psi/\partial\phi))$. These latter three quantities are invariants with regard to changes in the coordinate system but depend on the particular set of orthogonal directions at P .

The medium will be said to be isotropic (with regard to the structure-tensor c_{rs}^{pq}) relative to the given rotation or reflexion if the invariants \bar{K} of the structure-tensor relative to the new ennuple are the same as its invariants relative to the original ennuple i.e. if

$$\bar{K}_{rs}^{pq} = K_{rs}^{pq}.$$

If the invariants \bar{K} keep their numerical values but change their signs under reflexions the medium will be said to be relatively (as opposed to absolutely) isotropic with respect to the structure-tensor.

ISOTROPY WITH REGARD TO ROTATIONS IN THE COORDINATE PLANES

Now a rotation through a right angle in the 2-3 plane is described by the matrix

$$\begin{array}{c|cccc} & 1\lambda & 2\lambda & 3\lambda & 4\lambda \\ \hline 1\mu & 1 & 0 & 0 & 0 \\ 2\mu & 0 & 0 & 1 & 0 \\ 3\mu & 0 & -1 & 0 & 0 \\ 4\mu & 0 & 0 & 0 & 1 \end{array}$$

so that $s_2^3 = 1$, $s_1^1 = 1$, $s_3^2 = -1$, $s_4^4 = 1$ all the others being zero. Upon substituting these values in the 256 equations

$$K_{rs}^{pq} = K_{\alpha\beta\delta\epsilon}^{pq} s_\epsilon^{\delta\epsilon} s_\delta^{\alpha\beta} s_r^{\alpha\beta} s_s^{\delta\epsilon} \quad (2.3)$$

(which express the assumption that the invariants of the structure tensor are not affected by a rotation through a right angle in the 2-3 plane) we find that many of the invariants of the structure-tensor must be zero; thus if $r = 1$, $s = 1$, $p = 3$, $q = 1$, the only term in the quadruple summation which is different from zero is that for which $\alpha = 1$, $\beta = 1$, $\delta = 2$, $\epsilon = 1$ whence $K_{11}^{31} = -K_{11}^{21}$; similarly $K_{11}^{21} = K_{11}^{31}$ and combining these results we find that $K_{11}^{31} = K_{11}^{21} = 0$. Proceeding in this manner we find that out of the 256 invariants 128 are zero whilst there are 58 relations amongst the remaining 128 so that there are 70 distinct invariants. These may be succinctly displayed in the accompanying table where blanks indicate zero values, and where an abbreviation is introduced for K_{rs}^{pq} . Thus for instance, we write aa for K_{11}^{11} ; ig for K_{31}^{24} and so on. The key to this notation is given by

$$\begin{array}{|cccc|} \hline 11 & 12 & 13 & 14 \\ 21 & 22 & 23 & 24 \\ 31 & 32 & 33 & 34 \\ 41 & 42 & 43 & 44 \\ \hline \end{array} \equiv \begin{array}{|cccc|} \hline a & h & g' & u \\ h' & b & f & v \\ g & f' & c & w \\ u' & v' & w' & d \\ \hline \end{array}$$

TABLE I.

		i															
		11	22	33	44	23	32	31	13	12	21	14	41	24	42	34	43
j	11	aa	ba	ba	da	fa	-fa					ua	u'a				
	22	ab	bb	bc	db	fb	-fb					ub	u'b				
	33	ab	bc	bb	db	fc	-fb					ub	u'b				
	44	ad	bd	bd	dd	fd	-fd					ud	u'd				
	23	af	bf	bf'	df	ff	ff'					uf	u'f				
	32	-af	-bf'	-bf	-df	ff'	ff					-uf	-u'f				
	31							gg	g'g	-g'h'	-gh'			vg	v'g	vh'	v'h'
	13							gg	g'g	-g'h	-gh			vg'	v'g'	vh	v'h
	12							gh	g'h	g'g'	gg'			vh	v'h	-vg'	-v'g'
	21							gh'	g'h'	g'g	gg			vh'	v'h'	-vg	-v'g
	14	au	bu	bu	du	fu	-fu					uu	uu'				
	41	au'	bu'	bu'	du'	fu'	-fu'					uu'	uu				
	24							gv	g'v	g'w	gw			vv	v'v	-vw	-v'w
	42							gv'	g'v'	g'w'	gw'			vv'	v'v'	-vw'	-v'w'
	34							gw	g'w	-g'v	-gv			vv	v'w	vv	v'v
	43							gw'	g'w'	-g'v'	-gv'			vv'	v'w'	vv'	v'v'

In the application of this analysis to electromagnetic theory the table will have 6×6 instead of 16×16 constituents. For isotropy as regards rotation through a right angle in the (2, 3) plane it will read

TABLE IA.

		i					
		23	31	12	14	24	34
j	23	ff			uf		
	31		gg	-gh		vg	-vh
	12		gh	gg		vh	vg
	14	fu			uu		
	24		gv	-gw		vv	-vw
	34		gw	gv		vw	vv

so that sixteen of the invariants are zero and only twelve of the remaining 20 are distinct.

When, on the other hand, the structure-tensor is symmetric in both its covariant and contravariant labels (a state of affairs which will arise when both of the tensors between which it sets up a linear relationship are symmetric) the columns and rows must coincide with the corresponding columns and rows for which the order of the labels is altered so that instead of $100 = 10 \times 10$ ($10 = 4 + 6$) distinct constituents there remain only 28, the table reading as follows:

TABLE IB.

		i									
		11	22	33	44	23	31	12	14	24	34
j	11	aa	ba	ba	da				ua		
	22	ab	bb	bc	db	fb			ub		
	33	ab	bc	bb	db	-fb			ub		
	44	ad	bd	bd	dd				ud		
	23		bf	-bf		ff					
	31						gg	-gh		vg	vh
	12						gh	gg		vh	-vg
	14	au	bu	bu	du				uu		
	24						gv	gw		vv	-vw
	34						gw	-gv		vw	vv

We shall now find the new relations between the 70 distinct invariants of Table I, introduced by a rotation through any angle θ (other than a right angle) in the 2-3 plane. This rotation is described by the matrix

$$\begin{array}{c|cccc} & \begin{array}{c} \rightarrow i \\ 1\lambda \quad 2\lambda \quad 3\lambda \quad 4\lambda \end{array} \\ \begin{array}{c} \downarrow j \\ 1\mu \\ 2\mu \\ 3\mu \\ 4\mu \end{array} & \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos \theta & \sin \theta & 0 \\ 0 & -\sin \theta & \cos \theta & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \end{array}$$

so that $s_1^1 = s_4^4 = 1$; $s_2^2 = s_3^3 = \cos \theta$; $s_2^3 = \sin \theta$; $s_3^2 = -\sin \theta$.

Upon substituting these values in the equations (2.3) and using the results embodied in Table I, we find the following new relations:

$$\begin{aligned} (a) \quad & 2(K_{22}^{22} - K_{33}^{22} - K_{23}^{23} - K_{32}^{23}) \sin \theta \cos \theta = (K_{23}^{22} + K_{32}^{22}) \\ (b) \quad & 2(K_{22}^{22} - K_{33}^{22} - K_{23}^{23} - K_{32}^{23}) \sin \theta \cos \theta = -(K_{23}^{22} + K_{32}^{22}) \end{aligned}$$

from which we have that $K_{22}^{22} = K_{33}^{22} + K_{23}^{23} + K_{32}^{23}$ and $K_{23}^{22} = -K_{32}^{22}$

$$\begin{aligned} (c) \quad & (K_{22}^{22} - K_{33}^{22} - K_{23}^{23} - K_{32}^{23})(\sin^2 \theta - \cos^2 \theta) \sin \theta \cos \theta = 2K_{23}^{22} \sin^2 \theta \\ (d) \quad & (K_{22}^{22} - K_{33}^{22} - K_{23}^{23} - K_{32}^{23})(\sin^2 \theta - \cos^2 \theta) \sin \theta \cos \theta = 2K_{32}^{22} \sin^2 \theta \end{aligned}$$

so that $K_{23}^{22} = K_{32}^{22}$ which combined with $K_{23}^{22} = -K_{32}^{22}$ gives $K_{23}^{22} = K_{32}^{22} = 0$

$$(e) \quad 2(K_{22}^{22} - K_{33}^{22} - K_{23}^{23} - K_{32}^{23}) \sin \theta \cos \theta = (K_{23}^{22} - K_{32}^{22}) + (K_{22}^{23} - K_{33}^{23})$$

or combined with the results of a , b , and c gives us

$$K_{22}^{23} = K_{33}^{23}.$$

Thus the new relations between the invariants K_{rs}^{pq} introduced by this rotation through an angle θ (excluding 90°) are

$$K_{22}^{22} = K_{33}^{22} + K_{23}^{23} + K_{32}^{23}; \quad K_{23}^{22} = 0; \quad K_{32}^{22} = 0; \quad K_{22}^{23} = K_{33}^{23}.$$

If we include these relations in Table I we shall have the conditions on the invariants for isotropy with regard to a rotation through any angle in the 2-3 plane. There are thus $70 - 4 = 66$ distinct invariants.

Table IA remains unchanged, whilst Table IB (since $K_{23}^{22} = 0$ and $K_{22}^{22} = K_{33}^{22} + 2K_{23}^{23}$) contains only $28 - 2 = 26$ distinct invariants, when we include the rotation through an angle θ .⁵

⁵ We remark that Table IB (disregarding the coefficients involving the 4th index) applies to the case of a tetragonal crystal with one of the edges an axis of symmetry in the sense that the other two edges of the crystal issuing from P and all rays (in the plane of these two edges) which may be made to coincide with either of these edges by a 90° rotation, are equivalent.

If we wish to find the conditions on the invariants for isotropy with regard to a rotation through any angle θ in some other coordinate plane, let us say the 1-2 plane, we may do so by inspection of Table I. We simply replace 23 by 12 and 32 by 21, whilst 1 is replaced by 3; for 3 stands in the same position with respect to 12, as 1 does to 23. For example, the condition $K_{11}^{32} = -K_{11}^{23}$ of table 1 is replaced by the relation $K_{33}^{21} = -K_{33}^{12}$. Similarly, instead of the relations

$$K_{22}^{22} = K_{33}^{22} + K_{23}^{23} + K_{32}^{23}; \quad K_{23}^{23} = K_{32}^{22} = 0; \quad K_{22}^{23} = K_{33}^{23}$$

we have

$$K_{11}^{11} = K_{22}^{11} + K_{12}^{12} + K_{21}^{12}; \quad K_{12}^{11} = K_{21}^{11} = 0; \quad K_{11}^{12} = K_{22}^{12}$$

In this way we may construct a table of invariants such that there will be structural symmetry with regard to any rotation θ in the 1-2 plane.

ISOTROPY WITH REGARD TO COMBINED ROTATIONS IN PLANES 2-3 AND 1-2.

If in addition to symmetry of structure with regard to a rotation through any angle in the 2-3 plane there is structural symmetry with regard to a similar rotation in the 1-2 plane we find without much fresh calculation the table of invariants for structural symmetry in the 2-3 and 1-2 planes. For example the relation $K_{11}^{12} = 0$ of Table I becomes $K_{33}^{23} = 0$ in the table of invariants for the 1-2 plane, both relations holding for the table of invariants for structural symmetry with regard to combined rotations in the 2-3 and 1-2 planes. Proceeding in this way we find that 192 of the 256 invariants are zero whilst of the remaining 64 only 12 are distinct. The following Table II expresses these facts and the symmetry of it shows that there is structural symmetry with regard to combined rotations through any angle in each of the planes 23, 31 and 12.

TABLE II.

	i	11	22	33	44	23	32	31	13	12	21	14	41	24	42	34	43
j	11	aa	ab	ab	da												
	22	ab	aa	ab	da												
	33	ab	ab	aa	da												
	44	ad	ad	ad	dd												
	23					ff	ff'					uf	u'f				
	32					ff'	ff					-uf	-u'f				
	31							ff	ff'					uf	u'f		
	13							ff'	ff					-uf	-u'f		
	12									ff	ff'					uf	u'f
	21									ff'	ff					-uf	-u'f
	14					fu	-fu					uu	uu'				
	41					fu'	-fu'					uu'	uu				
	24							fu	-fu					uu	uu'		
	42							fu'	-fu'					uu'	uu		
	34									fu	-fu					uu	uu'
	43									fu'	-fu'					uu'	uu

with $K_{11}^{11} = K_{22}^{11} + K_{23}^{23} + K_{32}^{23}$

If we include rotations through any angle θ , i.e. the material now possesses an axis of symmetry such that all rays at right angles to this axis are equivalent, the table corresponding to IB contains a less number of coefficients, there being nine in the first case and only six in the second.

Corresponding to Tables IA we have Table IIA with only four distinct invariants and 24, zero.

TABLE IIA.

		$i \rightarrow$	23	31	12	14	24	34
$j \downarrow$	23		$\bar{f}\bar{f}$			uf		
	31			$\bar{f}\bar{f}$			uf	
	12				$\bar{f}\bar{f}$			uf
	14		fu			uu		
	24			fu			uu	
	34				fu			uu

Similarly, when the structure-tensor is symmetric in both its covariant and contravariant labels we have a Table IIB corresponding to Tables IB. Thus

TABLE IIB.

		$i \rightarrow$	11	22	33	44	23	31	12	14	24	34
$j \downarrow$	11		aa	ab	ab	da						
	22		ab	aa	ab	da						
	33		ab	ab	aa	da						
	44		ad	ad	ad	dd						
	23						$\bar{f}\bar{f}$					
	31							$\bar{f}\bar{f}$				
	12								$\bar{f}\bar{f}$			
	14									uu		
	24										uu	
	34											uu

With $K_{11}^{11} = K_{22}^{11} + 2K_{23}^{23}$

there being 78 invariants out of the possible 100 zero, whilst of the remaining 22 only 6 are distinct.

In resumé, the three Tables II, IIA and IIB present the surviving invariants under the assumption that the invariants of the structure-tensor are not affected by a rotation through any angle in the 23, 31 and 12 planes.

We shall now consider the most general orthogonal rotation of the 123-space about the 4th direction. That is, we shall investigate the invariants for structural symmetry about the 4λ -axis.

ISOTROPY WITH REGARD TO A GENERAL ROTATION ABOUT THE λ -AXIS

The general rotation of the 123-space about the 4th direction is given by the matrix

		$\lambda \rightarrow$	1λ	2λ	3λ	4λ
$\mu \downarrow$	1μ		s_1^1	s_1^2	s_1^3	0
	2μ		s_2^1	s_2^2	s_2^3	0
	3μ		s_3^1	s_3^2	s_3^3	0
	4μ		0	0	0	1

Upon substituting these values in the fundamental equations

$$K_{rs}^{pq} = K_{\alpha\beta\gamma\delta}^{\delta\epsilon\zeta\eta} s_{\epsilon}^{p\zeta} s_{\zeta}^{q\eta} s_{\delta}^{\alpha\gamma} s_{\delta}^{\beta\gamma}$$

(using the conditions expressed in Table II) we find the following new relations

$$K_{23}^{14} = \Delta K_{23}^{14}; \quad K_{23}^{41} = \Delta K_{23}^{41}; \quad K_{14}^{23} = \Delta K_{14}^{23}; \quad K_{41}^{23} = \Delta K_{41}^{23}$$

where Δ is the determinant of the matrix of this rotation, namely

$$\Delta = \begin{vmatrix} s_1^1 & s_1^2 & s_1^3 \\ s_2^1 & s_2^2 & s_2^3 \\ s_3^1 & s_3^2 & s_3^3 \end{vmatrix}$$

and since our matrix is an orthogonal one, we have

$$\Delta^2 = 1 \text{ or } \Delta = \pm 1.$$

If $\Delta = +1$ then the rotation characterizes a movement of a rigid body about a fixed point. If $\Delta = -1$ the change of directions involves reflexion together with rotation.

ISOTROPY WITH REGARD TO A GENERAL ROTATION ABOUT A POINT P

We shall now consider the effect on the invariants K_{rs}^{pq} , if in addition to structural symmetry with respect to a general rotation about the λ -direction there is symmetry of structure with regard to a rotation through any angle in, let us say, the 1-4 plane.

Without fresh calculations but simply by inspection of Table I, we see that corresponding to the following relations therein; $-K_{23}^{22} = K_{33}^{23}$; $K_{11}^{33} = K_{33}^{22}$; $K_{33}^{33} = K_{22}^{22}$ we have (for the 1-4 plane) respectively: $K_{11}^{11} = K_{44}^{44}$; $K_{22}^{44} = K_{44}^{22}$; $K_{44}^{11} = K_{11}^{44}$ which when combined with Table II, yield

$$(a) \quad K_{44}^{44} = K_{11}^{11}; \quad K_{11}^{44} = K_{44}^{11} = K_{22}^{11}.$$

Similarly, the relations $K_{41}^{31} = K_{21}^{21}$ and $K_{13}^{31} = K_{12}^{21}$ for the 2-3 plane become respectively, $K_{42}^{42} = K_{12}^{12}$ and $K_{24}^{42} = K_{21}^{21}$ for the 1-4 plane which when taken together with table 2, yield

$$(b) \quad K_{14}^{14} = K_{23}^{23} \text{ and } K_{41}^{14} = K_{32}^{23}.$$

Finally, the relations $K_{31}^{24} = -K_{12}^{43}$, $K_{12}^{42} = -K_{21}^{43}$, $K_{24}^{31} = -K_{34}^{21}$ for the 2-3 plane become respectively $K_{42}^{13} = -K_{12}^{43}$, $K_{43}^{31} = -K_{12}^{34}$, $K_{13}^{42} = -K_{43}^{12}$ for the 1-4 plane which, when combined with Table II, yield

$$(c) \quad K_{23}^{14} = K_{14}^{23}; \quad K_{23}^{41} = -K_{14}^{23}; \quad K_{41}^{23} = -K_{14}^{23}.$$

If now we impose on the invariants K_{ns}^{pq} the conditions that they be unaffected by a general orthogonal rotation of the ennuple (as a whole) about P , the matrix of this rotation being

$$\begin{array}{c|cccc} & 1\lambda & 2\lambda & 3\lambda & 4\lambda \\ \hline 1\mu & s_1' & s_1^2 & s_1^3 & s_1^4 \\ 2\mu & s_2' & s_2^2 & s_2^3 & s_2^4 \\ 3\mu & s_3' & s_3^2 & s_3^3 & s_3^4 \\ 4\mu & s_4' & s_4^2 & s_4^3 & s_4^4 \end{array}$$

we find upon substitution in the fundamental equations $K_{ns}^{pq} = K_{\alpha\beta}^{\delta\epsilon} s'^p s'^q s'^\alpha s'^\beta$ taking into account the conditions expressed by Table II and (a), (b) and (c) above, that the new relation obtained is simple

$$K_{14}^{23} = \Delta \cdot K_{14}^{23}$$

where

$$\Delta = \begin{vmatrix} s_1^1 & s_1^2 & s_1^3 & s_1^4 \\ s_2^1 & s_2^2 & s_2^3 & s_2^4 \\ s_3^1 & s_3^2 & s_3^3 & s_3^4 \\ s_4^1 & s_4^2 & s_4^3 & s_4^4 \end{vmatrix} = \pm 1.$$

These results are best expressed in Tables III, IIIA and IIIB corresponding to Tables II, IIA and IIB. Thus

TABLE III.

j	i															
	11	22	33	44	23	32	31	13	12	21	14	41	24	42	34	43

	23					ff					
	31						ff				
	12							ff			
	14								ff		
	24									ff	
	34										ff

with $K_{11}^{11} = K_{22}^{11} + 2K_{23}^{23}$

so that as in table IIB, 78 of the invariants are zero, whilst only two of the remaining 22 are distinct.

APPLICATIONS TO ELECTROMAGNETIC THEORY

a. *Absolute isotropy with regard to a general rotation around the λ -direction.* This means that $\Delta = +1$. Then from Table IIA, we find the relations between the invariants j_{rs} and i_{rs} of the two alternating covariant electromagnetic tensors b_{rs} and a_{rs} respectively:

$$\begin{aligned} j_{23} &= \alpha i_{23} + \beta i_{14}; & j_{31} &= \alpha i_{31} + \beta i_{24}; & j_{12} &= \alpha i_{12} + \beta i_{34} & \text{where } \alpha &= K_{23}^{23}; \beta &= K_{23}^{14}; \\ j_{14} &= \lambda i_{23} + \gamma i_{14}; & j_{24} &= \lambda i_{31} + \gamma i_{24}; & j_{34} &= \lambda i_{12} + \gamma i_{34} & \lambda &= K_{14}^{23}; \gamma &= K_{14}^{14}. \end{aligned} \quad (2.4)$$

Equations (2.4) are relations between the invariants j_{rs} and i_{rs} of the two electromagnetic tensors b_{rs} and a_{rs} respectively and are valid for any Riemannian space of four dimensions R_4 . If, however, we wish to find the corresponding set of relations between the tensor components we must know definitely the ennuple with respect to which the invariants j_{rs} and i_{rs} are taken.

Suppose that the system of coordinates of our R_4 is an orthogonal-curvilinear one for which the fundamental quadratic form is

$$ds^2 = H_1^2(dx^1)^2 + H_2^2(dx^2)^2 + H_3^2(dx^3)^2 + H_4^2(dx^4)^2,$$

and furthermore that the ennuple at P coincides with this reference frame. Then, the relations between the invariants j_{rs} , i_{rs} and the corresponding tensors b_{rs} , a_{rs} are such that

$$j_{rs} = b_{rs}/H_r H_s; \quad i_{rs} = a_{rs}/H_r H_s$$

so that corresponding to equations (2.4) between the invariants j_{rs} and i_{rs} we have the following set of relations between the tensors b_{rs} and a_{rs} :

$$\begin{aligned} \frac{H_1}{H_2 H_3} b_{23} &= \frac{H_1}{H_2 H_3} \alpha a_{23} + \frac{\beta}{H_4} a_{14}; & \frac{1}{H_4} b_{14} &= \frac{H_1}{H_2 H_3} \lambda a_{23} + \frac{\gamma}{H_4} a_{14} \\ \frac{H_2}{H_3 H_1} b_{31} &= \frac{H_2}{H_3 H_1} \alpha a_{31} + \frac{\beta}{H_4} a_{24}; & \frac{1}{H_4} b_{24} &= \frac{H_2}{H_3 H_1} \lambda a_{31} + \frac{\gamma}{H_4} a_{24} \\ \frac{H_3}{H_1 H_2} b_{12} &= \frac{H_3}{H_1 H_2} \alpha a_{12} + \frac{\beta}{H_4} a_{34}; & \frac{1}{H_4} b_{34} &= \frac{H_3}{H_1 H_2} \lambda a_{23} + \frac{\gamma}{H_4} a_{34} \end{aligned} \quad (2.5)$$

We now recall that the tensor a_{rs} consists of the magnetic induction vector \mathbf{B} and the electric intensity vector \mathbf{E} ; whilst the other electromagnetic tensor b_{rs} consists of the electric displacement vector \mathbf{D} and of the magnetic force vector \mathbf{H} . Furthermore, let us suppose that $H_1 = H_2 = H_3 = 1$ and that $H_4 = ic$ i.e. our space-time is a Galilean one. Then equations (2.5) become simply

$$\begin{aligned} -\mathbf{D} &= \alpha \mathbf{B} - i\beta \mathbf{E} \quad \text{and} \quad \frac{1}{i} \mathbf{H} = \lambda \mathbf{B} + \frac{\nu}{i} \mathbf{E} \\ \text{or } \mathbf{D} &= i\beta \mathbf{E} - \alpha \mathbf{B} \quad \text{and} \quad \mathbf{B} = \frac{1}{i\lambda} \mathbf{H} - \frac{\nu}{i\lambda} \mathbf{E} \end{aligned} \quad (2.6)$$

and comparing with the relations $\mathbf{D} = \epsilon \mathbf{E} + \rho \mathbf{B}$; $\mathbf{B} = \mu \mathbf{H} + \delta \mathbf{E}$ we have that $\epsilon = i\beta$, $\mu = 1/i\lambda$, $\rho = -\alpha$ and $\delta = -\gamma/i\lambda$ or $\epsilon\mu = \beta/\lambda$ and $\rho/\delta = \mu\alpha/\gamma$

b. *Absolute isotropy with regard to a general rotation about P.* By definition $\bar{K}_{rs}^{pq} = K_{rs}^{pq}$ and $\Delta = +1$ so that from Table IIIA we have the following relations between the invariants j_{rs} and i_{rs}

$$\begin{aligned} j_{23} &= \alpha i_{23} + \beta i_{14}; & j_{31} &= \alpha i_{31} + \beta i_{24}; & j_{12} &= \alpha i_{12} + \beta i_{34} \\ j_{14} &= \beta i_{23} + \alpha i_{14}; & j_{24} &= \beta i_{31} + \alpha i_{24}; & j_{34} &= \beta i_{12} + \alpha i_{34} \end{aligned} \quad (2.7)$$

where we now have only two distinct invariants $\alpha = K_{23}^{23}$, and $\beta = K_{14}^{23}$. Corresponding to equations (2.6) we have

$$\begin{aligned} \mathbf{D} &= i\beta \mathbf{E} - \alpha \mathbf{B} \quad \text{and} \quad \mathbf{B} = \frac{1}{i\beta} \mathbf{H} - \frac{\alpha}{i\beta} \mathbf{E} \\ \text{or } \mathbf{D} &= \epsilon \mathbf{E} + \gamma \mathbf{B} \quad \text{and} \quad \mathbf{B} = \mu \mathbf{H} + \delta \mathbf{E} \end{aligned} \quad (2.8)$$

where $\mu\epsilon = 1$ (Maxwell's relation for the aether), and $\rho/\delta = \mu$ or $1/\epsilon$.

c. *Relative isotropy with regard to a general rotation about the λ -axis.* That is, $\bar{K}_{rs}^{pq} = -K_{rs}^{pq}$ with $\Delta = -1$. Then in Table IIA $K_{23}^{23} = K_{14}^{14} = 0$ whilst $K_{23}^{14} = -\Delta K_{14}^{23} = K_{14}^{23}$ and $K_{14}^{23} = -\Delta K_{23}^{14} = K_{23}^{14}$ so that the relations between the invariants j_{rs} and i_{rs} are

$$\begin{aligned}j_{23} &= \beta i_{14}; \quad j_{31} = \beta i_{24}; \quad j_{12} = \beta i_{34} \\j_{14} &= \lambda i_{23}; \quad j_{24} = \lambda i_{31}; \quad j_{34} = \lambda i_{12}\end{aligned}$$

where β and λ are distinct invariants (2.9) and corresponding to equations 2.6 we have simply

$$D = i\beta E \text{ and } B = \frac{1}{i\lambda} H \quad (3.0)$$

with $i\beta = \epsilon$ and $i\lambda = 1/\mu$; or $\epsilon\mu = \beta/\lambda$.

Equations (3.0) are precisely the ones we wished to investigate and we see that the conditions necessary for them to be valid are a relatively-isotropic medium round the time-direction vector orthogonal to the space R_3 (considered as a hypersurface in space-time).

The equations $B = \mu H$, $D = \epsilon E$ (where μ , ϵ are distinct) are valid wherever matter is present. Considered from the point of view that our space R_3 is a hypersurface in space-time R_4 , we may say that if matter is present at a point P in our space-time, this fact is made known to an observer (in space-time) by a time-direction ${}_4\lambda$ attached to this point and orthogonal to the hypersurface R_3 .

d. *Relative isotropy with regard to a general rotation about a point P .* Table IIIA with $\bar{K}_{rs}^{pq} = -K_{rs}^{pq}$ and $\Delta = -1$ applies to this case. Corresponding to equations (2.9) we have the following set:

$$\begin{aligned}j_{23} &= \beta i_{14}; \quad j_{31} = \beta i_{24}; \quad j_{12} = \beta i_{34} \\j_{14} &= \beta i_{23}; \quad j_{24} = \beta i_{31}; \quad j_{34} = \beta i_{12}\end{aligned} \quad (3.1)$$

where $\beta = K_{14}^{23}$, which in the special case of coincidence between the ennuple at P and a Galilean reference frame attached to P , become

$$D = i\beta E \text{ and } B = \frac{1}{i\beta} H \quad (3.2)$$

or

$$D = \epsilon E \text{ and } B = \mu H$$

with $\epsilon\mu = 1$ (Maxwell's relation for empty space). We thus see that when the entire space-time is relatively isotropic, i.e. $B = \mu H$ and $D = \epsilon E$ with $\mu\epsilon = 1$, then the fact that *no matter* is present in the neighborhood of the point P (x, y, z, t) is made known to an observer (in space-time) by the absence of a time-direction vector at P , orthogonal to the hypersurface R_3 .

APPLICATIONS TO ELASTICITY THEORY

Hooke's law on the linear dependence of stress on strain when the latter is small, says that each of the six components of the stress at any point of a body is a linear function of the six components of the strain at that point.

Thus at each point of our medium we are provided with two symmetric tensors, the stress tensor T_{rs} and the strain tensor e_{rs} . The linear relation between them is expressed by the equation

$$T_{rs} = c_{rs}^{\alpha\beta} e_{\alpha\beta} \quad (r, s = 1, 2, 3) \quad (3.3)$$

where $c_{rs}^{\alpha\beta}$ may be assumed, without any loss in generality, to be symmetric in the covariant and contravariant indices separately.

Corresponding to the tensor equation (3.2) we have an invariant equation

$$p_{rs} = K_{rs}^{\alpha\beta} q_{\alpha\beta} \quad (3.4)$$

where p_{rs} , $K_{rs}^{\alpha\beta}$ are the invariants of T_{rs} , $c_{rs}^{\alpha\beta}$ respectively, with respect to an orthogonal ennuple attached to the point P at which these tensors are defined.

ABSOLUTE ISOTROPY ROUND AN AXIS

If the medium possesses structural symmetry round an axis we have what is known as *transverse-isotropy*. We find from Table IIB that in this case there are only six distinct invariants. One finds, however, in the literature on the subject that only five independent coefficients are involved in Hooke's law for transverse-isotropy. This disagreement is due to the fact that we have not assumed the existence of an energy-density of deformation, which assumption would lead us to the equation

$$K_{rs}^{pq} = K_{pq}^{rs}$$

and therefore would reduce the number of distinct coefficients of elasticity from six to five. However, we see that as far as Hooke's law is concerned we have six distinct coefficients.

ABSOLUTE ISOTROPY WITH REGARD TO THE ENTIRE SPACE

When the medium possesses structural symmetry round all lines, i.e. there is complete or absolute isotropy, then from Table IIIB (which applies in this case) we see that Hooke's law contains only two independent coefficients of elasticity K_{11}^{11} and K_{23}^{23} which in the familiar notation of Lamé are identified with λ and μ .

THE EQUILIBRIUM BETWEEN MATTER
AND RADIATION

BY LOUIS S. KASSEL*

GATES CHEMICAL LABORATORY, CALIFORNIA INSTITUTE

(Received February 7, 1930)

ABSTRACT

The equilibrium concentration of electrons and protons is recalculated on the basis of Dirac's new theory of the nature of the proton; it is found to be exceedingly small, of the same order of magnitude as had been found in previous calculations.

THERE have recently been a number of attempts to calculate the equilibrium between matter and radiation in the universe.^{1,2,3} There are two difficulties in these calculations; one of these is the generalization of energy and entropy which must be made before the equilibrium state of the entire universe can be treated; this problem has been discussed in particular by Tolman. The other difficulty is the assignment of entropy to a perfect crystal at the absolute zero; it cannot be regarded as entirely certain that this entropy is equal to that of a perfect vacuum, as is assumed. Nevertheless, all calculations agree in yielding for the final equilibrium state one in which the ratio of the energy in the form of matter to that in the form of radiation is exceedingly small; this ratio is dominated by the exponential factor $e^{-mc^2/kT}$ which completely wipes out the effect of all the other factors; the final state of the universe indicated by these calculations is thus one in which there is practically no matter left.

Quite recently Dirac⁴ has proposed a theory of the nature of the proton which seems to call for a new calculation of the equilibrium concentration of matter. Briefly stated, Dirac's theory is that the fundamental unit of matter is the electron; in addition to the usual states in which the electron is observed, there are others in which its mass is negative; in these states its total energy is negative, and in fact becomes more negative as its velocity increases. These negative energy electrons are attracted by ordinary electrons, but ordinary electrons are nevertheless repelled by them. All these properties correspond to solutions of the wave equation of the electron which were previously known, but generally considered extraneous. Dirac proposes the hypothesis that space contains great numbers of these negative energy electrons, which obey the Fermi statistics; the states of lowest energy (highest velocity) are therefore full, but a few of the states of low velocity are not

occupied; these gaps constitute irregularities in the normal arrangement of space, and are observable. It is evident that the gaps will attract ordinary electrons, and be attracted by them; they will also have in effect a positive energy, since they correspond to the absence of a particle of negative energy.

The most natural assumption is that the total number of electrons in the universe is just equal to the number of cells of negative energy; then at the absolute zero every electron would be in the lowest possible state, there would be complete uniformity throughout space, and the universe would be observationally empty. The problem to be solved is simply that of finding the distribution of electrons among the various cells at higher temperatures; we shall confine our solution to a finite region in which there is flat space-time. The problem then differs from the usual applications of the Fermi statistics chiefly in that there are two continuous ranges of energy values. We divide these ranges into intervals in the usual way, and write for the number of cells in the s^{th} interval of the positive energy range

$$Q_s = 4\pi V / h^3 (2m)^{3/2} E_s^{1/2} \Delta E \quad (1)$$

and for the number in the t^{th} interval of the negative energy range

$$Q_t = 4\pi V / h^3 (2M)^{3/2} E_t^{1/2} \Delta E. \quad (2)$$

We have included in these formulae a factor 2 arising from the spin, which we suppose exists for all energies, and in (2) we use the observed proton mass M ; there is some doubt about the correct procedure at this point; $-M$ is what the chemist would call the partial molal (or partial molecular) mass of the electrons of true mass $-m$; it is the right value to use for the change in mass produced in a system by creating the first proton in it; when another proton is created sufficiently close a different value will be needed. The result of our calculations will be that the concentration of matter is exceedingly small, and M therefore is certainly the correct mass for most purposes, though possibly not for ours; it would not make any important change in the results if m did replace M in (2). Also it is unnecessary to use the correct relativistic expressions for (1) and (2), since all cells of large positive kinetic energy are empty, and all those of large negative kinetic energy are full; the number of cells of these kinds will not be correctly given by our result, but this number does not concern us.

The number of distribution of N_s particles among Q_s cells, using the Fermi statistics, is known to be $Q_s! / N_s! (Q_s - N_s)!$ and hence the number of distributions for the entire system, the numbers N_s and N_t being specified, is

$$W = \prod_s \frac{Q_s!}{N_s! (Q_s - N_s)!} \prod_t \frac{Q_t!}{N_t! (Q_t - N_t)!} \quad (4)$$

This is to be a maximum subject to the conditions of conservation of charge and of energy. Proceeding in the usual way we have

$$\sum_s \{ -\log N_s + \log (Q_s - N_s) \} \delta N_s + \sum_t \{ -\log N_t + \log (Q_t - N_t) \} \delta N_t = 0 \quad (4)$$

$$\sum_s \delta N_s + \sum_t \delta N_t = 0 \quad (5)$$

$$\sum_s (E_s + mc^2) \delta N_s - \sum_t (E_t + Mc^2) \delta N_t = 0. \quad (6)$$

Using multipliers e^α and e^β for (5) and (6) we add these three equations and then require each term in the two sums to vanish. Upon rearranging the necessary conditions we have

$$N_s = \frac{Q_s}{e^{\alpha + (E_s + mc^2)\beta} + 1} \quad (7)$$

$$N_t = \frac{Q_t}{e^{\alpha - (E_t + Mc^2)\beta} + 1}. \quad (8)$$

It is easily shown in the usual manner that $\partial E / \partial S = 1/k\beta$ and since thermodynamics requires $\partial E / \partial S = T$, we have as always in this type of calculation

$$\beta = 1/kT. \quad (9)$$

For positive values of α the first term in the denominator of (7) will be very large and (7) may be written approximately

$$N_s = Q_s e^{-\alpha - (E_s + mc^2)/kT}. \quad (10)$$

For values of α not too large the first term in the denominator of (8) will be extremely small and we will have

$$N_t = Q_t \{ 1 - e^{\alpha - (E_t + Mc^2)/kT} \}. \quad (11)$$

We now determine α from the state of electrification of the system. The condition for neutrality is

$$\sum_s N_s = \sum_t (Q_t - N_t) \quad (12)$$

which becomes

$$\sum_s Q_s e^{-\alpha - (E_s + mc^2)/kT} = \sum_t Q_t e^{\alpha - (E_t + Mc^2)/kT}. \quad (13)$$

Upon introducing the values of Q_s and Q_t and replacing the sum by an integral we find

$$(2m)^{3/2} e^{-\alpha - mc^2/kT} \int_0^\infty e^{-E/kT} E^{1/2} dE = (2M)^{3/2} e^{\alpha - Mc^2/kT} \int_0^\infty e^{-E/kT} E^{1/2} dE \quad (14)$$

or

$$e^\alpha = (m/M)^{3/4} e^{(M-m)c^2/2kT}. \quad (15)$$

This value of α is evidently such that the approximations (10) and (11) are justified. Upon inserting (15) and (1) into (10) and integrating we obtain for the number of electrons of positive energy

$$\begin{aligned} N_+ &= \frac{4\pi V}{h^3} (4mM)^{3/4} e^{-(m+M)c^2/2kT} \int_0^\infty e^{-E/kT} E^{1/2} dE \\ &= 2V \left(\frac{2\pi(mM)^{1/2}kT}{h^2} \right)^{3/2} e^{-(m+M)c^2/2kT}. \end{aligned} \quad (16)$$

This then is the number of electrons and also the number of protons which the system contains. It is very closely similar to Stern's result for the number of particles of mass m

$$N = V \left(\frac{2\pi mkT}{h^2} \right)^{3/2} e^{-mc^2/kT}. \quad (17)$$

The vanishingly small amount of matter permitted by this equation has already been pointed out, and our result may be regarded as in some measure supporting the view that if any matter is to be preserved in the final equilibrium of the universe it must be rescued by the tendency of matter toward aggregation. But the evidence of astronomy suggests that the stars are constantly gaining matter in the form of dust and meteors, transforming it into radiation and sending it back into space; this may mean, of course, that the universe cannot save its matter by any device and that it is steadily fading away. On the other hand the evidence of the cosmic rays may be supposed to indicate that in the depths of space radiation is converted back into matter; if this process is occurring it can only mean that the foregoing calculation, and all others of a similar nature, are utterly incorrect.

ON THE INTERACTION OF STARK EFFECT AND ELECTRON SPIN IN ALKALI ATOMS¹

BY VLADIMIR ROJANSKY

WASHINGTON UNIVERSITY, ST. LOUIS, MISSOURI

(Received February 19, 1930)

ABSTRACT

The Stark effect in alkali metal atoms in weak fields is, on the basis of both theory and experiment, a second order effect. It is shown here on the basis of the quantum mechanics that when the second order Stark effect is large enough to be comparable with the multiplet structure, there appears, due to the interaction of the Stark effect and spin, an effect which, in its influence on the multiplet structure, is not unlike the Paschen-Back effect in the magnetic case. It causes a distortion of the multiplet structure and a redistribution of the intensities of the spectral lines.

INTRODUCTION

THE Stark effect in complex atoms has not yet been studied extensively in the light of the quantum mechanics, and some time will probably elapse until its more delicate features will be worked out. However, the general aspects of the effect, especially in case of the alkali atoms, have been worked out, and are confirmed by experiment. A review of this subject was recently given by Ladenburg.²

Experimental data available at present with respect to the alkali atoms in weak electric fields, i.e., fields which produce shifts of the spectral lines small compared to the fine structure separations, show that the effect is quadratic, i.e., that the separations between the Stark components of the energy levels are proportional to the square of the external field F . The quadratic nature of the effect may be inferred theoretically, in a more or less classical manner, as follows³: The valence electron, which does all the radiating, moves in the field due to the nucleus and the inner electrons. This field may be assumed to be central. Since it deviates from a Coulomb field

¹ An abstract of this paper was given in the program of the April, 1929, meeting of the American Physical Society. *Phys. Rev.* **33**, 1084 (1929).

² R. Ladenburg, *Phys. Zeits.* **30**, 369 (1929):

³ This familiar argument is repeated here mostly in order to emphasize that it is not entirely general when the effect of electron spin is considered. For example, it has been shown^{4,5} that the conclusions of such an argument do not agree with the deductions of the quantum mechanics in case of hydrogenic atoms: an insipient linear effect is to be expected in these atoms due to the degeneracy caused by the effects of the electron spin. Though the difficult task of detecting the linear effect directly by experiment has not been carried out, and therefore these deductions of the quantum mechanics remain untested directly, the theory has answered in agreement with experiment a related question, that of the metastability of the $2s$ level in atomic hydrogen.

⁴ R. Schlapp, *Proc. Roy. Soc.* **119A**, 313 (1928).

⁵ V. Rojansky, *Phys. Rev.* **33**, 1 (1929).

the orbit of the electron precesses. Due to the precession the electrical center of the atom coincides, on the average, with the nucleus. If a weak external field is applied in the direction Z the behavior of the system is not appreciably altered, and the time average of the excursion z of the valence electron in the Z direction remains zero. Now, the first order energy correction due to the field is given by the time average of Fz , and since this vanishes effects only of orders higher than the first are to be expected.

Explicit formulas for the Stark effect in alkali atoms were calculated on the Bohr theory by Becker and by Thomas.⁶ With the advent of the quantum mechanics Unsoeld⁷ considered the effect in the light of the new theory for fields insufficient to break down the l -quantization, i.e., for fields which we call weak here. Unsoeld's treatment neglects electron spin, and thus his results should apply strictly only in fields (it is difficult to find a satisfactory adjective for the description of such fields) which are weak if gauged by the effect of l on the energy but are very strong if gauged by the multiplet separations.

The purpose of the present paper is to consider the Stark effect in alkali atoms in weak fields in somewhat greater detail by taking into account the electron spin, and, particularly, to show that as the field becomes sufficiently intense, so that its effects within a doublet become comparable to the doublet separation, there should appear an effect not unlike the Paschen-Back effect in the magnetic case, consisting in a distortion of the multiplet structure and in a redistribution of intensities.⁸

The procedure leading to this conclusion is as follows: The appropriate energy matrix is first set up. Then the approximations to the perturbed energy levels are obtained, not by the general matrix perturbation formulas derived for non-degenerate systems but by actually transforming the energy matrix. In doing this it is found that after the energy matrix has been diagonalized in such a way that no first order terms in F appear off the diagonal it acquires elements whose transition frequencies are those between the components of spin doublets. If, as is the case in light atoms, the spin doublets are narrow the transformed matrix is nearly degenerate⁹ and use of methods applicable to degenerate systems leads then to the effect referred to above.

We adopt, with a few unimportant but convenient exceptions, the terminology and notation used in reference 5.

ENERGY LEVELS

We write the matrix representing the energy of an alkali atom in a weak electrostatic field in the form

⁶ R. Becker, *Zeits. f. Physik* **9**, 332 (1922); W. Thomas, *Zeits. f. Physik* **34**, 586 (1925).

⁷ A. Unsoeld, *Ann. d. Physik* **82**, 390 (1927).

⁸ The theoretical necessity for such an effect in the alkali atoms was recognized by Professor J. H. Van Vleck, who suggested the problem to the writer.

⁹ See Van Vleck's paper "On the σ -Type Doubling and Electron Spin in Diatomic Molecules," *Phys. Rev.* **33**, 467 (1929). In that paper, especially in Section 4, he develops a procedure for handling a system in which a degeneracy appears only in the higher approximations.

$$H = H_0 + H_1 = H_0 + Fez. \quad (1)$$

Here H_0 is the (diagonal) energy matrix of the unperturbed atom, whose elements are the experimental energy levels, which we denote by $H_0(n, m, l, j; n, m, l, j)$, or, for brevity, by $H_0(l, j)$. The additional term $H_1 = Fez$ is the perturbation term due to the external field F , the matrix z representing the z -coordinate of the valence electron. As the elements of z are diagonal in the axial quantum number m , and as transitions involving a change in the principal quantum number n contribute but a negligible part of the total perturbation, we shall be concerned here only with elements of the form $z(n, m, l, j; n, m, l', j')$, which we denote, for brevity, by $z(l, j; l', j')$. In writing the elements it is also convenient to eliminate the inner quantum number j through its relation to the azimuthal quantum number l , i.e., $j = l \pm \frac{1}{2}$ (reference 5 employs the inverse elimination). The expressions for the elements of z can be taken over from the theory of the Stark effect in hydrogenic atoms in weak fields, so long as the valence electron is assumed to move in a central field.¹⁰ These expressions are given explicitly in reference 5. With the abbreviations

$$\begin{aligned} K(\alpha) &= -3a_1 n(\alpha^2 - m^2)^{1/2} / 8Z\alpha, & L(\alpha) &= [n^2 - (\alpha + \frac{1}{2})^2]^{1/2}, \\ M(\alpha) &= -3a_1 n \{ [n^2 - (\alpha + \frac{1}{2})^2] m^2 \}^{1/2} / 4Z\alpha(\alpha + 1), \end{aligned} \quad (2)$$

they are, since $Z = 1$ in arc spectra:

$$\begin{aligned} z(l, l - \frac{1}{2}; l - 1, l - 1\frac{1}{2}) &= 2K(l - \frac{1}{2})L(l - \frac{1}{2}); & z(l, l - \frac{1}{2}; l + 1, l + \frac{1}{2}) &= 2K(l + \frac{1}{2})L(l + \frac{1}{2}); \\ z(l, l + \frac{1}{2}; l - 1, l - \frac{1}{2}) &= 2K(l + \frac{1}{2})L(l - \frac{1}{2}); & z(l, l + \frac{1}{2}; l + 1, l + 1\frac{1}{2}) &= 2K(l + \frac{1}{2})L(l + \frac{1}{2}); \\ z(l, l - \frac{1}{2}; l - 1, l - \frac{1}{2}) &= M(l - \frac{1}{2}); & z(l, l + \frac{1}{2}; l + 1, l + \frac{1}{2}) &= M(l + \frac{1}{2}). \end{aligned} \quad (3)$$

Multiplication of these elements by Fe gives the corresponding elements of the matrix H_1 . Thus for the present purpose the elements of the energy matrix H can be regarded as known.

With these elements on hand one might proceed to calculate the perturbed energy levels of the atom by using the formulas¹¹

$$W^{(1)}(n; n) = H(n; n); \quad W^{(2)}(n; n) = \sum_k \frac{H(n; k)H(k; n)}{h\nu_0(n; k)}; \text{ etc.}, \quad (4a, b, \dots)$$

where n , or k , is the totality of the quantum numbers defining a state, and where $\nu_0(n; k)$ is the transition frequency of the unperturbed system, pre-

¹⁰ With regard to the assumption of a central field for the valence electron see D. R. Hartree, Proc. Camb. Phil. Soc. **24**, 89 (1928), and J. C. Slater, Phys. Rev. **32**, 339 (1928). With regard to the generality of the Kronig's factors see, for example, E. Wigner, Zeits. f. Physik **43**, 644-646, (1927), for the case without spin; as to the effect of including spin see p. 93 of J. v. Neumann and E. Wigner, Zeits. f. Physik **49**, 73, (1928).

¹¹ M. Born, W. Heisenberg, and P. Jordan, Zeits. f. Physik **35**, 557 (1926). Since the diagonal elements of our H contain no F , and the off-diagonal elements are all of the first order, we write the formulas in a simplified way.

sumably known from experiment. The direct application of these formulas to H would yield expressions, quadratic in F , for the Stark effect in alkali atoms. An examination of the transformations leading to formulas (4) will, however, presently show that in the case of alkali atoms such a procedure is not necessarily legitimate, and that for certain values of F the expressions obtained by applying (4) to H are inaccurate.

Formulas (4) are the results of the process of diagonalization of a matrix, assumed to be non-degenerate, by means of appropriate canonical transformations, a process which we shall now consider more closely. The standard procedure is to use a transformation matrix of the form $S = 1 + \lambda S' + \lambda^2 S'' + \dots = 1 + S_1 + S_2 + \dots$. Let H' represent the new energy matrix resulting from the diagonalization of the original matrix H to terms in F^2 . We have:

$$H' = (1 + S_1)H(1 + S_1)^{-1} = (1 + S_1)(H_0 + H_1)(1 - S_1 + S_1^2 - \dots), \quad (5)$$

where $S_1(n; m) = H_1(n; m)/h\nu_0(n; m)$. Neglecting terms in F^3 , we have

$$H'(n; m) = H_0(n; m) + [H_1(m; m) - H_1(n; n)] \frac{H_1(n; m)}{h\nu_0(n; m)} + \sum_k'' \frac{H_1(n; k)H_1(k; m)}{h\nu_0(n; k)},$$

where the double dash is used in Σ'' to indicate that only terms for which $k \neq n$ and also $k \neq m$ are included in the summation. Since the diagonal elements of our H_1 are zero

$$H'(n; m) = H_0(n; m) + \sum_k'' \frac{H_1(n; k)H_1(k; m)}{h\nu_0(n; k)}.$$

The elements of H' are found to correspond to transitions:

$$(l, l - \frac{1}{2}) \rightarrow (l, l - \frac{1}{2}); (l - 2, l - 1\frac{1}{2}); (l - 2, l - 2\frac{1}{2}); (l + 2, l + 1\frac{1}{2}); \text{ and } (l, l + \frac{1}{2});$$

$$(l, l + \frac{1}{2}) \rightarrow (l, l + \frac{1}{2}); (l + 2, l + 1\frac{1}{2}); (l + 2, l + 2\frac{1}{2}); (l - 2, l - 1\frac{1}{2}); \text{ and } (l, l - \frac{1}{2})$$

The elements which will prove of particular interest are:¹²

$$H'(l, l \pm \frac{1}{2}; l, l \pm \frac{1}{2}) = \frac{4F^2 e^2}{h} \left[\frac{K^2(l \pm \frac{1}{2})L^2(l - \frac{1}{2})}{\nu_0(l, l \pm \frac{1}{2}; l - 1, l - 1 \pm \frac{1}{2})} + \frac{K^2(l + 1 \pm \frac{1}{2})L^2(l + \frac{1}{2})}{\nu_0(l, l \pm \frac{1}{2}; l + 1, l + 1 \pm \frac{1}{2})} \right. \\ \left. + \frac{M^2(l \pm \frac{1}{2})}{4\nu_0(l, l \pm \frac{1}{2}; l \pm 1, l \pm \frac{1}{2})} \right] + H_0(l, l \pm \frac{1}{2}) = F^2 A_{3/2 \pm 1/2} + B_{3/2 \pm 1/2}, \quad (7)$$

and

$$H'(l, l \pm \frac{1}{2}; l, l \mp \frac{1}{2}) = \frac{2F^2 e^2 K(l \pm \frac{1}{2})}{h} \left[\frac{L(l \mp \frac{1}{2})M(l \mp \frac{1}{2})}{\nu_0(l, l \pm \frac{1}{2}; l \mp 1, l \mp \frac{1}{2})} \right. \\ \left. + \frac{L(l \pm \frac{1}{2})M(l \pm \frac{1}{2})}{\nu_0(l, l \pm \frac{1}{2}; l \pm 1, l \pm \frac{1}{2})} \right] = F^2 C_{3/2 \pm 1/2}. \quad (8)$$

¹² In (7), or in (8), either the upper or the lower of the double signs is to be taken throughout, the subscripts of A , B , and C included.

Application of (4a) to H' yields, of course, the same results as does application of (4a) and (4b) to H . To show that the latter procedure is not necessarily accurate it suffices to show that it is not always legitimate to apply (4a) to H' . This, however, follows from the appearance in H' of the "troublesome" elements $H'(l, l \pm \frac{1}{2}; l, l \mp \frac{1}{2})$. Since in the alkali atoms the energy differences between states having different azimuthal quantum numbers are much greater than those between the levels of a spin doublet, the transition frequencies corresponding to these troublesome elements are much smaller than those corresponding to other off-diagonal elements of H' . Thus the energy matrix of an alkali atom in a weak electric field, while not strictly degenerate, displays, after being transformed by means of a first order canonical transformation, off-diagonal elements whose perturbing influence cannot be unconditionally disregarded. Formula (4a), on the other hand, disregards entirely the contributions of the off-diagonal elements of a matrix to which it is applied and therefore it cannot be applied directly to H' , unless the troublesome elements are themselves negligible due to an extremely small value of the factor F .

To circumvent this difficulty we shift to methods adapted to handling degenerate systems and seek a new transformation matrix T , such that in the new energy matrix H'' , given by

$$H'' = TH'T^{-1} \quad (9)$$

all the troublesome elements ($\Delta l = 0, \Delta j \neq 0$) vanish. Application of (4a) to H'' is then legitimate, i.e., the diagonal elements of H'' are the required energy levels, correct to terms in F^2 .

To determine just the energy levels it is unnecessary actually to evaluate T , as the diagonal elements of H'' can be found by solving the appropriate secular equation. The procedure is rather simple as in alkali atoms we can neglect the contribution of the elements of H'' which are non-diagonal in l , and can thus treat the interaction of the Stark effect and spin within a given spin doublet separately from that in the other spin doublets. We then obtain for each non-vanishing value of l an independent secular equation of the form

$$\begin{vmatrix} H'(l, l - \frac{1}{2}; l, l - \frac{1}{2}) - W & H'(l, l - \frac{1}{2}; l, l + \frac{1}{2}) \\ H'(l, l + \frac{1}{2}; l, l - \frac{1}{2}) & H'(l, l + \frac{1}{2}; l, l + \frac{1}{2}) - W \end{vmatrix} = 0. \quad (10)$$

The solutions, in terms of the abbreviated notation of (7) and (8), are, (for $l \neq 0$):

$$W(l, l \mp \frac{1}{2}) = \frac{1}{2}(A_1 + A_2)F^2 + \frac{1}{2}(B_1 + B_2) \pm \frac{1}{2} \{ [(A_1 - A_2)F^2 + (B_1 - B_2)]^2 + 4C_1C_2F^4 \}^{1/2}. \quad (11a)$$

The single energy level ($l = 0, j = \frac{1}{2}$) remains unaltered:

$$W(0, \frac{1}{2}) = H'(0, \frac{1}{2}; 0, \frac{1}{2}). \quad (11b)$$

To calculate $W(l, l \mp \frac{1}{2})$ to terms in F^2 we expand the radical in (11a) in powers of F . It is now seen that the consideration of the interaction of the Stark effect and electron spin, embodied in the removal of the "troublesome" elements of H' , leads to a distorted multiplet structure. The distortive effect becomes vanishingly small, of course, when $(A_1 - A_2)F^2$, (the relative shift of the terms of the spin doublet due to the quadratic Stark effect¹³), is negligible compared to $(B_1 - B_2)$, (the spin separation of the doublet in the unperturbed system).

The asymptotic forms of (11a) for small and large values of F are of interest. When F is very small we have, to terms in F^2 :

$$W(l, l \mp \frac{1}{2}) = \frac{1}{2} [(1 \pm 1)B_1 + (1 \mp 1)B_2] + \frac{1}{2} [(1 \pm 1)A_1 + (1 \mp 1)A_2]F^2. \quad (11c)$$

This formula is essentially equivalent to (7). When F is very large the expansion of (11a) becomes, if terms involving reciprocals of F^2 are neglected:

$$W(l, l \mp \frac{1}{2}) = \frac{1}{2} \{A_1 + A_2 \pm [(A_1 - A_2)^2 + 4C_1C_2]^{1/2}\}F^2 \\ + \frac{1}{2} \{(B_1 + B_2) \pm (A_1 - A_2)(B_1 - B_2)[(A_1 - A_2)^2 + 4C_1C_2]^{-1/2}\}. \quad (11d)$$

If the spin separation is assumed to shrink to zero (11d) goes over into the formula of Unsoeld,⁷ as it should.¹⁴

It was the unsatisfactory aspect of H' —its being nearly degenerate—that necessitated the transformation T . But it is seen now that this transformation is indispensable whenever the F^2 terms are comparable with the multiplet structure, quite apart from the fact that the spin doublets are narrow. It is not the "absolute" width of the doublet but its "relative" width, as compared to some unit (such as Fea_1) which measures the effect of the field, that is of importance.

RELATIVE INTENSITIES OF THE STARK COMPONENTS

For a calculation of the relative intensities of the spectral Stark components it is necessary actually to evaluate the matrix T . This is accomplished easiest by again considering singly the matrices of two rows and two columns whose energy determinants are given by (10). The procedure can be simplified still further as follows: The small matrices under consideration are not Hermitian, their two off-diagonal elements being F^2C_1 and F^2C_2 . However, the quantity $(C_1 - C_2)/(C_1 + C_2)$ is very small, of the order of magnitude of the ratio $\nu_0(\Delta l = 0, \Delta j \neq 0)/\nu_0(\Delta l \neq 0)$. We can thus introduce a new quantity C , defined by $C^2 = C_1C_2$, and set $C_1 = C_2 = C$, without reducing the order of accuracy employed in the calculations above. (These approximations are not intrinsically necessary, and are employed only to attain simplicity in the final formulas for the elements of T). When these approximations are made in H' the small matrices become Hermitian, but their eigenvalues are not al-

¹³ In view of (11a) this is only approximately so.

¹⁴ It must be noted that the quantum number which Unsoeld denotes by m is denoted by m_l in the notation of reference 5, adopted here. The quantum numbers denoted by m and by m_l , respectively, in the latter notation are related thus: $m = m_l \pm \frac{1}{2}$.

tered. The indeterminateness in T can now be removed by setting $T\tilde{T}^* = 1$, and the non-vanishing elements of T , written in terms of (7), (11a), and the quantity C , become:

$$\text{for } l=0: \quad T(0, \tfrac{1}{2}; 0, \tfrac{1}{2}) = 1 \quad (12a)$$

$$\text{for } l \neq 0: \quad T(l, l-\tfrac{1}{2}; l, l-\tfrac{1}{2}) = T(l, l+\tfrac{1}{2}; l, l+\tfrac{1}{2}) = F^2 C / \xi, \quad (12b)$$

$$T(l, l+\tfrac{1}{2}; l, l-\tfrac{1}{2}) = -T(l, l-\tfrac{1}{2}; l, l+\tfrac{1}{2}) = [H_1 - W](l, l-\tfrac{1}{2}; l, l-\tfrac{1}{2}) / \xi,$$

where

$$\xi = [F^4 C^2 + \{ [H_1 - W](l, l-\tfrac{1}{2}; l, l-\tfrac{1}{2}) \}^2]^{1/2}.$$

To calculate the relative intensities of the components we may now proceed as outlined in the first paragraph of Section 11 of reference 5, except that instead of the transformation S given there we must use the successive transformations S and T given in the present paper, formulas (5) and (12).

The interaction effect described above is probably not beyond observation in light atoms.

It is a pleasure for the writer to express here his thanks to Professor J. H. Van Vleck for the suggestion of this problem and for the criticism of this work.

ALTERNATING INTENSITIES AND ISOTOPE EFFECT IN THE BLUE-GREEN ABSORPTION BANDS OF Li_2

BY A. HARVEY* AND F. A. JENKINS

DEPARTMENT OF PHYSICS, UNIVERSITY OF CALIFORNIA

(Received February 17, 1930)

ABSTRACT

Term analysis. The analysis of the blue-green Li_2 bands previously given by Wurm is extended by new data obtained with second order plates from the 15-ft. concave grating. The band heads are given by $\nu_k = 20,398.40 + 267.3\nu' - 3.1\nu'^2 - 347.4\nu'' + 2.5\nu''^2$. Wave-numbers of the rotational structure lines of the (0, 1) band are tabulated, and the evaluation of the rotational term-differences in the lower state completely confirms the assignment of this system to the electronic transition ${}^1\Pi \leftarrow {}^1\Sigma$. The molecular constants, as completely re-determined from our data, using a more accurate procedure than that of Wurm, agree closely with his values. The new constants resulting from our work are $F_e' = 1.337 \times 10^{-10} \text{ cm}^{-1}$, $F_e'' = 1.535 \times 10^{-10}$, $\alpha'' = 0.00744$, and $\beta'' = 0.765 \times 10^{-8}$. By means of the final constants and the theoretical equations, an accurate representation of the wave-numbers of the lines of the (0, 0) band is obtained. The origin of this band is found to be $20,395.96 \text{ cm}^{-1}$.

Isotope effect. The vibrational isotope effect is established by the identification of three band heads (1, 0), (2, 0), and (3, 0), due to the less abundant isotopic molecule, Li^6Li^7 , which were found in their calculated positions within the error of measurement. The rotational isotope effect in the (0, 0) band is shown by the detection of two faint line series fitting closely the theoretical equations for the Q and P branches due to Li^6Li^7 .

Alternating intensities The alternation ratio of the intensities of successive lines in the Li_2^7 bands is determined by a new method, depending partly on the theory of intensity distribution in this type of bands given by Mulliken. The best value is found from the Q branches of the (0, 0) and (1, 0) band to be 1.78 ± 0.2 . A less reliable determination from the (0, 1) band gives 1.50. Evidence is given pointing to the true value as 1.67, which corresponds to a nuclear spin of the Li atom of $3/2(h/2\pi)$. This disagrees with the value $\frac{1}{2}(h/2\pi)$ found from hyperfine structure investigations by Schüller and Brück. As required theoretically, the isotope lines due to the unsymmetrical molecule Li^6Li^7 show no alternation.

CERTAIN interesting features of the absorption bands of lithium vapor have recently been discussed by the writers in two preliminary communications.^{1,2} Spectrograms taken with both low and high dispersion showed that with a suitable adjustment of the density of the absorbing vapor, the vibrational and rotational structures of the blue-green system are simple enough to permit the quantum analysis. The close analogy of these bands with the corresponding Na_2 system³ led us to ascribe them to a transition from a ${}^1\Sigma$ normal state to a ${}^1\Pi$ excited state. This is in harmony with the observed simple PQR

structure of the individual bands, which was verified by applying the combination principle. As was to be expected for a symmetrical molecule, the

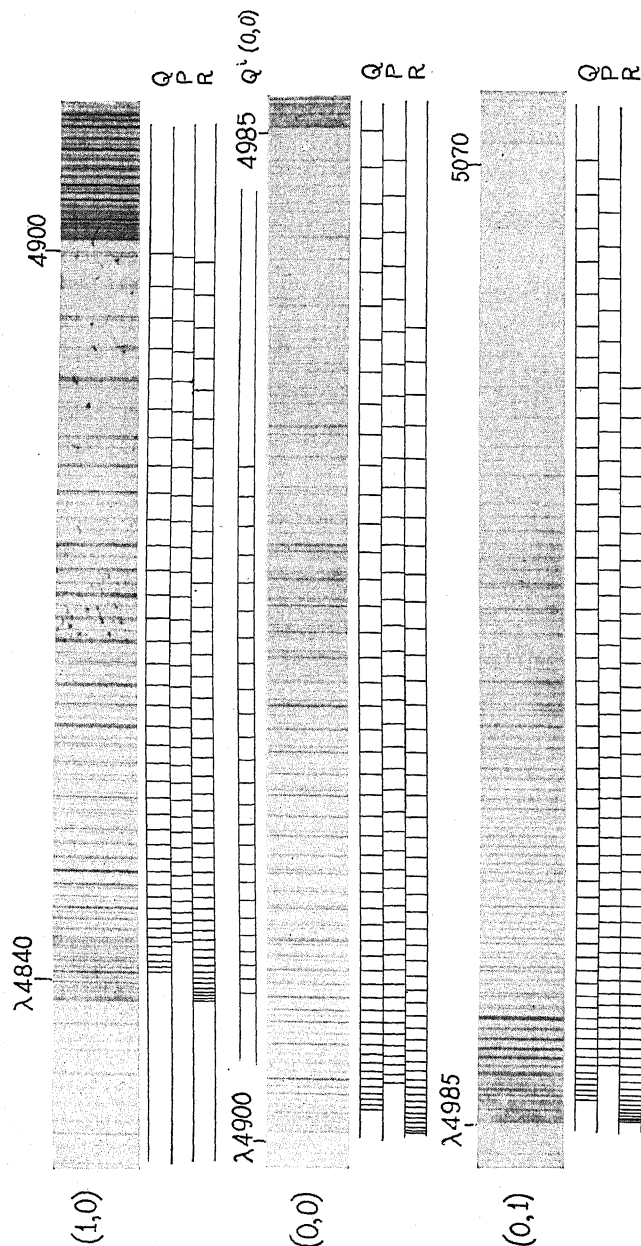

Fig. 1. Three bands of the blue-green system. Length of absorbing column 45 cm, $T=630^{\circ}\text{C}$. Second order of the 15 ft. grating.

intensities of successive lines showed a definite alternation. The alternation factor was estimated as between 1.20:1 and 1.33:1, but for reasons given be-

low the estimate was low. The vibrational isotope effect was also detected.² Li has isotopes of masses 6 and 7 in the proportion of about 1:16 (atomic weight 6.94). Besides the strong bands due to Li^7Li^7 , two weaker systems should be present, due to Li^6Li^7 and Li^6Li^6 , having respectively intensities 1/7.8 and 1/245 that of the strong system. The three most favorably placed band heads of the Li^6Li^7 system were observed. Measurements of heads are difficult in this case, especially at high temperatures, because the head occurs at a very low rotational quantum number. More satisfactory evidence of the isotope effect comes from a study of the rotational effect in the (0, 0) band the results of which will be given in the following section.

Near the completion of our work, two articles by Wurm^{4,5} appeared, dealing with the blue-green and red systems of Li_2 . The agreement of his analysis of the blue-green system with our unpublished results is excellent, not only in the wave-length data, but also in the quantum interpretation and in the resulting molecular constants. In point of self-consistency, our data seem nearly as accurate as those of Wurm, although obtained with somewhat lower dispersion (second order of a 15-ft. grating). This circumstance may be partly due to somewhat more favorable experimental conditions in our case, such as accurate control of the temperature of the electrically heated absorption tube. The spectra obtained in the present work, part of which are shown in Fig. 1, are undoubtedly less confused by the structure of faint underlying bands, since Wurm was only able to analyse the (0, 0) and (1, 0) bands. We have been able to identify the branches of the (0, 1) band without difficulty, thus permitting a check on the combination differences in the lower, as well as in the upper state. Agreements in both states are required to be absolutely certain of a correct analysis.

ISOTOPE EFFECT

Vibrational terms. From measurements of the heads of the blue-green bands an equation for the vibrational structure was derived,¹ which agreed well with that previously given by Wurm.⁴ By suitably weighting the two sets of data, we have adopted the following equation for heads:

$$\nu_h = 20,398.40 + 267.3v' - 3.1v'^2 - 347.4v'' + 2.5v''^2, \quad (1)$$

where v is the true vibrational quantum number, $v = 0, 1, 2 \dots$, formerly called n . In seeking evidence for the vibrational isotope effect, it was apparent that the faintest (Li^6Li^6) system could not be detected, due to the complexity of the spectrum, and to the fact that few of the heads are pronounced. On a low-dispersion spectrogram, taken with a carefully adjusted vapor density, it was, however, possible to find the Li^6Li^7 heads of the (2, 0)₂ and (3, 0) bands, the measured isotope shifts being 4.5 and 6.4 Å toward the

⁴ K. Wurm, *Zeits. f. Physik* **58**, 562 (1929). We had unfortunately overlooked the preliminary notice of this work, (*Naturwissenschaften* **48**, 1028 (1928)), in which a vibrational analysis of the blue-green system is given, and an equation for heads which is in close agreement with that independently derived by us (Ref. 1). Alternation of intensities is also mentioned, but the rotational analysis had not been done.

⁵ K. Wurm, *Zeits. f. Physik* **59**, 35 (1929).

violet, with a possible error of several tenths of a cm^{-1} . The theoretical shifts are most easily found by the following formula.⁶ Denoting by a superscript i quantities appropriate to the Li^6Li^7 bands, this may be written

$$\nu_0^i - \nu_0 = (\rho - 1)(\nu' + \frac{1}{2})\omega_{\nu'}' - (\rho - 1)(\nu'' + \frac{1}{2})\omega_{\nu''}'' \quad (2)$$

where $\rho = (\mu/\mu^i)^{1/2} = 1.040833$. From Eq. (1) we have

$$\omega_{\nu'}' = \omega_e' - 2x_e'\omega_e'(\nu' + \frac{1}{2}) = 270.4 - 2 \times 3.1(\nu' + \frac{1}{2}); \quad \omega_{\nu''}'' = 349.9 - 2 \times 2.5(\nu'' + \frac{1}{2}),$$

assuming that the coefficients apply equally well to band origins. This is justified here because the heads are at a small and nearly constant distance from the origins. The computed shifts in the above two cases are 4.3 and 6.3A, respectively. The (1, 0) isotope head is too close to the main band to be resolved with the prism spectrograph, but on a first order grating plate the attendant (1, 0) head could be measured with difficulty. The observed and calculated shifts in this case were 2.06 and 2.08A. On the red side of the system-origin, the fainter bands are entirely concealed by the Li^7Li^7 bands.

Rotational terms. In identifying the individual lines of the (0, 0) isotope band, more accurate and complete rotational constants of the strong system than those given by Wurm were required. We have therefore made an independent evaluation of these from our data. The wave-numbers of the rotational lines of the (0, 0) and (1, 0) band agree very well with Wurm's published data, although there is a small, nearly constant, discrepancy amounting to about 0.1 cm^{-1} on the average, our values being higher. Measurements of these bands are therefore omitted here, although the constants obtained from them are tabulated below. Table I gives wave-numbers in vacuum for the (0, 1) band, which was not analysed by Wurm, and also shows the agreement of the resulting term-differences, $\Delta_2 F_0'$, with his values from the (0, 0) band.

In the calculation of rotational constants, we have assumed the following expressions for the rotational energy:

$$\begin{aligned} \text{I}\Sigma: F(K) &= B''K(K+1) + D''[K(K+1)]^2 + F''[K(K+1)]^3 \\ \text{I}\Pi: F(K) &= B'[K(K+1) - 1] + D'[K(K+1) - 1]^2 + F'[K(K+1) - 1]^3. \end{aligned} \quad (3)$$

The observed rotational term-differences definitely require the F term, as is evident from Fig. 3 of Wurm,⁴ where it was not taken into account. With the above term formulation, the $R-P$ differences should be given by

$$\Delta_2 F(K) = 4BK + 8DK^3 + 12FK^5, \quad (4)$$

in which some negligible terms have been omitted. By means of the relations

$$D_e = -\frac{4B_e^3}{\omega_e^2}; \quad F_e = \frac{D_e^3}{B_e} \left(2 - \frac{\alpha\omega_e}{6B_e} \right);$$

⁶ The general equation for the vibrational isotope effect has recently been considered by Birge (unpublished work). A sufficiently accurate approximation, in the present case, is given by the formula quoted, a form already used by Patkowski and Curtis, *Trans. Farad. Soc.* 25, 725 (1929).

$$\beta = \frac{\alpha^2}{6\omega_e} + \frac{20\alpha B_e^2 - 32x_e B_e^3}{\omega_e^2};$$

$$B_v = B_0 - \alpha v = B_e - \alpha(v + \frac{1}{2}); D_v = D_e + \beta(v + \frac{1}{2}); F_v \cong F_e,$$

we have solved Eqs. (4) for the four states $v' = 0, 1; v'' = 0, 1$, by a well-known procedure⁷ involving a number of successive approximations. In this calculation, the vibrational constants from Eq. (1) were used; $\omega_e' = 270.4$, $\omega_e'' = 349.9$, $x_e' = 1.146 \times 10^{-2}$, $x_e'' = 0.7145 \times 10^{-2}$. Table II gives the final constants and a comparison with their values as found by Wurm.

Fig. 2. Deviations (obs-calc) of all rotational term-differences from their values as given by Eq. (4).

Fig. 2 gives the residuals of the available term-differences from those calculated by Eqs. (4) using the above constants. The small linear trend which appears in the $\Delta_2 F_0'$ residuals indicates the necessity for a small constant term in the true expression for $\Delta_2 F$. Such a "secondary ρ " term is justified theoretically, but was not used here since the error is small.

As is expected in a $^1\Pi$ state, the Λ -type doubling of rotational terms causes a small combination defect to appear when an attempt is made to obtain $\Delta_1 F$ values by combinations with the Q branch. This doubling is proportional⁴ to $(K + \frac{1}{2})^2$ and hence the initial terms of the Q branch may also be represented by Eq. (3), using a slightly smaller value of B . Wurm has found

⁷ Method 3 of Birge, "Molecular Spectra in Gases," pp. 173-5.

this difference for the (0, 0) band to be $B_B' - B_A' = 0.00018$, and since our data on the combination defect are in essential agreement with his, we have adopted $B_0' = 0.55303$ for the Q branch.

Fig. 3. Differences in wave-numbers of all lines of the (0, 0) band from the calculated Q lines. Solid lines, theoretical values from Eqs. (5); dotted lines, Q and P branches of the (0, 0) isotope band, from Eqs. (6).

A rigorous test of the accuracy of these constants is obtained by finding how well the observed *wave-numbers* of the P , Q and R branches are reproduced by the theoretical formulas:

$$\begin{aligned}
 R(K) &= \nu_0 - \frac{1}{4}C_B + 2B_B'(K + \frac{1}{2}) + (C_B + 4D')(K + \frac{1}{2})^2 + 4D'(K + \frac{1}{2})^3 \\
 &\quad + (E + 12F')(K + \frac{1}{2})^4 + 6F'(K + \frac{1}{2})^5 + G(K + \frac{1}{2})^6, \\
 P(K) &= \nu_0 - \frac{1}{4}C_B - 2B_B'(K + \frac{1}{2}) + (C_B + 4D')(K + \frac{1}{2})^2 - 4D'(K + \frac{1}{2})^3 \\
 &\quad + (E + 12F')(K + \frac{1}{2})^4 - 6F'(K + \frac{1}{2})^5 + G(K + \frac{1}{2})^6, \\
 Q(K) &= \nu_0 - B_A' - \frac{1}{4}C_A + (C_A - 2D')(K + \frac{1}{2})^2 + E(K + \frac{1}{2})^4 + G(K + \frac{1}{2})^6,
 \end{aligned} \tag{5}$$

where $C_A = B_A' - B''$, $C_B = B_B' - B''$, $E = D' - D''$ and $G = F' - F''$. Since the origin ν_0 , is as yet undetermined, this amounts to testing the constancy of ν_0 as computed from the various lines. We find small trends of the order of 0.3

cm.⁻¹ and have taken 20,395.96 as the best average. To show the results of the calculation of wave-numbers of the lines by Eqs. (5), it is convenient to use a graphical method due to Loomis and Wood.³ For this, a plot is made of the differences of every measured line in the band from the calculated values of the *Q* lines. Since the line series in bands of this kind run nearly parallel, the *P* and *R* branches also show on the diagram as series of points lying on a smooth curve. In Fig. 3 is given such a graph for the (0, 0) band. The two solid curves represent the differences of the *calculated R* and *P* lines from the adjacent *Q* lines. The agreement is as close as can be expected. This method of plotting was first used in identifying the branches of the (0, 0) band. It was then found that a number of lines were not accounted for as *P*, *Q* or *R* lines,

TABLE III. Comparison of calculated and observed wave-numbers for the *Q* branches of the Li^7Li^7 and Li^6Li^7 (0, 0) bands.

and, in fact, a number formed a distinct fourth series, with indications of a fifth. The explanation of these extra branches appears when the positions of the isotope lines of the (0, 0) band of Li^6Li^7 are determined by the theory of the isotope effect. The origin ν_0^i , of this band is, from Eq. (2), 1.635 cm^{-1} lower in wave-number than that of the strong (0, 0) band. Assuming, as is usual, a negligible electronic isotope effect, we may now compute all the lines of the fainter band. It is only necessary to multiply the coefficients of Eqs. (5) by the appropriate powers of ρ , and to insert the new origin. There results:

$$\begin{aligned} R^i(K) &= \nu_0^i - \frac{1}{4}\rho^2 C_B + 2B_B' \rho^2 (K + \frac{1}{2}) + (\rho^2 C_B + 4\rho^4 D') (K + \frac{1}{2})^2 + 4\rho^4 D' (K + \frac{1}{2})^3 \\ &\quad + (\rho^4 E + 12\rho^6 F') (K + \frac{1}{2})^4 + 6F' \rho^6 (K + \frac{1}{2})^5 + \rho^6 G (K + \frac{1}{2})^6, \\ P^i(K) &= \nu_0^i - \frac{1}{4}\rho^2 C_B - 2B_B' \rho^2 (K + \frac{1}{2}) + (\rho^2 C_B + 4\rho^4 D') (K + \frac{1}{2})^2 - 4\rho^4 D' (K + \frac{1}{2})^3 \quad (5') \\ &\quad + (\rho^4 E + 12\rho^6 F') (K + \frac{1}{2})^4 - 6F' \rho^6 (K + \frac{1}{2})^5 + \rho^6 G (K + \frac{1}{2})^6, \\ Q^i(K) &= \nu_0^i - \rho^2 B_A' - \frac{1}{4}\rho^2 C_A + (\rho^2 C_A - 2\rho^4 D') (K + \frac{1}{2})^2 + \rho^4 E (K + \frac{1}{2})^4 + \rho^6 G (K + \frac{1}{2})^6. \end{aligned}$$

The calculated Q^i and P^i branches are shown in Fig. 3 to be in excellent agreement with the two anomalous series, although P^i is rather fragmentary, due to its faintness. With these isotope lines explained, only two measured lines in the (0, 0) band remain unaccounted for, and one perhaps belongs to the R^i branch. This constitutes probably the most exacting test of the theory of the isotope effect yet applied. The numerical accuracy of the agreement appears in Table III. This is within the error of the calculation, and hence discrepancies cannot be taken as indicating that the atomic weights of Li^6 and Li^7 do not differ by integers.

Further confirmation of the isotope character of these lines is found in their failure to show alternating intensities, as discussed below.

ALTERNATING INTENSITIES

The alternation of the intensities of successive lines in each branch already established by the writers,¹ and by Wurm,⁴ is of special interest, since the alternation ratio gives a measure of the spin of the Li nucleus.⁸ To determine the latter, a quantitative measure of the ratio is required. This is particularly difficult in the present case, due largely to the many erratic fluctuations resulting from superpositions with faint underlying structure. There is also the difficulty, at least with our experimental arrangements, that neither the density of vapor nor length of the absorbing column can be found accurately, so that calculations of the absorption coefficients cannot be made, even though the intensities of the absorption lines themselves be correctly evaluated. It was at first thought that the vapor density was low enough for the observed intensities of absorption to be proportional to absorption coefficients, and a preliminary estimate of the ratio was made with this assumption. Density curves were obtained with the Zeiss-Koch recording microphotometer. An example of these curves is given in Fig. 4. In each branch of the (0, 0) band, the average electrometer deflection (background to line center) for the stronger set of lines, those with odd K'' , was compared with

⁸ For a review of this theory see R. S. Mulliken, Trans. Faraday Soc. 25, 634 (1929).

the average deflection for the weaker set. The ratio of these gave 1.2:1. Using the usual law relating densities to intensities, the alternation ratio was estimated as lying between 1.2 and 1.33. Uncertainty in the estimated contrast factor, γ , allowed considerable latitude in this result. Upon repeating the microphotometer curves with a better spectrogram, it was found that, by

Fig. 4. Microphotometric trace (retouched) of part of the (0, 0) band, showing alternation of intensity in the Q branch of the stronger (Li^7Li^7) band. No alternation is apparent in the weaker branch, Q^2 , due to Li^6Li^7 .

plotting the electrometer throws for a given branch two fairly good curves were obtained, corresponding to the stronger and weaker sets, as shown in Fig. 5. A number of values lie definitely above the general run, and many of these lines are shown by the structure analysis to be blended with other lines of the band. Neglecting these, and giving the smaller values more weight

Fig. 5. Height of peaks on microphotometer curves for the Q branches of the (0, 0) and (1, 0) bands as a function of K. To render the two sets of data comparable, that for the (1, 0) band has been multiplied throughout by 0.84. Dots represent the stronger set of lines (K odd) and circles the weaker (K even). Lines known from the analysis to be blends are indicated by small dots or circles. The arrow indicates the theoretical intensity maximum, from Eq. (7). The significance of points A, B and C is discussed in the text.

in drawing the curves, satisfactory curves could be obtained for the Q branches of the three bands studied. The mean ratio of the deflections now becomes about 1.4:1. It will be seen that failure to take into account the evident superpositions tended to render our earlier estimate of the ratio too low.

A new method has now been applied which renders unnecessary the evaluation of absorption coefficients, or determination of γ , since it rests purely on the *equality* of certain intensities. Thus, in Fig. 5, we first determine the value of K for the point A , at which the deflections for the stronger set have fallen to that of the maximum value, B , in the weaker set. Since the blackening is the same at A and B , the intensities are equal at these points. We may then calculate, using the well-established theoretical formulas for intensities in $^1\Sigma-^1\Pi$ bands,⁹ the ratio of intensities of two lines having the K values of points A and B , which ratio is then the required one, because the intensity ratio of points C to A equals that of C to B .

The intensity distribution in the Q branch of a band with $\Lambda'-\Lambda''=+1$ is given, according to Mulliken's formulas,⁹ by

$$I_Q = [2A(K+\frac{1}{2})(K+\Lambda')(K+1-\Lambda')/K(K+1)]e^{-E/kT}$$

or, when $\Lambda'=1$

$$I_Q = A(2K+1)e^{-E/kT}. \quad (6)$$

Since we are dealing with absorption, $E = F''(K)$. This formula has been shown⁹ to be in agreement with experimental data in a number of cases. The corresponding equations for the P and R branches were not of use for the purpose in hand, since the data for these branches, which are roughly half as intense as the Q branch, are not as complete or as consistent. Appreciable deviations of experiment from theory have also been found,⁹ particularly in the case of the P branch. It therefore seems best to restrict ourselves to the Q branches, and to evaluate the alternation ratio from the curves of Fig. 5.

First we may show that Eq. (6) is in agreement with the observed K value of the maximum intensity. Differentiating, and equating to zero:

$$\frac{dI_Q}{dK} = 2Ae^{-E/kT} + A(2K+1)e^{-E/kT} \frac{d}{dK} \left(-\frac{E}{kT} \right) = 0$$

whence we find, inserting for E its value $B''[K(K+1)] + D''[K(K+1)]$,² that, for the intensity maximum,

$$2B''(K+\frac{1}{2})^2 + 4D''(K+\frac{1}{2})^4 = kT. \quad (7)$$

The temperature of the absorption tube was measured by a thermocouple in direct contact with the heavy Ni tube which was covered with asbestos and electrically heated from the outside. For the plate used in this work $T = 630^\circ \pm 10^\circ \text{C} = 903^\circ \text{K}$. Solving Eq. (7), using the B_0'' and D_0'' from Table II, it is found that, for the maximum of intensity, $K = 21.5$. Fig. 5 shows that this is in good agreement with the observed value.

Such a check on the correctness of the theory lends more confidence to the application of the method for determining the alternation ratio outlined above. From Eq. (6) we obtain the ratio of any two lines of the Q branch,

$$I_{Q(K_1)}/I_{Q(K_2)} = \frac{K_1 + \frac{1}{2}}{K_2 + \frac{1}{2}} e^{(E_2 - E_1)/kT}. \quad (9)$$

⁹ R. S. Mulliken, Phys. Rev. 29, 391 (1927).

The stronger lines of the Q branch become equal to the maximum of the weaker set at $K=40$ (point A, Fig. 5). The ratio of intensities at C and A then becomes, from Eq. (6),

$$I_{Q(22)}/I_{Q(40)} = \frac{22 + \frac{1}{2}}{40 + \frac{1}{2}} \exp \left[\frac{1070.62 - 336.04}{903 \times 0.698} \right] = 1.78.$$

A similar evaluation from the (0, 1) band with much less reliable data, and fewer points, gave 1.50. The limit of accuracy of these figures is determined principally by the accuracy with which the curves can be drawn. It is found, however, that the highest possible value for the ratio, corresponding to a reasonable fit with the observed points is 2.0, and the lowest 1.6. The result is also rather sensitive to the value of T assumed. A change of T by 10° changes the ratio by 0.02. We obtained consistent readings of the temperature with the Pt-Pt, Rh thermocouple in various positions along the length of the tube, and it was standardized at the melting point of antimony, 630.5° C. A certain portion of the vapor near the water-cooled ends of the tube must of course have been at a lower temperature, but the vapor density decreases rapidly at this temperature, the absorption with the tube at 580° C being negligible.¹⁰ Hence the effects of the cooler ends should not be great.

According to the theory of alternating intensities in band spectra,⁸ only certain definite values of the alternation ratio are possible. Denoting by i the angular momentum of the Li nucleus in units $\hbar/2\pi$, the statistical weights of successive rational levels contain a factor alternating in the ratio $(i+1)/i$. The nuclear spin, i , may in general be integral or half-integral. In the neighborhood of the observed value we have the following possibilities:

$i = 1$	$3/2$	2
Ratio 2:1	1.67:1	1.50:1

The value 1.67 is within the limit of error of our measurement, but the others are not excluded. In view of relations discussed below, however, they must be regarded as improbable. From eye estimate of intensities by Wurm,⁴ the average ratio of successive lines is 1.7:1, and in the red bands⁵ he estimates the factor to be 2:1.

These results therefore indicate the spin of the Li nucleus to be $3/2$ $\hbar/2\pi$. This is in harmony with some recent generalizations¹¹ which have been drawn by considering all known values of i . For convenience the latter are collected in Table IV.

The conclusion of Heitler and Herzberg¹² that the spin of the electron is not effective in the nucleus, and that the addition of one proton adds or subtracts $\frac{1}{2}$ unit finds strong support in such a table. On this view, an integral value of i would not be expected for Li^7 , nor for any atom with an odd number of protons. One is fairly sure that in Li^7 the α -particle configuration gives a resultant spin of zero; for the He nucleus it is proven by the absence of alter-

¹⁰ Wurm, Ref. 4, estimates absorption to begin at 400° C. We were unable to detect any molecular absorption below 580° C.

¹² W. Heitler and G. Herzberg, *Naturw.* **17**, 673 (1929).

nate lines in the band spectrum that $i=0$. The probable value of $3/2$ in our case may then be interpreted as due to the parallel orientation of the spins of the three remaining protons. It will be seen in Table IV that all atoms with an odd number of nuclear protons heretofore studied have yielded only values of $i=\frac{1}{2}$, $5/2$, and $9/2$, differing by $4/2$. The possible significance of

Bi	209	126	$9/2$	{ Hyperfine structure Zeeman effect

this has been mentioned by White,¹³ but it may be that the absence of intermediate values is due to the scarceness of data for the lighter elements. In a preliminary announcement of their work on the hyperfine structure of the Li II line $\lambda 5485$, Schüler and Brück¹¹ state that the pattern can be completely explained on the assumption that $i=\frac{1}{2}$ for the Li⁷ nucleus. It will be readily seen even upon visual inspection of the bands in Fig. 1, that the alternation ratio of 3:1 required by this is out of the question.

In conclusion, we may mention that a careful examination of the photometric curves has failed to reveal any consistent alternation in the intensities of the lines in the Q branch of the (0, 0) band due to the isotope molecule, Li⁶Li⁷. The ratio of the average height of the peaks for odd K to that of even K was 1.05:1, which means sensible equality when we are dealing with such faint lines. The absence of alternation is of course to be expected for a non-symmetrical molecule, and our result is similar to that obtained by Elliott¹⁴ from his study of the Cl₂ bands.

INTENSITY MEASUREMENTS IN THE
ARC SPECTRUM OF THALLIUM*

BY O. U. VONWILLER

DEPARTMENT OF PHYSICS, UNIVERSITY OF SYDNEY, AUSTRALIA

(Received December 9, 1929)

ABSTRACT

Measurements were made by the photographic method of the ratio of the intensities of the lines $2p_2-2s$, $2p_1-2s$ in the arc spectrum with a current of 1.6 amp. using alloys of lead and thallium in varying proportions. The ratio increased with decreasing concentration of thallium reaching a limit at about 0.01 per cent, the effects of absorption being negligible at this stage. The limiting value for $\overline{a_2^2}/\overline{a_1^2}$ is 0.388, where $I=a^2\nu^4$. Commercial lead was found to have a considerable thallium content making it necessary to use chemically pure lead. Measurements of the ratios of intensities of doublets in the principal series $2s-m p_1$, $2s-m p_2$ were made for $m=4, 5, 6$ and 7 the values obtained for $\overline{a_1^2}/\overline{a_2^2}$ being respectively 4.5, 5.7, 6.4 and 7 of which the last two are very uncertain. The values were found to be independent of concentration of thallium and of the current over a restricted range of tests. The fraction of light transmitted through an antimony film reducer was found to vary with wave-length as follows: λ , 6550, 0.270; λ , 5530, 0.243; λ , 5350, 0.243; λ , 4890, 0.175; λ , 3780, 0.093. The diffraction effects recorded by Shenstone were observed and photometer diagrams are given in illustration.

A CONSIDERABLE amount of work has been done by several investigators on the measurement of intensities of doublets in the arc spectra of the alkalis and a number of interesting and important results have been obtained such as the relations between the ratio of intensities in the doublet, the effective quantum number and the atomic number, found by Sambursky.¹ It is therefore a matter of interest that similar observations should be made with another metal giving doublets but belonging to a different group and for this reason this investigation on the arc spectrum of thallium was commenced.

The method employed was the photographic one developed by Professor Ornstein and in general use in the Physical Laboratory in Utrecht.² A Hilger quartz spectrograph, type E-2, was used with photographic plates of several kinds, namely, Ilford Iso-Zenith, Ortho-Chromatic, Pan-Chromatic and Soft Gradation Pan-Chromatic according to the spectral region being examined.

Density marks were taken on all the plates; these consisted of continuous spectra from a quartz tungsten band lamp, the varying slit method being employed. For the calibration of the lamp and the calculation of the spectral distribution of the energy for the various currents used I am indebted to Mr. D. Vermeulen. With most of the plates for each exposure, both of arc and continuous spectra, two intensities were obtained by means of a reducer placed

in front of the slit of the spectrometer. This consisted of a quartz plate on half of one surface of which a thin film of antimony had been deposited by evaporation in vacuum. By this means it was possible to overcome the difficulty arising from the very great differences between the intensities of the lines on the plates found with some of the doublets examined though in the case of each pair, by selection of suitable times of exposure and the use of absorbing screens, many comparisons were made using the same half of the spectrum for both lines so that errors due to inequalities in the comparatively narrow spectrometer slit were negligible. The two intensities were used mainly to extend the range of calibration of the plate and as a means of checking the trustworthiness of the work by the parallelism of the two graphs obtained when the photometer records of the density marks were plotted against the logarithms of the slit widths. In all cases the transmission of the antimony screen was determined photographically from the distance between the two curves thus obtained so that the values are free from any error which might be introduced in a direct determination with a somewhat different optical system.

Several of the lines examined, in particular that of wave-length 5350A occur in a region where the sensitiveness of the plate changes to a marked degree for a very small spectral displacement, and special care was needed in the calibration of the plates with the photometer in these cases. It was found that when the plateholder was moved up and down in the camera its path was slightly curved so that if the plate were aligned in the photometer in such a way that the images of a given line in spectra at the top and bottom of the plate passed across the middle of the thermopile slit, the images of corresponding lines in spectra in the middle of the plate were appreciably displaced from this position. The path of the plateholder was, however, reproduced with sufficient exactness when the up and down motion was repeated and errors arising from this were minimized by taking many arc spectra on the plate with not more than two continuous spectra between successive arc spectra. By aligning the plate in the photometer for each successive pair of arc spectra satisfactory records were obtained for the intervening continuous spectra, as was shown by the two graphs being continuous and parallel.

THE DOUBLET $2p_1-2s$, $2p_2-2s$.

The first pairs of lines examined was the first doublet in the Sharp series, $2p_1-2s$, $2p_2-2s$ of wave-lengths 5350.46 and 3775.72. Some difficulty was experienced with these lines because of the feature of plate sensitiveness discussed above and because of the very great disparity between the ratio of intensities of the two lines on the plates and the ratio of the intensities of the continuous spectrum in the same regions. In the final cases with the tungsten band at a temperature of 2750°K the slit widths making the continuous spectrum equivalent to the lines were in the ratio of 40:1, that for the ultra-violet line being the greater. It was found convenient to use in the path of the light a screen consisting of a glass cell containing a dilute aqueous solution of potassium ferrocyanide, which absorbed the ultra-violet to a much greater

extent than the green though of course the same occurred in the case of the continuous spectrum. The fact that the transmission of the antimony reducer was more than 2.5 times as great for the green as for the ultra-violet line was also helpful.

These two lines are strongly reversed when the intensity is at all great and to make a satisfactory determination of the ratio of intensities it was necessary to obtain conditions under which the absorption causing this reversal does not occur.

In the first trials an arc was used between poles made of an alloy of lead and thallium; these were rods, 12 mm in diameter forced into slightly smaller hollows in heavy copper rods. The relative intensities of the two lines were measured using alloys with several different concentrations of thallium it being expected that when the proportion of thallium was reduced the effect of absorption would become less because of the smaller amount of thallium vapor in the arc so that the true value of the ratio would be approached. The current was kept at the same value, 1.5 to 1.6 amp. throughout, the supply voltage being 440. With decreasing concentration it was found that the ratio of intensity of the ultra-violet to the green line increased, this being explained by the absorption being greater in the case of the line of shorter wave-length so that this line should gain relatively when the conditions favored decreased absorption. With the strongest concentrations used, probably 2 or 3 percent thallium, a wide range of values was obtained the explanation of which is the lack of homogeneity of the poles, there being comparatively large regions relatively rich or poor in thallium, so that the arc at different times corresponded with alloys of different concentrations. With smaller concentrations of thallium more regular results were obtained, due probably, in part to a more nearly homogeneous alloy, and in part to the fact that the exposures were longer, minutes instead of seconds, so that various parts of the pole surfaces were in turn the source of the vapor in the arc and a more uniform average value was obtained.

The ratio of intensities was found still to increase with extremely small concentrations and, as it was found at this stage that the commercial lead used in making the alloys contained an appreciable amount of thallium, it became uncertain whether even the dilution in this lead without the addition of any thallium would give the limiting ratio sought. Other specimens of lead examined were found to contain thallium but some "chemically pure" lead was obtained in which the thallium content, if any, was certainly very much smaller so that fresh trials were made in which this lead was used to make the alloys. The results of the experiments with the impure lead are shown in the upper part of Fig. 1, the ordinates being proportional to the ratio of intensities (ultra-violet to green) and the abscissas to the logarithms of the concentration of thallium on an arbitrary scale. The latter are certainly incorrect being based on the assumption that the lead was free from thallium.

As in the first method of producing the arc there was a considerable loss of material through the melting of the poles a new method had to be employed

with the chemically pure lead, especially as it was clear that very small concentrations of thallium would be required, and therefore very long exposures. A Pfund type of arc was used with copper poles, the alloy being placed in a cup shaped hollow on the lower one. The current had the same value as in the earlier experiments, 1.6 amp. Generally it was not found possible to maintain the arc between the upper pole and the alloy for a long time; either the arc would go out or else run to the side of the lower pole. When this occurred the light was at once cut off and the copper cup scraped free of the layer of lead oxide formed on it and a fresh supply of alloy introduced when the arc could be re-started. In this way spectra were obtained in which the copper lines were relatively weak. When the arc passed from copper to copper the thallium lines were still present but of course corresponded with a much smaller concentration of thallium than that in the alloy under examination. It was much easier to maintain a larger current in this way but the small current seemed more likely to give the limiting value for the ratio of intensities.

By this method of experiment consistent results were obtained with various concentrations of thallium and it was found that a point was reached at which a reduction in the proportion of thallium gave no further increase in the ratio of intensities. Several values with very much smaller concentrations confirmed this.

TABLE I. Ratio \bar{a}_2^2/\bar{a}_1^2 for the doublet $=2p_2-2s, 2p_1-2s$ for various concentrations of thallium.

Percentage of thallium	Number of observations	Mean value of \bar{a}_2^2/\bar{a}_1^2	Mean error
0.072	5	0.093	0.009
0.040	3	0.236	0.040
0.087	10	0.372	0.045
0.0051	2	0.395	0.018
0.00143	1	0.382	
0.00024	2	0.388	0.032

The results are given in Table I and shown graphically in the lower part of Fig. 1. The alloys of lower concentration were made by melting stronger ones with lead and the actual numerical values of the concentrations may not be correct because the lead might contain an amount of thallium comparable with that intended in the weakest concentrations and because in melting the product was always less than the sum of the constituents used there being always some loss in which the metals might be in very different proportions from those in which they are placed in the crucible. In the case of the larger concentrations the errors cannot be great and that the concentration became successively less is shown by the fact that the time needed for satisfactory intensities of the lines became greater for each dilution so that there is no room for doubt that the limiting value was attained. On account of the long exposures required with the smallest concentrations—of the order of an hour—the effect of the “continuous spectrum” became relatively great and the value is not very accurate. On the other hand the others are trust-

worthy it being considered for example that the error in that for concentration 0.0087 percent is not more than 2 percent.

In Table I and Fig. 1 the ratio $\overline{a_2^2}/\overline{a_1^2}$ is obtained from the ratio of intensities I_2/I_1 by multiplying by the factor λ_2^4/λ_1^4 , a_1 and a_2 being the amplitudes of the virtual resonators given by the equation $I = a^2\nu^4$.

Fig. 1. Values of $\overline{a_2^2}/\overline{a_1^2}$ as a function of thallium concentration.

The values of I_2/I_1 were of course obtained from the ratio determined from the photometer records multiplied by factors for the relative intensities of the lamp radiation at the two regions and for the relative dispersion of the spectrometer.

The limiting values found are

$$I_2/I_1 = 1.56; \quad \overline{a_2^2}/\overline{a_1^2} = 0.388$$

where the suffixes 1 and 2 refer respectively to the line of longer and shorter wave-length.

The last column of Table I gives the mean of the differences between the individual observations and the mean.

THE PRINCIPLE SERIES $2s - mp_1$, $2s - mp_2$.

Measurements were next made of several doublets in this series. The first, occurring in the infra-red could not be attacked by this method but trustworthy determinations were made in the case of the second and third doublets and values were obtained for the fourth and fifth which must be taken simply as indicating the order of the true values as large errors may have been made in their measurement.

The problem is simpler than that of the lines first examined because the separation of the doublets is less and because the effects of absorption are negligible. The Pfund arc was employed, generally with pure thallium though some determinations were made with a lead alloy of 50 percent thallium, and some with a current of 3.5 amp. instead of 1.6, used in most of the work. No appreciable differences were found in the results, justifying the view that the effects of absorption are negligible. That no error was introduced by copper lines in the proximity of lines examined in the case of the first two doublets measured was shown by obtaining spectra of a copper arc with a current of the same value, 1.6 amp., with exposures longer than any used in the measurements. Such lines did not appear, though with a copper arc of 6 amp. copper lines in the neighborhood of the first pair, 6700-6500, were recorded.

The results obtained with these two doublets, recorded below in Table II, show the ratio of intensities, that of shorter wave-length to that of longer, to be distinctly greater for the pair of greater quantum number and attempts were made to obtain values for doublets of higher order. As much longer exposures were needed with these, difficulties arose from the greater continuous spectrum and from the presence of neighboring copper lines not obtained before with the relatively short exposures. Spectra were obtained using poles of carbon and other materials in the hope of obtaining better results. In several cases, mostly with the copper arc, the conditions were such that both lines of one or both doublets were obtained free from appreciable reinforcement from neighboring lines of other elements and of sufficient intensity to allow measurements to be made.

TABLE II. Ratio $\overline{a_1^2}/\overline{a_2^2}$ for doublets in the principal series $2s-mp_1, 2s-mp_2$.

m	Wave-lengths	Number of observations	Mean value of $\overline{a_1^2}/\overline{a_2^2}$	Mean error
4	6549.77 6713.69	8	4.5	0.44
5	5527.90 5583.88	11	5.7	0.92
6	5109.47 5136.84	1	6.4	
7	4891.11 4906.3	3	7	1

The values obtained for the doublets in this series are given in Table II. The ratio of $\overline{a_1^2}/\overline{a_2^2}$ rises with the quantum number but in view of the possibility of large error in the last two values it is impossible to decide whether the values conform with the equation found by Sambursky¹ in the case of the alkalis, namely

$$I_1/I_2 = cn^{a_{eff}}$$

where n_{eff} is the effective quantum number.

As it was impossible for me to remain longer in Utrecht further work could not be done at this stage. It is my intention to continue this investigation on my return to Sydney.

Note 1. The fraction of light transmitted by the antimony screen was determined in the individual cases with an error not exceeding 2 percent. The values, however, were found to vary somewhat according to the part of the screen employed and as it was frequently removed and replaced between the taking of one plate and another a fairly wide range of values was obtained particularly for the shortest wave-length employed. The mean values obtained have some interest and are given in Table III.

TABLE III. *Transmission of antimony film.*

λ	fraction transmitted	λ	fraction transmitted
6549	0.270	4891	0.175
5527	0.243	3776	0.093
5350	0.243		

Note 2. In the first stage of the work there was in many of the photometer records of line 3776 an indication of a companion line on the red side as illustrated in Fig. 2 a. Further examination with altered conditions of the optical system showed that this was a diffraction effect and that similar effects were obtained with many of the intense lead lines. A lack of symmetry of the diffraction pattern in many cases and abnormal intensities of the

Fig. 2. Photometer records of line 3776 showing presence of secondary maxima, (a) obtained with wide spectrometer slit giving unsymmetrical pattern, (b) with narrow slit, nearly symmetrical.

fringes were observed similar to those recorded by Shenstone³ whose paper came to hand while this work was in progress. In Fig. 2b is given a photometer record of line 3776 the spectrum being taken with a fine spectrometer slit. In this case the pattern is symmetrical and measurement of the displacements agree closely with those calculated from the ordinary theory.

In conclusion I wish to express my warm thanks to Professor Ornstein for giving me the opportunity, during my stay in Utrecht, of obtaining an intimate knowledge of the research methods used in his laboratory and in particular for his continued interest and help in this work.

THE FREQUENCY OF OCCURRENCE OF THE DISINTEGRATIVE-SYNTHESIS OF OXYGEN 17 FROM NITROGEN 14 AND HELIUM

WILLIAM D. HARKINS AND A. E. SCHUH

UNIVERSITY OF CHICAGO AND BELL TELEPHONE LABORATORIES

(Received February 20, 1930)

ABSTRACT

By the use of a modified Wilson-Shimizu apparatus 39000 photographs were taken of the tracks of α -rays in nitrogen. The rays used were those from thorium C and C' as in earlier work in this laboratory. Two disintegrative syntheses were obtained of oxygen of mass 17 and isotopic number 1 by the attachment of the α -particle in each case to the nucleus of an atom of nitrogen. Evidence is presented which shows that the nitrogen atoms which are acted on in this way are in general those of mass 14 and isotopic number 0. The number of disintegrative syntheses per million α -tracks is 8, while the average of this and all other work gives 15. In this work the ratio of the number of inelastic to elastic collisions was smaller than in any earlier work, but this was due largely to the occurrence of an abnormally high number of elastic collisions.

INTRODUCTION

THE procedure now in use for the detection of the synthesis of a heavier atom from two lighter ones is that suggested and used by Harkins and Ryan.¹ They considered that if very fast α -particles were shot into a Wilson cloud-expansion chamber, and if a sufficiently large number of photographs were taken, the mechanism of any atomic disintegrations would be partly revealed. By the use of this method Harkins and Shadduck² found that two disintegrative syntheses of oxygen of mass 17 and isotopic number 1 were obtained by shooting about 250,000 α -rays of 8.6 cm range from thorium C' through nitrogen gas. Although 135,000 tracks of 4.9 cm range were also obtained, the analysis of the forks indicates that only the long range particles were effective in producing disintegrative-syntheses.

This yield of eight such events per million long range tracks is very small, and Kirsch and Petterson consider that the number should be very much higher. While it is true that one or two hydrogen tracks might have escaped observation, it is improbable that this is the case, on account of the method of observation. The 39,000 photographs were projected on a screen, one at a time, usually with two observers present. Every negative which showed a deflection in an α -track was cut out from the film, whether the track of another atom was present or not. All films on which the forks were well defined were segregated, and particular attention was paid to the observation in the other photographs of those deflections which were not so clear, and in which there was any possibility of the occurrence of a disintegra-

tion. A second observation of all of the film in order to find deflections which might have been missed earlier, was also made. Pettersson and Kirsch³ consider that short range protons would be more likely to be missed than long range particles, such as are commonly found by the photographic method, but it is our opinion that they should be more easily seen, on account of the increase of ionization with decrease of speed of the particle, within the limits of the range of speed involved.

Fig. 1. Modified Shimizu-Wilson apparatus.

EXPERIMENTS ON THE SYNTHESIS OF OXYGEN ATOMS OF MASS 17

The Wilson Cloud-track apparatus used in this laboratory since 1923 was again modified, Fig. 1, and 39,000 photographs, each with two views

³ Pettersson-Kirsch, *Atomzertrümmerung*, p. 139-40.

at right angles, were taken. The gas used was nitrogen, and the α -rays were obtained from thorium C and C' as before.

Since the photographs represented about 10 tracks per picture, the number of α -rays used in this work was 390,000, and of these about 250,000 were of long range (8.3 cm) from thorium C'.

From these experiments two disintegrative-syntheses of oxygen 17 were obtained, and one view of one of these is shown in Fig. 2. The remaining range of the α -particle is 6 cm, its velocity 1.86×10^9 cm, and the velocities of the proton and of oxygen 17 are about 3×10^9 cm and 0.31×10^9 cm per second, respectively.

RESULTS AND DISCUSSION

In each of three sets of experiments a quarter of a million α -rays of long range were shot through nitrogen. The yield per million fast α -rays of disintegrative syntheses represented by the following equation

was 8, 29, and 8, respectively for the work of Harkins and Shadduck, of Blackett,⁴ and of the writers.

These results are of somewhat more interest if compared with the number of elastic collisions in which no disintegrative syntheses were involved (Table I).

TABLE I. Number of disintegrative syntheses as related to the number of elastic collisions in which the α -particle was deflected through more than 90° (per million α -rays of 8.6 cm range).

	Elastic collisions	Non-elastic collisions or disintegrative syntheses	Sum
Harkins and Shadduck	22	8	30
Blackett	32	29	61
Harkins and Schuh	100	8	108
	<u>154</u>	<u>45</u>	<u>199</u>

The number of inelastic collisions is about 29 percent as large as the number of collisions in which the α -particle is deflected by an angle greater than 90° . It is apparent, however, that the number of events of either type is too small to give an accurate knowledge of the ratio. In the observations recorded in this laboratory, only about 4 cm of the 8.6 cm range of the fast rays was photographed, but this was the effective region of highest velocity.

Since only about one atom of nitrogen in 800 has an atomic weight of 15 (isotopic number = 1) it is evident, since approximately a fourth of the total number of sharp collisions result in disintegrative syntheses, that the nitrogen affected is in general that of atomic weight 14 and isotopic number 0, which constitutes almost the whole of atmospheric nitrogen.

It seems probable that at least a part of the atoms of mass 17 in atmospheric oxygen are formed by this particular disintegrative synthesis. There is also in the atmosphere a still more abundant oxygen isotope of mass 18

⁴ P. M. S. Blackett, Proc. Roy. Soc. A107, 349 (1925).

and isotopic number 2, which, if formed by an entirely similar process, could only come from the less abundant nitrogen isotope of mass 15.

In this connection it may be noted that while the higher isotopes (17 and 18) of oxygen are very rare in comparison with the 16 isotope, nevertheless, *provided the oxygen of rocks has the same composition as atmospheric oxygen*, these seemingly rare isotopes are actually about as abundant on earth as ordinary nitrogen.

In connection with the problem of the origin of the higher isotopes of oxygen, it would be important to obtain and analyze the band spectrum of oxygen from non-radioactive minerals, and particularly from oxygen compounds present in meteorites. Unfortunately it is difficult to determine the

Fig. 2. Disintegrative synthesis of oxygen 17 and hydrogen from nitrogen and helium.

minute amount of the isotope 17 in experiments in the laboratory, since at ordinary pressures the intensity of the absorption band is too small, and the use of high pressures causes a considerable error due to a change in width of the lines and a resultant effect upon the apparent intensity.

Table II gives the abundance of the different atomic species of the elements nitrogen and oxygen as nearly as is now known.

If the oxygen of the earth's crust has the composition of that in the atmosphere, the isotope of mass 17 cannot have been formed entirely by the disintegrative synthesis from nitrogen in any reasonable period unless the amount of radioactive material was formerly very much greater than at present. For example, provided the effective α -rays passed through ni-

TABLE II. *Abundance relations for nitrogen and oxygen and carbon in the twenty-mile crust of the earth (atomic percentage).*

At. No.	Element	Atomic weight	Isotopic	Atomic percentage
8	Oxygen	16	0	57.38
6	Carbon	12 and 13	0 and 1	0.152
8	Oxygen	18	2	0.057
7	Nitrogen	14	0	0.022
8	Oxygen	17	1	0.007
7	Nitrogen	15	1	0.000027

trogen alone, it would require a period of the order of 10^{14} years for the known radioactive material to give the requisite amount of oxygen 17. Since, however, only about one atom in 4,000 in the crust is nitrogen, the period required would be of the order of 10^{18} years, since the stopping power of nitrogen is less than that of the average atom. It would take an extremely large error in the estimated amount of radioactive material in the earth's crust, and in the yield of oxygen 17 from nitrogen, to reduce this period to 10^{16} years, which is very much in excess of the supposed life of the earth. The simplest assumption is that oxygen 17 has been formed by other processes, although there is no need to restrict the time for the formation of this species from nitrogen to the period of existence of the crust of the earth. If oxygen 17 should prove to be very much more abundant in the oxygen of the atmosphere than in that in rocks, then it would be more probable that a considerable fraction has been formed by the disintegrative-synthesis.

The relations of the isotopes of oxygen to the other atomic species, and the relative abundance as well, indicate that the isotope of mass 16 and isotopic number 0 is by far the most stable, while that of mass 17 and isotopic number 1, is by far the most unstable. By analogy the nuclear spin of the zero isotope should be zero, and if recent estimates of the spins for the cadmium isotopes are correct, it seems probable that the spin (in units $h/2\pi$) is also zero for isotope 2, and equal to $1/2$ for the species of isotopic number 1. Thus it seems probable that the oxygen isotope of mass 17 produced by bombardment of a nitrogen nucleus by an alpha-particle, should exhibit a hyperfine structure in its line spectrum, and an alternation of intensities in its band spectrum (alternate lines not missing).

If the nitrogen molecule has a radius of 1.47×10^{-8} then in order to obtain one non-elastic collision, that is one disintegrative synthesis, a fast α -particle would need to shoot through 3.2 billion; to obtain an elastic collision, through five hundred million; and for any collision, through 370 million nitrogen molecules. In each molecule there are two nuclei which may be hit. On this basis the diameter of the nitrogen nucleus is of the order of 10^{-12} cm. This is of the general order of size found by Geiger and Marsden (3.2×10^{-12} cm.) for the nucleus of an atom of gold.

The number of deflections of the α -particle through more than 90 degrees is very large in comparison with the deflection through smaller angles, and in agreement with other work this indicates that the inverse square law does not hold at the small distances of approach between the α -particle and the nucleus of the nitrogen atom.

SOME INVESTIGATIONS INTO THE VELOCITY OF
SOUND AT ULTRA-SONIC FREQUENCIES
USING QUARTZ OSCILLATORS

BY CHARLES D. REID

CRUFT LABORATORY, HARVARD UNIVERSITY

(Received February 10, 1930)

ABSTRACT

The velocity of sound at ultra-sonic frequencies is measured over a frequency range from 40 to 216 kilocycles per second using quartz crystals as sound oscillators. The emitted sound is reflected back upon the source and as its phase changes the plate current of the quartz oscillator goes through a series of maximum values. The distance moved by the sound reflector between these maxima is a half wave-length of the emitted sound.

The velocity is obtained in air free from CO_2 at three values of the relative humidity, dry, 45 percent relative humidity at 20°C , and in air saturated with water vapor at 20°C .

The velocity is found to change with the distance from the source, becoming smaller as the distance becomes greater. This was particularly noticeable at 42 kilocycles.

At a distance of 45 centimeters, all values except those below 60 kilocycles become within 0.03 percent of an asymptotic value of 331.60 meters per second.

The velocity is found to depend upon the number of wave-lengths from the source.

The effect of humidity upon the velocity is found to be expressed by

$$V_H = V_0 + 0.14H$$

where V_0 is the velocity in dry air at 20°C and V_H is the velocity at any relative humidity " H " at 20°C .

THE scope of the present work was intended to include the measurement of sound velocities from about a frequency of 40 kc up to 2000 kc in several ordinary gases. Actually the investigation up to the present has been limited to measurements in air for other problems came by the way which needed solution before the research could be pushed further. As a start it was decided to check the work which had been done in air by Professor Pierce,¹ in particular, to see if the considerable increase in velocity reported by Professor Pierce for the region about 40 kc could be checked. This turned out to be somewhat difficult, and the problem has become a study of the velocity in air in the frequency range from 40 to 216 kilocycles and at various distances from the source. The effect of humidity upon velocity has been studied experimentally. The results seem to shed some light upon the reported increase in sound velocity at 40 kilocycles and indicated that the whole phenomenon is extremely complicated and interesting.

In the following experiments, the control and measurement of four variables constituted the major part of the problem in hand. These were, the

¹ G. W. Pierce, Proc. Am. Acad. of Arts and Sciences 60, No. 5 (1925).

wave-length of the emitted sound; the frequency of this sound; the temperature at which the measurements were made; and finally, the constitution of the medium through which the waves were propagated.

As in Professor Pierce's paper the sound was produced by means of quartz crystals, the use of which has by this time become quite common as frequency-control devices. If quartz crystals are used in conjunction with a vacuum tube circuit of the proper sort, the circuit will oscillate electrically with a frequency determined by one of the natural mechanical periods of vibration of the crystal. Such a circuit based on Figs. 5 and 6 of Professor Pierce's paper is shown in the accompanying diagram, Fig. 1, together with an amplifier.

Fig. 1. The oscillating circuit together with the audiofrequency amplifier and microammeter, showing shunting and bucking arrangement for the microammeter.

THE MEASUREMENT OF WAVE-LENGTH

Simultaneously the mechanical motion of the crystal produces longitudinal elastic waves of the same frequency in the medium in which it is situated. To measure the wave-length of such a disturbance a very convenient method is available. It has been found by Professor Pierce that if a solid reflector be moved in a direction perpendicular to the sound emitting face of the crystal so that the sound is reflected back to the crystal face, small changes occur in the plate current of the circuit shown. This current goes through a series of maximum and minimum values as the reflector is moved. The distance between successive maximum values of the current represents a half wave-length of the emitted sound. Since this change is small in comparison with the steady plate current, it may be detected more readily by means of a microammeter which is made to read zero for the normal plate current by means of a local bucking battery and a proper variable resistance. It was also convenient to have a variable shunt and short-circuiting switch, as indicated in the diagram, Fig. 1. Such an arrangement made it possible to use current variations of as little as four microamperes to determine the wave-length.

The position of the reflector was obtained by means of a precision screw of half millimeter pitch provided with a micrometer head divided into 100

parts so that one division on the dial indicates a motion of 0.005 millimeters. This screw was calibrated under actual working conditions by checking against a good standard meter for every five centimeters of length.

THE MEASUREMENT AND CONTROL OF FREQUENCY

The frequency of the sound source was measured in terms of a standard crystal which was kept in a fixed position during any set of measurements. This standard was calibrated directly from the clock at the Harvard Observatory by means of the method of coincidences described by Professor Pierce.² Its frequency was known at any one temperature and its temperature correction was also known. The value of this frequency was close to 421 kilocycles. At any temperature its frequency was known to about three parts in four hundred thousand.

All the crystals used in this experiment had been cut by Professor Pierce and had been ground by him so that they had a frequency such that some harmonic would produce an audible beat with the 421 kc standard. The frequency of this audible beat with the standard was measured on a calibrated

Fig. 2. Relative position of the piezoelectric sound oscillator and the oscillators and amplifiers used in determining the frequency of the sound.

audiofrequency meter and could be determined within two or three cycles per second giving an accuracy better than one part in one hundred thousand in the frequency of the sound source. The harmonic was identified by means of a wave meter.

The control of the frequency offered no difficulty, as the crystals once oscillating continued at constant frequency so long as they were undisturbed. The frequency measured at the beginning and at the end of each run was never significantly different. The disposition of the oscillators is shown in Fig. 2.

THE MEASUREMENT AND CONTROL OF TEMPERATURE

The effect of temperature on velocity was computed from the known relation between velocity and temperature. If one wishes an accuracy of 0.01 percent or better, then the temperature must be measured within 0.05°C.

The temperature was measured by means of a mercury in glass thermometer (No. 6466) divided directly into tenths of degrees centigrade which

² G. W. Pierce, Proc. Am. Acad. of Arts and Sciences 63, No. 1 (1928).

could be read to 0.02°C . This was placed within 10 centimeters of the vibrating air column. Precaution was taken to have it at the same vertical height as the crystal, so that any vertical temperature gradient would be avoided.

This thermometer was compared with a German Standard thermometer (P.T.R. 42547) kept in the Jefferson Coolidge Chemical Laboratory. The thermometer was carefully calibrated against this throughout the range over which it was used. This range was only five degrees in length, viz. 18.00°C . to 23.00°C . Corrections have been applied as they were found in the calibration.

The problem of keeping the air at nearly constant temperature forced the apparatus to be arranged in a manner such that the sound chamber was in a separate room from the operator. This room was only entered when crystals were changed, and its temperature altered very little since the room was below ground level and had no windows and no heating system. During the period over which a single set of measurements were taken, say half an hour, the observed reading on the thermometer seldom changed perceptibly. This thermometer was read from the operator's room by means of a short focus telescope. Since the room was undisturbed and the sound container was metal, it was believed that this observed value indicated accurately the temperature of the enclosed air. This is further substantiated by the fact that on several occasions when air inside was thoroughly stirred, no variation of the reading took place, nor did any occur when the thermometer was forced more deeply into the container.

THE MEASUREMENT AND CONTROL OF HUMIDITY

Professor Pierce had been led to the conclusion that change in humidity produced little effect upon the velocity of sound at these frequencies, but since this is not true at lower frequencies, it was thought advisable to control this factor if possible.

The method used for the determination of humidity was that suggested in International Critical Tables³ depending upon the constancy of the vapor pressure over saturated solutions of various salts. For example, if excess KNO_3 be dissolved in distilled water, the vapor pressure is such that the relative humidity at 20°C is 45 percent. Such a solution was placed inside the sound box while measurements were taken. A hair hygrometer placed in the sound box observed through a window served as an indicator for change in humidity.

When dry air was required the air was pumped through CaCl_2 and then over fused sodium hydroxide which also removed CO_2 . To conserve drying agents and facilitate the drying, the intake of the blower was connected to the sound chamber and thus the same air was passed many times over the drying reagents. Beside this a dish containing P_2O_5 was placed in the container. When air saturated with water vapor was needed, a bubbler was put in series with the pump, and an open dish of distilled water replaced the P_2O_5 . The CO_2 was removed by bubbling the air through a solution of NaOH .

³ International Critical Tables Vol. 1, p. 67

Attention may be called here to the fact that while all results have been reduced to values at 0°C , the amount of moisture present is still referred to 20°C .

ALIGNMENT OF CRYSTAL

In most of the work the crystal was mounted on a platform rigidly attached to the gas container and was made level when the apparatus was in position. Later, a means of tipping the crystal was devised. It was found that the error produced by lack of alignment was small, for when the crystal was deliberately tipped, the change in length of a given number of half-waves was less than would have been predicted by the use of the cosine of the angle. The crystal was set by tipping it up and down until a maximum reaction was obtained with the reflector at a great distance away. In this manner the crystal could be lined within half a degree.

Fig. 3. A typical current peak a short distance from the source at 42 kilocycles per second.

EXPERIMENTAL METHOD FOR LOCATION OF NODAL POSITIONS

While it was possible to measure frequency, temperature, and humidity quite as indicated in the preceding pages, the measurement of the wavelength was a question which turned out to be much more difficult in several respects.

If the readings of the microammeter be plotted against the distance as read by the screw, a series of maxima appear. These maxima will be referred to as "peaks" and the length of a half wave as the distance between two successive peaks.

To obtain the position of the peak with the greatest accuracy, it was impossible to set on it by moving the reflector to the position where the meter gave its largest reading, for it was found that in all cases the top of the peak was flat over a number of scale divisions. This is evident from Fig. 3. To

avoid this, readings on either side of the peak were taken (e.g. when the meter reads "110"). At this point the motion of the needle was great for a small displacement of the piston. Thus the reading can be made with greater accuracy. The mean position of the reflector on the two sides of the peak was taken as its true position.

Back lash existed, but its effect was avoided by taking readings travelling first in one direction and then in the opposite. This also avoided trouble due to change in back lash from point to point. The calibration of the precision screw was also carried out in this manner. Even without any back lash the position of the peak in space is different when the reflector is being moved out from that when the movement of the reflector is in the opposite direction.

Hence a mean position of the reflector going in and out has been taken in every case. The procedure is illustrated by the following readings taken to determine the position of the maximum.

- | | |
|--|---|
| 1. Reflector moving in | 2. Reflector moving out |
| 57707 meter reading increasing | 57732 meter reading increasing |
| 57665 meter reading decreasing | 57764 meter reading decreasing |
| 57686 average | 57748 average |
| 3. Actual position | 4. Difference between two indicated positions |
| 57686 | 57748 |
| 57748 | 57686 |
| 57717 average | 62 divisions |
| 5. Known back lash 48 divisions | |
| 6. Shift of position independent of back lash is 14 divisions. | |

The shift in "6" is not constant, but by using the above method the length of an interval could be determined consistently, with an accuracy dependent upon the frequency of the sound emitter, but seldom with an error of more than ± 3 divisions on the graduated wheel and usually not more than ± 1 .

POSSIBLE PERCENTAGE ERROR

Having dealt with the control and measurement of the four variables concerned, it is interesting to note the accuracy with which sound velocities might be obtained under such conditions. Let us suppose 50 centimeters of the screw could be utilised for measuring purposes and that the maximum points could be located to two divisions on the wheel. The percentage error thus introduced would be 0.004 percent. The frequency can be found to better than one part in thirty thousand and hence introduces a possible error less than 0.003 percent. The temperature can be measured to 0.02°C and thus introduces an error of four parts in one hundred thousand or 0.004 percent. Since the air is kept at a fixed humidity the accumulated percentage error may amount to as much as 0.01 percent.

The work had not progressed very far before it was observed that the number of variables concerned had been underestimated, for with all possible precautions results did not check each other unless taken at exactly the same distance from the vibrating crystal.

PRECAUTIONARY EXPERIMENTS TO PROVE
REALITY OF CHANGE IN WAVE-LENGTH

It must be noted here, that the word "velocity" is used to denote the product of the measured frequency and distance moved by the reflector between alternate "peaks" of current in the plate current of the oscillator. The words "half wave-length" will be used to denote the distance moved by the reflector between peaks.

It was found that velocities computed from measured intervals close to the crystal showed a marked increase in magnitude. While this seems to be true to some extent at all frequencies, the effect is much more marked in the case of 40 kc and most of the experimenting has been done using this frequency.

In order to give an account of these experiments, it will be necessary to describe briefly the apparatus in use at this time. This consisted of a brass box containing two compartments connected by a rectangular opening. In one of these compartments the crystals were arranged on a movable slide in such a way that any crystal which was to be used could be moved to a position where it could radiate sound into the adjoining chamber. This has been designated "the sound chamber." The whole box was mounted on one end of a lathe bed which supported the measuring screw. As a result only a little more than half of the total length could be used for measuring. The reflector was on the end of a piece of one-inch brass tubing which passed through a snug-fitting gland in the end of the sound chamber remote from the crystal. This made a system that was tight enough to prevent very much diffusion of gas from the outside.

The aperture which led from the crystal chamber was larger than the largest crystal face, and hence all radiation from the face entered the sound chamber. The latter had a square cross section 18 centimeters to a side and had a length of about 35 centimeters. The actual interior space was really smaller than this due to the padding.

Padding was always necessary, but no change in it altered the fact that high results were obtained close to the crystal face. The size of the reflector was altered with no results. A felt tunnel was constructed of the same size as the reflector, but this produced no change. A felt pad of cross section equal to that of the sound chamber was fastened to the back of the reflector, and hence the length of the box changed with each setting. Thus any resonant effect due to the fixed size of the sound chamber should be discovered. This also failed to produce any decrease in the wave-length. Two crystals having approximately the same frequency but with different areas of radiating faces were available, both of which produced similar high results.

It was thought that the sagging of the reflector due to its own weight might introduce errors. This would be specially true when the reflection was near the crystal face at which time it hung far out from its support. With this in mind, one of the crystals was set up outside the chamber and the length of groups of waves measured in a region quite close to its face. Then the crystal was moved closer to the lathe bed and the readings repeated. The same in-

crease was noted, but this time the piston hung only half the distance over its support. Thus it was decided that there was no measureable error due to the sagging of the reflector.

At the same time the effect of placing objects in the vicinity of the vibrating column was tried. It was found that even when solid objects were placed but a few centimeters below the direct path of the sound, no noticeable change was made in the position of a particular peak which had been located previously.

Rough measurements made at this time indicated that for all the frequencies used an increase in wave-length could be noted close to the source with or without the container.

Fig. 4. Two views of the crystal holder and crystal chamber. a. Horizontal section of crystal and holder. b. Elevation of crystal and electrodes as viewed from within sound chamber.

DESCRIPTION OF APPARATUS

As a result of these experiments, it was concluded that the inequalities of the distances between peaks were real and that sound velocity determinations carried out in this way gave values apparently different for different distances from the source and suggested measurements at greater distances from the source. This made it necessary to reconstruct the chamber of the apparatus. The revised disposition of this apparatus has been partly described in the general discussion, but since the revised arrangement has been used for all measurements recorded here, a fuller description is warranted. The revised arrangement consisted of a sound box long enough to permit the use of the full length of the measuring screw, and of sufficient diameter to permit its use without padding the walls. The actual dimensions were 60 centimeters

in length and 45 centimeters in diameter. The crystal holder had circular electrodes whose distance apart could be changed easily. The crystal con-

Fig. 5. A general view of the position of the precision screw and sound chamber.

tainer was arranged to permit easy access without opening up the whole sound chamber to the outside air. This was attained by having a slide that could be used to cover the aperture between the crystal chamber and sound box when crystals were to be changed. This slide is shown in the diagram, Fig. 4 by a dotted line. Since the whole container was located in a separate room, the temperature stayed very constant as mentioned.

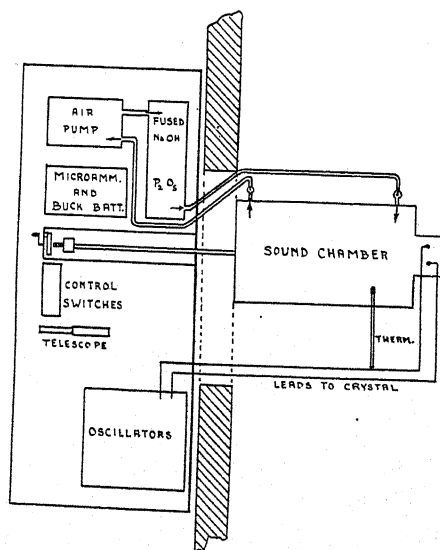

Fig. 6. A plan of all the apparatus.

An attempt was made to shield the lead which went from the piezo-oscillator circuit to the crystal, but the crystals refused to oscillate. The

leads were kept apart for best results. A complete diagram of the apparatus is appended in Fig. 5 and the disposition of the apparatus is shown in Fig. 6.

EXPERIMENTAL METHOD

The procedure for taking data was as follows. The sound oscillator was started, and the switch putting the bucking battery in circuit was closed. This was allowed to run for at least half an hour so that the change in voltage of the bucking battery would not cause the needle of the microammeter to drift. Immediately before the reflector was moved, the temperature of the air was taken, and the beat note with the standard crystal was recorded. Then the position of peaks for equal intervals of from 10 to 50 half waves were recorded as rapidly as could be done conveniently. This completed, the temperature and frequency were taken again, and averaged with the values taken before the run.

METHOD OF USING DATA

The fact that the wave-length changes with position makes it necessary to alter the method of averaging employed previously. The method used by

TABLE I.

Freq. (kc/sec.)	Veloc. (m/sec.)	No. of runs	Distance from source (cm) wave-lengths

140	331.60	9	49	200

Professor Pierce¹ assumes the presence of equal intervals, the only difference being the experimental uncertainty of measurements. In the present case this is not true except in a limited region for the two highest frequencies used.

The manner in which the results were finally computed was decided after most of the runs were made. The readings were taken as if Professor Pierce's method were to be followed, but the method actually used is described below.

The average wave-length was taken over a distance which could be measured with an accuracy of better than 0.01 percent (viz., three hundred turns of the screw, or 15 cm). *This gave the mean velocity about a point midway between the ends of this interval.* The number of half wave-lengths used was dictated by convenience so long as the total interval did not greatly exceed three hundred turns of the screw. The average was found merely by taking the difference between the end points and dividing by the number of wave-lengths in the interval. When the waves were equal in length in the interval, the average obtained in this way did not differ significantly from that obtained by Professor Pierce's more elaborate method.

The results have been calculated for the most remote 15 centimeters of the screw, then for the next 15 centimeters, and so forth. The distance from the crystal face in wave-lengths at which the results may be considered as average velocities has been listed in Table I. In most cases the 15 centimeter divisions are only approximate as will be seen upon referring to the table.

The results tabulated in Table II are those computed from readings taken over a distance about 15 centimeters in length at an average distance of 45 centimeters from the source.

TABLE II. *Dry air at 0°C. free from CO₂.*

Freq. (kc/sec.)	No. of runs	Velocity m/sec.	Freq. (kc/sec.)	No. of runs	Velocity m/sec.
140	16	331.60	70	8	331.63
105	20	331.63	60	17	331.73
84	17	331.74	42	6	331.75

If this velocity be assumed constant, the maximum variation from the mean is 0.08 meters which is 0.024 percent and is within the limit of error of the experiment.

Taking the average velocity over the same region, remote from the source I have found the following (Table III) for air free from CO₂ at 45 percent humidity at 20°C.

TABLE III. *Air, free from CO₂ at 45 percent relative humidity at 20°C.*

Freq. (kc/sec.)	No. of runs	Velocity m/sec.	Freq. (kc/sec.)	No. of runs	Velocity m/sec.
140	8	332.20	70	8	332.31
105	7	332.27	60	10	332.16
84	8	332.28	42	5	332.38

With the same conditions as above, we have a maximum deviation from the mean of 0.06 meters which is 0.018 percent, which is also within experimental error.

The values of the velocity in air saturated with moisture are not so consistent due to the fact that the crystals would only oscillate for a few minutes in the moist air and measurements were necessarily hurried. This was more serious at low frequencies where more time was needed to make the measurements. Results are given here (Table IV) for four different frequencies. These results were found for the sections of the sound chamber most remote from the crystal.

TABLE IV. *Water saturated air, free from CO₂ at 20°C.*

Freq. (kc/sec.)	No. of runs	Velocity m/sec.	Freq. (kc/sec.)	No. of runs	Velocity m/sec.
140	14	332.97	84	6	332.86
105	8	333.00	42	4	333.34

The maximum variation here is 0.16 meters which gives 0.05 percent, which is a little worse than the other results. The results in Tables II, III, and IV are plotted in Fig. 7.

Fig. 7. The velocity of sound in air at 0°C at different frequencies and under different humidity conditions.

By taking the average values at all frequencies for dry, 45 percent humidity, and saturated air we obtain the following velocities in meters per sec.

Dry	45% relative humidity	Wet
331.68	332.27	333.05

These values of the velocity are plotted against the relative humidity at 20°C in Fig. 8. For convenience the actual values of velocity have been reduced to 0°C.

Fig. 8. The relation between the average values of the velocity of sound at all frequencies and the relative humidity at 20°C.

As a result the velocity " V_H " at any relative humidity at 20°C, is related to the velocity " V_0 " in dry air at 20°C by the equation.

$$V_H = V_0 + 0.14H$$

where " H " gives the value of the relative humidity (i.e., that fraction of the amount of moisture which would be required to saturate the air at 20°C).

In addition to the values for the velocity in dry air given in Table II, some further values have been obtained using a so-called direct current amplifier which has been built in order to work at points still more remote from the crystal.

The values tabulated below are the average values taken in a region beyond 40 centimeters from the face.

TABLE V.

Freq. kc/sec.	Velocity at 0°C meters/sec.	Freq. kc/sec.	Velocity at 0°C meters/sec.
216	331.66	70	331.56
140	331.64	60	331.63
105	331.61	54	331.87
84	331.61	42	332.00

As in the preceding work, the values for the low frequencies seem high.

VARIATION OF VELOCITY WITH DISTANCE FROM FACE OF CRYSTAL

The fact still remains that the values of this velocity seem to vary with distance from the crystal, and enough data are available to give some idea of how this variation takes place. In Fig. 9 the values of the velocity are plotted against frequency for intervals at different average distances from the source. In Fig. 10, the same values of the velocity are plotted against the average number of wave-lengths from the source, at which the measurements were made.

From the former plot, it will be seen that as the chosen interval becomes more remote from the source the values of the velocity approach more nearly

Fig. 9. The relation between the velocity of sound at 0°C and different frequencies to the distance from the sound source at which these measurements were taken.

a common value. The greatest deviations from this common value occur at the lower frequencies.

Fig. 10. A curve showing the relation between the velocity of sound, as measured by this method, with the number of wave-lengths from the source, for the frequencies indicated.

It will be seen from Fig. 10 that the size of this deviation depends upon the number of wave-lengths distant from the source at which the measurements are taken.

It will be noted that to obtain the velocity values shown in Fig. 10 it was necessary to make the readings over a considerable distance. For lower frequencies this meant about 40 half waves, while for the frequency of 140 kc this number is of the order of 150 half waves. Hence the closest permissible values at 140 kc will give a mean velocity about 75 wave-lengths away. It will be seen that an increase in velocity in the vicinity of the source would be

Fig. 11. A plot of the amplitude of 36 consecutive peaks (reading of microammeter against distance) against the number of the peak (starting from the source).

masked in this manner. Thus no real close-up values have been obtained for the higher frequencies. Similar experimental difficulty presents itself at a large number of wave-lengths for the lower frequencies, as the most extreme position at 42 kc was only 80 wave-lengths, and it seems improbable that this is far enough to give the asymptotic value obtained at a great distance.

Fig. 12. The logarithm of the deflection plotted in Fig. 11.

Since the velocity close to the source could be studied better by means of the 42 kc crystal, some extra attention has been bestowed upon this. Starting from a position about fourteen half wave-lengths from the source, the next 36 consecutive peaks were plotted (ie., the reading of the microammeter was plotted against the distance), from this point on, every tenth wave was plotted until the 129th half wave was reached.

From these curves a decrement curve, Fig. 11, was plotted to a different scale and also the logarithm of the microammeter deflection, Fig. 12. The latter was very nearly a straight line except for the first few readings. The

decrement was found to be 0.015 per half wave. This is altogether too small to affect the velocity to the extent which is indicated by these experiments.

A graphical examination was made to ascertain the shift in the position of the peak due to this decrement and the effect of the decrement on the position of the peak was found to be negligible. Since the equation of the reaction current was unknown, this was the only available method.

It is worth noting that in addition to the change in wave-length with distance from the source, variations beyond experimental error occur in the separate intervals at the lower frequencies and in extreme cases amount to about 0.5 percent of the length of the interval when this is in the vicinity of the source.

SUMMARY AND DISCUSSION OF RESULTS

An attempt has been made to obtain the value of the velocity of sound at frequencies from 40 kc to 216 kc under conditions simulating outdoors, but at the same time to have greater control over the variables concerned.

Values have been obtained at eight different frequencies for three humidity conditions and at different distances from the source. An apparent rise in wave-length has been noted for regions close to the source, but which at any given position is greater the lower the frequency. As one recedes from the face of the oscillator, the velocities at various frequencies appear to approach a common value. If the velocity as found for all frequencies be plotted against the mean distance from the source in wave-lengths, some relation appears. A study at 42 kc shows that as the reflector recedes from the crystal, the value of the microammeter deflection (the change in plate current in the oscillator) decreases smoothly with a decrement nearly logarithmic, but too small to affect the length of the interval appreciably.

The method employed here has the advantage over tube methods since there is no tube correction to be considered. With the apparatus used, the diameter was equal to sixty of the longest wave-lengths used. This would correspond to a room about 60 feet in diameter for sound of about 1000 cycles.

While it is quite probable that some trouble arose due to reflections from the walls, it is hoped that at some distance from the source such effects are small. Small variations were noted from day to day which may have been due to this cause. Small temperature changes would cause marked alterations in any disturbance of this sort, as the path of wave reflected from the sides of the sound chamber would be much longer than that of the direct beam.

The rise in velocity near the sound source has been observed before. At Chicago in 1905 T. C. Hebb,⁴ working in a large hall with audible sound of wave-length approximately 10 inches, found this same effect. He noted the increase in the wave-length as the source was approached and specifically mentions that it was beyond experimental error. The length of the wave seemed to approach a limit as he reached positions fifty to sixty wave-lengths from the source. A shorter wave-length used seemed to make the trouble less obvious, though it was noted that he was farther from the source to begin

⁴ T. C. Hebb, *Phys. Rev.* 20, 89 (1905).

with and took a greater number of waves for his average length. No explanation was offered save that he thought that his reflecting mirrors were not large enough for the first wave-length he used. Since the above experiment was similar to the present experiment in many ways, it is interesting to note a similar phenomenon was observed.

The cause of this rise in velocity near the source has not been determined definitely so far, but several possibilities present themselves. Regnault found that velocities near the source were high and assumed that this was due to intensity. This can scarcely be true here as the energy radiated as sound is extremely small, for the input to the crystal oscillator, (exclusive of filament) was less than one-tenth of a watt. Some apparent increase would result from the lack of a plane wave system when a comparatively large reflector is used. However the effect is too large to be altogether accounted for by this argument.

An investigation using two crystals with different faces but having the same frequency indicated that the face of the crystal affects the result when the reflector is close to the face. Furthermore it seems probable from some recent work that in the case of higher frequencies no large rise in velocity takes place. A recent experiment showed that this was true when a 54 kc crystal with a small face was used. It is difficult to study the effect of the shape of the crystal face as they are not available in general with differing faces and the same frequency.

It is difficult to see why the reaction in the microammeter should fall off smoothly when passing through a region which must have an elaborate diffraction pattern, unless the reflector was large enough to average out diffraction effects.

The values of the ratio of the specific heats of air deduced from the velocity at 140 kc which seems to be close to the asymptotic velocity, Fig. 10, is 1.4035. This is in good agreement with the average of the best results today, computed from the velocity of sound at audible frequencies.

The average velocity in dry, CO_2 free, air as computed from the values at six frequencies is 331.68 meters per second. This result is felt to be too high, and if measurements at greater distances from the source could be taken for the lower frequencies, it seems that the results ought to decrease to 331.60 meters per second, as this seems to be the asymptotic value.

It will be noted that if the investigator had been limited to any particular region on the screw the results would have indicated, Fig. 9, a higher value for the velocity especially at the lower frequencies. As the interval over which measurements were taken was moved further from the source this increase in velocity becomes less noticeable. A further examination of the data published by G. W. Pierce¹ was undertaken by Professor Pierce and the author and revealed that these measurements were taken in a region extending from the face of the crystal, out to a point about twenty centimeters distant. This will account for the similarity of the shape of the dotted curve, Fig. 9, with those obtained by the writer. Although the numerical values of the velocity are altered by the fact that no correction was made for humidity,

yet the humidity did not change appreciably during the experiments and hence the values lie along a curve similar to those obtained by the present investigator. Notice must be taken that no experimental values have been made below 40 kilocycles per second by this method, either by Professor Pierce or by the writer. The dotted curve, Fig. 9, is merely a reproduction of that published earlier.

The change in the velocity of sound caused by saturation with water vapor at 20°C has been found to be 1.37 meters per second. This agrees very well with values calculated by McAdie⁵ and with values computed by the writer, assuming that the change in velocity is due to change in density only. Some work on this subject at audio frequencies has been done by Barss and Bastille,⁶ but their results gave a change of only 0.57 meters per second.

An examination of Professor Pierce's note-book by Mr. W. J. Cahill has resulted in showing that at that time there was evidence of a change in velocity with humidity which was overlooked. This has been affirmed by Professor Pierce.

It may be added here that this work was done in three parts several months having elapsed between each set, and that the results check well. In one of these intervals the mounting of the standard was changed and recalibrated.

The following conclusions have been reached. The increase in apparent velocity at frequencies around 40 kc grows smaller as the measurements are taken in regions more remote from the source, and, the velocity in this range of frequencies does change with the humidity.

These experiments have been carried out in the Cruft Laboratory under the direction of Professor G. W. Pierce. Further experiments are now under way in this laboratory by the aid of which it is hoped that many of the present difficulties may be cleared up.

THE VELOCITY OF PROPAGATION OF LONGITUDINAL WAVES IN LIQUIDS AT AUDIO-FREQUENCIES

BY LOUIS GORDON POOLER
COLUMBIA UNIVERSITY, NEW YORK, N. Y.

(Received February 1, 1930)

ABSTRACT

A method for measuring the velocity of propagation of longitudinal waves in liquids is described which is at the same time precise and convenient of application. A column of liquid contained in a cylindrical vertical steel tube was brought into resonance vibration at audio frequency by an electromagnetically excited diaphragm at the bottom. From the solution of the equation of propagation it is shown that when the resonance frequency of the system is the same as that of the diaphragm the reaction of the latter on the system is very small. The height of the column of liquid in the tube was adjusted until its natural frequency nearly corresponded with the predetermined resonance frequency of the diaphragm. The height was then varied slightly and the frequency adjusted until resonance occurred. From several observations of this type the appropriate height corresponding to the resonance frequency of the diaphragm was obtained by interpolation. The velocity of propagation of the longitudinal waves was then calculated from the relation $V=f_0\lambda$, where f_0 is the natural frequency of the diaphragm when clamped in the holder and λ is the wavelength.

Correction for the elasticity of the walls of the tube.—The correction formulas of Korteweg, Lamb and Gronwall were tested experimentally on tubes of different dimensions. The latter was found to give the most satisfactory agreement, the two former being unsuitable for precision measurements.

Measurements.—The velocity of sound was measured in air-free distilled water at 25°C. The average of 52 observations gave for this velocity 1485.4 ± 2.3 m/sec. From this value the bulk modulus, G , and the adiabatic compressibility, κ , were calculated. Curves were plotted illustrating the variation of the velocity of sound with temperature for the range 25°–70°C and with concentration for solutions of NaCl and KCl of different normalities. Curves for the corresponding variations of G and κ are also given.

A. INTRODUCTION

PRECISE determinations of the velocity of sound in liquids by resonance methods at audio-frequencies have not until recently been possible because of the uncertainty regarding the correction required to compensate for the elasticity of the walls of the tube. Wertheim in 1847 observed a large discrepancy between the velocity of sound measured by direct methods in large bodies of water and the velocity calculated from experiments with organ pipes filled with water from the same source. This difference was shown by Helmholtz¹ to be due to a lowering in the wave-velocity caused by yielding of the walls of the tube. Since then several correction formulas for this effect have been developed notably by Korteweg² and Lamb,³ but the approxima-

¹ Helmholtz, *Gesammelte Abhandlungen*, Vol. 1, p. 246.

³ H. Lamb, *Memoirs and Proceedings of the Manchester Literary and Philosophical Society* 42, No. 9 (1898).

tions made are not sufficiently close to permit their use in precision measurements. A steel tube 4.32 cm in diameter and having a thickness of wall equal to 0.136 cm when filled with water requires a correction to the measured velocity of sound of 16 and 17 percent according to the Lamb and Korteweg formulas, respectively. Recently Gronwall⁴ has derived a more precise correction formula. This has been tested by the writer under widely varying conditions in experiments described in the present paper.

Previous work on this problem has been done by Dorsing⁵ and Busse.⁶ The former from the measurements on the dust figures in a glass Kundt's tube has calculated the velocity of sound in several liquids with an estimated precision of about one percent; he made use, however, of the Korteweg correction formula. The latter using the same method with some slight improvements measured the velocity of sound in fifteen different liquids and by employing thick walled glass tubes reduced the magnitude of the Korteweg correction.

The purpose of the experiments described in the present paper was to develop a method for measuring the velocity of propagation of longitudinal waves in a liquid at audio-frequencies which would be at the same time precise and convenient of application. Preliminary experiments indicated that it was possible to produce resonance vibrations in a column of water contained in a vertical tube excited at the proper frequency by an electromagnetically driven diaphragm at the bottom, that the frequency which produced a maximum response for a given height of the column could readily be determined, and finally that the resonance curves were very sharp (for air-free water the sound intensity fell away to less than one half its maximum value when the frequency was changed by two or three cycles in the neighborhood of 1000~).

B. APPARATUS

The original apparatus as it appeared when immersed in a thermostatically controlled oil bath is shown diagrammatically in Fig. 1. The steel tube containing the liquid is shown at the left. Its dimensions were: length 101 cm, inside diameter 3.89 cm, outside diameter 6.37 cm. A chromium plated soft iron diaphragm 0.050 cm thick and the magnets from a Western Electric Co. 500 ohm telephone receiver were mounted at the lower end of the tube as shown in Fig. 2. The base consisted of a brass plate screwed over the end of the chamber containing the receiver; the tube itself stood on a horizontal plate fitted with leveling screws. To balance the static weight of the column of liquid and to prevent distortion of the diaphragm, air was admitted to the air-chamber and the pressure measured by means of a water manometer.

Large alterations in the level of liquid in the resonating tube were effected when desired by changing the pressure on the liquid contained in the reservoir and helix of copper tubing shown on the right in Fig. 1. The

liquid flowed through a tube from the reservoir, through a needle valve and thence into the resonating tube through a small circular orifice drilled in the steel wall several centimeters above the diaphragm. When the liquid attained the desired height the needle valve was closed to prevent any variation in level during an experiment. Small variations in level were effected by means of a burette which was lowered into the open end of the resonating tube. The height of the column of liquid was measured by the jointed brass rod *A* attached to the scale *B* shown in Fig. 1. The rod had a sharp point on

Fig. 1.

Diagram of apparatus.

Fig. 2.

the end which upon making contact with the liquid surface closed an electrical circuit thereby producing a signal in a set of head-phones. The scale *B* could be raised or lowered and vertical distances measured with a precision of 0.01 cm by the use of a vernier.

The oscillator, amplifier and detector are shown diagrammatically in Fig. 3. The oscillator was designed to produce a current whose frequency did not vary with small changes in the filament current, B-battery voltage, or variable output. To obtain a circuit with these properties a master oscillator

was used in which the oscillations were excited in the grid circuit and the current was so small that the coils and condensers did not change appreciably in temperature under operating conditions. The plate current in tube *A* (Western Electric Co., Type E) was approximately one milliamper and the B-voltage, 180 volts, was supplied by dry batteries. The master oscillator was transformer-coupled to the amplifier as shown. The tubes *B*₁ and *B*₂ were UX 212 Radiotrons operated from the lighting circuit. The B-voltage was obtained from the two voltage regulator tubes, Radiotron type UX 874, shown at *D*. The oscillating current now amplified to 90–100 milliamperes passed through the tuned filter circuit *G*. The intensity of the output current was regulated by the autotransformer *E*, and then passed through the telephone transformer *F* to the receiver at the bottom of the tube. The oscillator

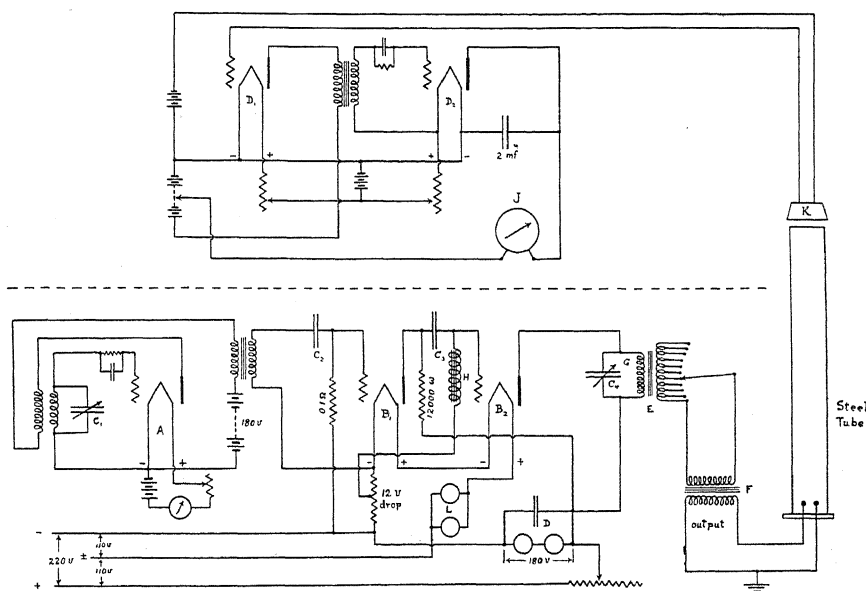

Fig. 3. Diagram of oscillator, amplifier and detector.

covered the range from 660–4500 cycles and the frequency remained appreciably constant throughout the whole range.

The oscillator was calibrated by obtaining the beat note between the current from the oscillator and the current produced in the coils of a telephone receiver by a toothed iron wheel (50 teeth) passing over the poles of the magnet. The shaft on which the toothed wheel revolved was geared (5-1) to a counter and any desired speed of rotation could be obtained by means of cone pulleys and a series resistance in the armature circuit of the motor. To measure the frequency the beat note was reduced to zero and held there and the time of 20,000 revolutions of the toothed wheel was measured with a stop watch. There was no difficulty in measuring the frequency with a precision of better than one tenth of one percent. The change in frequency produced by

varying the filament current of tube *A* by 0.05 amp. was not more than one part in two thousand and a variation of 4 volts in the B-battery did not show a detectable change in frequency.

The variable condenser *C*₁ consisted of a decade condenser, which could be varied in steps of 0.01 μf , in parallel with an air condenser filled with castor oil having a capacity of 0.012 μf . The frequency was determined at 10° and 90° on the scale of the air condenser and since the capacity varies linearly between these points the frequency could be determined for intermediate points by means of the relation

$$f = (b_1 + x b_2)^{-1/2}$$

$$\text{where } b_2 = \frac{f_1^2 - f_2^2}{(x_2 - x_1) f_1^2 f_2^2}$$

$$b_1 = \frac{1}{f_2^2} - x_2 b_2$$

and x_1 and x_2 are the readings on the condenser scale for the frequencies f_1 and f_2 , respectively. This method reduced considerably the number of readings necessary to calibrate the oscillating circuit. The calibration was checked from time to time against a standard. This standard consisted of a fused quartz rod 91.5 cm long which was suspended in a horizontal position by two threads. A small armature of soft iron was cemented to one end of the rod with shellac and a telephone receiver with the diaphragm removed was mounted several millimeters away with the magnets facing the armature. The receiver was excited from the oscillating set and the resonance frequency for the fundamental longitudinal vibration of the rod, 3115.7 ± 0.1 , was checked against the condenser setting.

The frequency of maximum intensity for the sound waves emitted by the column of liquid in the tube could be determined by ear, but the detector shown in Fig. 3 was more satisfactory for the purpose and also furnished qualitative information regarding the shape of the resonance curves. A telephone receiver *K* used as a microphone was placed about one centimeter above the open end of the tube. The current generated by the sound waves was amplified by the tube *D*₁ which was transformer-coupled to the grid of *D*₂. In tube *D*₂ the grid was maintained at a positive potential by connecting it to the positive end of the filament and, therefore it acted as a rectifier. A minimum in the plate current as recorded by the D.C. microammeter *J* indicated a maximum in the intensity of the sound waves incident on the microphone. The same procedure was followed in determining the natural frequency of the diaphragm itself.

C. DIAPHRAGMS

It is necessary to investigate the vibrating system in detail in order to determine the relation between λ the wave-length, f the frequency and V the velocity of propagation of the sound waves in the tube. Lord Rayleigh⁷ has

⁷ Lord Rayleigh, *Theory of Sound*, Vol. II, p. 158 *et seq.*

shown that for the case of forced vibrations of a fluid contained in a circular cylinder the waves ultimately become plane if $\lambda \geq 3.413 R$, where R is the radius of the tube, and that if the source of vibration be symmetrical with respect to the axis the waves ultimately become plane for a smaller value of λ than the one given by the above expression. The condition for plane waves was amply satisfied in this investigation and the law of reciprocity permits us to consider the waves produced by the vibrations of the diaphragm as equivalent to the waves produced by the forced vibrations of a piston. The wave equation for this case has the form

$$\frac{d^2 u}{dt^2} = V^2 \frac{d^2 u}{dz^2} + \frac{4}{3} \nu \frac{d^3 u}{dz^2 dt} \quad (1)$$

where u is the particle displacement, ν the kinematic coefficient of viscosity for the liquid and V represents the velocity of propagation in the tube. To determine the boundary conditions, G the bulk modulus of the liquid is defined by the equation $G = \rho V^2$, where ρ is the density of the liquid. The axis of z coincides with the axis of the tube; for the diaphragm $z=0$ and for the surface of the liquid $z=l$.

The boundary conditions for the propagation of a longitudinal wave along the axis of the tube require that at the free surface of the liquid the sum of the elastic and viscous stresses parallel to z vanish, namely,

$$G \frac{du}{dz} + Q \rho \frac{d^2 u}{dz dt} = 0 \quad \text{for } z=l; \quad (2)$$

and that at the surface of the liquid in contact with the diaphragm the pressure must be equal on the two sides, hence

$$\pi_0 e^{int} = K u + m \frac{d^2 u}{dt^2} + G \frac{du}{dz} + Q \rho \frac{d^2 u}{dz dt} \quad \text{for } z=0, \quad (3)$$

where $Q = 4\nu/3$; K is the stiffness per unit area and m the effective mass per unit area of the diaphragm and π_0 is the amplitude of the pressure. The displacement at all points in the system varies harmonically with the time and

$$u = A_1 e^{int + (\alpha + i\beta)z} + A_2 e^{int - (\alpha + i\beta)z} \quad (4)$$

will be a solution of (1), where

$$\alpha = \frac{1}{2} \frac{n^2 Q}{V^3} \quad (5)$$

$$\beta = \frac{n}{V}$$

provided $n^2 Q^2 / V^4$ is small compared with unity. The constants A_1 and A_2 are to be evaluated from the equations expressing the boundary conditions at $z=0$ and $z=l$.

From Eqs. (1) to (4) the following equation for the displacement u_l at the surface of the liquid can be found without trouble

$$|u_l|^2 = \frac{\pi_0^2}{(M^2 + P^2) \left\{ \left(\frac{1}{4} \frac{n^4 l^2}{V^6} + Nl \right) Q^2 + \cos^2(\phi - \epsilon) \right\}} \quad (6)$$

where

$$M = n\rho V, \quad P = K - mn^2, \quad N = \frac{P}{P^2 + M^2} \cdot \frac{1}{2} \cdot \frac{n^4 \rho}{V^4}$$

$$\phi = \beta l = \frac{n}{V} l, \quad \epsilon = \arctan \frac{M}{P}$$

Consider now the case of resonance $|u_l|^2 = \max$. Neglecting for the moment the term in Q^2 in the denominator on the right hand side of Eq. (6), $|u_l|^2$ will be a maximum when $\cos(\phi - \epsilon) = 0$, i.e. when

$$\phi - \epsilon = m\pi - (\pi/2)$$

where m is the number of half waves in the tube. For resonance, therefore, the relation between V , l and the resonance frequency of the system will be

$$f = \frac{V}{2l}(m + \eta) \quad (7)$$

or

$$V = \frac{2l}{T(m + \eta)} \quad (8)$$

where $T = 1/f$, and

$$\eta = \frac{\epsilon}{\pi} - \frac{1}{2} = \frac{1}{\pi} \left\{ \arctan \frac{n\rho V}{K - mn^2} \right\} - \frac{1}{2}. \quad (9)$$

At the resonance frequency of the diaphragm $K - mn^2 = 0$, hence $\eta = 0$, and

$$f_0 = \frac{V}{2l} m = \frac{V}{\lambda} \quad (10)$$

where f_0 is the resonance frequency of the diaphragm when clamped in the holder.

The effect of the term in Q^2 in shifting the maximum of $|u_l|^2$ represents the effect of viscosity on the resonance frequency of the system. It can easily be shown that this shift of the resonance frequency is but a fraction of the width of the resonance curve at half maximum. In the present experiments this corresponds to less than one cycle.

In the above discussion the give of the walls of the tube is ignored, but for the purpose in view Eq. (10) is nevertheless, sufficiently accurate. It is evident that f_0 is the frequency at which the measurements are best taken. for in this case, and in this case only, does the simple relation $V=\lambda f$ apply.

In the absence of sufficient knowledge regarding the constants of the diaphragm only qualitative information can be obtained from Eqs. (8) and (9). Fortunately, however, this information is sufficient to allow Eq. (10) to be tested experimentally. The manner in which V varies with T in Eq. (8) is shown in Table I where $T_1 > T_0 > T_2$.

TABLE I.

Period	$P = K - mn^2$	$\epsilon = \arctan M/P$	η	V
T_1	positive	$\epsilon < \pi/2$	negative	$V_1 > V$
T_0	0	$\epsilon = \pi/2$	0	$V_0 = V$
T_2	negative	$\epsilon > \pi/2$	positive	$V_2 < V$

In the preliminary experiments to test Eq. (10) two diaphragms D_1 ($f_0 = 1269 \sim$) and D_2 ($f_0 = 2590 \sim$) were investigated over a wide range of frequencies. The relation between the height of the column of liquid l ($=\lambda/2$) and the period for resonance is shown in a much exaggerated form by the curves in Fig. 4. The exaggeration is necessary as the curve is nearly a straight line throughout its entire length except near the extremities.

Fig. 4. Relation between height of the column of liquid and the period of resonance.

Inspection of these curves shows that they are in accord with the results predicted in Table I. It may also be observed that the tangents to the curves at the point for which $T = T_0$ pass through the origin; this is in agreement with Eqs. (8) and (9) as can easily be shown.

TABLE II.

Diaphragm	f_0	$\lambda/2$	$V = \lambda f$
D_1	1269	57.53 cm	1460 m/s
D_2	2590	28.07	1455

The observations which determine the shape of the curves in Fig. 4 were taken at the same temperature and with the same tube in both cases,

so that a comparison of the diaphragms can be made without requiring a correction for temperature or for the yielding of the walls of the tube. The observed data for $f=f_0$ and the calculated values of V are given in Table II.

A further experimental test of the equations is possible when the height of the column of liquid in the tube corresponds to several half wave-lengths. From Eq. (8) it is seen that unless $\eta=0$; $l_1=\lambda/2$, $l_2=\lambda$, and $l_3=3\lambda/2$ will not be in the ratio 1:2:3, since there will not be an integral number of half waves in the tube. Hence, the values of V obtained from l_1 , l_2 and l_3 should differ as m takes on successive integral values. A typical set of curves for this case is shown in Fig. 5 and Table III contains the data from another experiment of this type made with diaphragm D_2 .

TABLE III.

m	f_0	l	$\lambda/2$	Av. $\lambda/2$
1	2590	28.07 cm	28.07 cm	28.12 cm
2	2590	56.30	28.15	
3	2590	84.40	28.13	

D. METHOD OF EXPERIMENTATION AND TREATMENT OF DATA

The procedure followed in making a complete run on a given liquid was as follows:

1. The tube was placed in position, (see Fig. 1), the point of contact between the diaphragm and the measuring rod was determined and the reading on the vertical scale recorded.
2. The natural frequency f_0 of the diaphragm was determined by the method described under B.
3. The variable condenser in the oscillating set was adjusted for a frequency slightly higher than f_0 and the liquid admitted to the tube until the resonance height, $l=\lambda/2$, was reached.
4. The system was then left undisturbed for about 10 minutes to make certain that thermal equilibrium was established and the resonance frequency was then carefully determined and the height of the column of liquid measured.
5. Several cc of the liquid were then withdrawn from the tube and the resonance frequency was again determined and the new height measured.
6. This process was continued until four or five determinations had been made for frequencies slightly above and below f_0 .
7. In the investigation of diaphragms the procedure described in 3 to 6, corresponding to the resonance height $l_1=\lambda/2$, was then repeated for $l_2=\lambda$ and $l_3=3\lambda/2$.

The results of these experiments were then used as follows:

1. From the vertical heights recorded for contact between the measuring rod and the surface of the liquid the different lengths of the column were determined.
2. The condenser readings were expressed as reciprocals of the frequency.

3. A curve was plotted using the height of the column of liquid as ordinate and the period of vibration as abscissa.

4. The point corresponding to the natural period of the diaphragm was located on the curve and the height of the column at this point determined.

5. The velocity of propagation of the longitudinal waves in the liquid was then calculated from Eq. (10).

A typical set of curves for l_1 , l_2 , and l_3 plotted in accordance with the above method are shown in Fig. 5. The points indicated by the circles represent the experimental observations.

Fig. 5. Typical curves for l_1 , l_2 and l_3 .

E. THE GRONWALL CORRECTION FORMULA

The correction formulas of Korteweg and Lamb assume that the liquid completely fills the tube, thus introducing a requirement which in the present investigation would obviously be quite inconvenient to fulfill. Gronwall, however, considers the case where the liquid under observation only partly fills the tube, while the tube itself is supposed to be in a tank filled with another liquid, as would be the case when the tube is placed in a constant temperature bath.

The boundary conditions can all be satisfied experimentally, including that for the surface of separation between liquid and diaphragm, viz. $p=0$ at $z=0$ (reference 4, Eq. (31)), which is automatically satisfied for f_0 the natural frequency of the clamped diaphragm, except for the small viscous stress Qp ($d^2u/dzdt$). Gronwall's results show that B the observed velocity of the longitudinal waves in the liquid as obtained from Eq. (10) is related to V_0 their velocity in an unlimited body of the liquid by the equation

$$V_0 = \frac{V}{1-\delta} \quad (11)$$

where

$$\delta = y + 2y^2 + \left(7 - \frac{\pi^2}{3}\right)y^3 + \left(30 - \frac{7\pi^2}{3}\right)y^4 + \dots$$

For thick walled tubes

$$y = \frac{\rho V^2}{E} \left(\frac{b^2 + a^2}{b^2 - a^2} + \sigma \right) \quad (12)$$

and for thin walled tubes

$$y = \frac{\rho V^2}{E} \left[\frac{2}{3} \left(\frac{b^2 + a^2}{b^2 - a^2} + \sigma \right) + \frac{1}{3} \left(\frac{1}{2\sigma} - 1 \right) \frac{a}{b-a} \right] \quad (13)$$

where ρ is the density of the liquid, E and σ are Young's modulus and Poisson's ratio, respectively, for the material of the tube and a and b are the inner and outer radii.

The correction for the elasticity of the walls of the tube given by Eq. (11) was investigated for three tubes made of mild steel by the extrusion process. The dimensions are given in Table IV. The correction factors for the different tubes were computed, taking E for mild steel as 2.08×10^{12}

TABLE IV.

Tube	a	b	$b-a$	$1/1-\delta$
I	1.945 cm	3.185 cm	1.240 cm	1.0285
II	1.938	2.225	0.287	1.0771
III	2.024	2.160	0.136	1.1675

dynes/cm² and σ as 0.3. The quantity y was obtained from Eq. (12) for tubes I and II and from Eq. (13) in the case of tube III. A comparative analysis of an experiment with the three tubes containing air-free distilled water, using the same diaphragm and $l = \lambda/2$ is given in Table V. The diaphragm holder, Fig. 2, was so constructed that the tube did not come in contact with the diaphragm, hence, changing the tube did not alter the clamping at the boundary and f_0 was the same in each case.

TABLE V.

Tube	V (Eq. (10))	V (Correct.)	Temp.	V at 25°C [*]
I	1453.4 m./s.	1494.8 m./s.	24.8°C	1495.6 m./s.
II	1384.9	1491.7	25.6	1489.8
III	1277.6	1491.6	24.85	1492.1

The agreement between the calculated velocity of sound in the three tubes when corrected by Gronwall's formula is very good, but thin tubes require such a large correction that an appreciable error may be introduced

^{*} The temperature corrections have been made from a least square solution applied to forty observations taken between 23° and 30°C on air-free distilled water.

by uncertainty in the value of E , consequently tube I and two shorter tubes of the same dimension were used.

F. THE ASCOLOY TUBE

In the measurements made with tube I great difficulty was encountered from rusting and freshly distilled water showed traces of rust after having been in the tube for several hours at 25°C. When measurements were made at high temperatures it was necessary to keep the water in the tube over a period of many hours and the rusting became so serious that steps were taken to prevent it. The difficulty was finally overcome by chromium plating the diaphragm and by making a new tube of approximately the same dimensions from a stainless steel manufactured by the Allegheny Steel Co. under the trade name of Ascoloy 22. This tube had the dimensions $a=1.945$ cm, $b=3.155$ cm, $b-a=1.210$ cm, length 40 cm, $E=1.97 \times 10^{12}$ dynes/cm² and $\sigma=0.3$. The tube was designed for observations on $l=\lambda/2$ and since only a slight variation in the level of the liquid was required, the small hole in the wall was eliminated. In the new tube (tube V) the liquid was introduced through the open end and small changes in level were effected with the burette.

Tube V showed no signs of corrosion even with the most concentrated salt solution, but the calculated value of V for air-free distilled water was about 1/2 of one percent lower than the value previously obtained using tube I. Careful investigation showed that this difference in the value of V could only be explained by the influence of the hole in the wall. To test this point a small steel plug was made which just filled the hole and observations were taken with the plug in and then with it out. A definite lowering in the value of V was observed when the hole was plugged. Four sets of readings gave an average lowering of 6.2 m./s. and a new tube without a hole made from tube I gave results which agreed with those obtained from tube V within the limits of precision.

G. RESULTS

Following the method outlined above the velocity of sound was measured in air-free distilled water at 25°C and from 30° to 70°C at intervals of ten degrees, and in solutions of NaCl and KCl for different concentrations at 25°C.

TABLE VI.⁹

Diaphragm	Thickness	Res. Freq.	No. of Read's.	Av. Vel. at 25° C.
D ₁	0.031 cm	1269	3	1498.0 m./s.
D ₂	0.0505	2590	15	1494.2
D ₃	0.048	2318	4	1494.8
D ₄	0.052	2715	6	1492.5
		Height of Column	No. of Read's.	Av. Vel. at 25°C.
		$\lambda/2$	20	1492.2 m./s.
		λ	14	1493.1
		$3\lambda/2$	10	1494.1

⁹ The values of V in Table VI have not been corrected individually for the effect discussed in Section F.

1. *Air-free distilled water.* The value of V for air-free distilled water obtained with four different diaphragms at their respective resonance frequencies and with the same diaphragms, D_1 excepted, for $l=\lambda/2, \lambda, 3\lambda/2$ are given in Table VI.

The average of 47 observations on tube I with air-free distilled water at 25°C gave for the velocity of sound 1493.2 m./s. Correcting this value for the effect of the hole discussed under Section F and including 5 additional observations made with tube V gives for the velocity of propagation of the longitudinal waves in an unlimited body of the liquid

$$V_0 = 1485.4 \pm 2.3 \text{ m/s.}^{10}$$

From this value of V_0 and the relation $G = \rho V_0^2$ we can obtain the bulk modulus and the adiabatic compressibility of water.

$$G = 2.2000 \times 10^{10} \text{ dynes/cm}^2.$$

$$\kappa = 1/G = 4.5455 \times 10^{-11} \text{ cm}^3/\text{dyne}.$$

Fig. 6. G , V_0 and κ as functions of the temperature.

¹⁰ L. G. Pooler, Phys. Rev. 31, 157 (1928). In a note presented at the Chicago meeting of the Physical Society in Nov. 1927 the value was given as 1493.2 m/s. The effect of the hole in the wall of tube I was subsequently discovered.

Measurements on the velocity of sound, bulk modulus and compressibility at different temperatures taken from two experiments using tube I in which the agreement between corresponding values of V_0 was remarkably

close are given in Table VII. The curves in Fig. 6 have been plotted from these data and exhibit the variation of the measured quantities with the temperature.

Fig. 7. Variation of V_0 and bulk modulus with concentration.

Above 70°C the column of liquid could not be maintained in a state of vibration long enough to permit taking the necessary observations. This

phenomenon was apparently caused by the liquid boiling under reduced pressure as bubbles of gas could be seen adhering to the walls of the tube below the surface. When they were removed by stirring the liquid column came into resonance only to cease again in a very abrupt manner after several minutes.

2. *Salt solutions.* The velocity of sound was measured in aqueous solutions of NaCl and KCl for different normalities up to saturation using tube V. The results are given in Table VIII and the curves in Fig. 7 illustrate the variation in V_0 and the bulk modulus with the concentration.

H. DISCUSSION

The results obtained with air-free distilled water indicate that the method is one of high precision for the measurement of the velocity of sound in liquids and solutions and that much valuable information can be gained regarding the bulk modulus and the compressibility. The coefficient of viscosity enters into Eq. (6), but due to the excessively complicated relation which must exist at the boundary between the liquid and the tube it is doubtful if any information regarding it can be obtained from experiments of this type. It is felt that the limits of precision of this method have not as yet been reached and that with some further small refinements to the apparatus, the value of the velocity of sound can be measured to better than one tenth of one percent.

Recently two papers by Hubbard and Loomis¹¹ have appeared which present the results of an experimental determination of the velocity of sound in liquids at high frequencies (around 500,000~). The precision of their measurements is extremely high and they find that at the frequencies used the effect of the yielding of the walls of the tube can be completely neglected. The results of the present investigation correspond closely with theirs as regards the shape of the velocity-temperature curve and the velocity-concentration curves, but the measurements at audio frequencies are in all cases about one percent lower than at 500,000~. They were unable to obtain satisfactory readings at supersonic frequencies above 40°C while

¹¹ Hubbard and Loomis, *Phil. Mag.* **5**, 1177 (1928); Loomis and Hubbard, *J.O.S.A.* **17**, 295 (1928).

in the present investigation it was possible to continue observations up to 70°C before the column of liquid ceased to resonate. This difference can easily be explained when it is recalled that in a longitudinal wave the variation in pressure at a node is proportional to the frequency, and hence in their experiments ebullition would commence at a lower temperature.

The position of the maximum in the curve for the bulk modulus and the corresponding minimum in the compressibility curve at 63°C shown in Fig. 6 is in good agreement with the temperature found by other experimenters using entirely different methods. This peculiar behavior of the compressibility is fully discussed from the thermodynamical aspect in a paper by Bridgman¹² in which experiments with water at different temperatures and under static pressures up to 1200 kg/cm² are described.

The progress of this research indicates that many interesting facts can be discovered from measurements on the velocity of sound in liquids and particularly in solutions. It is hoped that through further experiments of this kind it may be possible, in the near future, to throw some light on the subject of dissolved substances in general and to derive an expression for the relation between the compressibility and the diminution in volume which occurs when many substances dissolve. The method also lends itself to a study of the rate of chemical reaction for cases in which the velocity of sound differs for the reacting liquids and the product of the combination.

The writer wishes to express his appreciation of the kindness of Dr. Wenté and the late Dr. I. B. Crandall of the staff of the Bell Telephone laboratories who furnished the thick diaphragms used in these experiments and to Professor Colin G. Fink in whose laboratory the diaphragms were chromium plated; and also to acknowledge his indebtedness to Professor A. P. Wills whose advice and encouragement have been of great assistance during the progress of this research.

THE DIELECTRIC CONSTANT AND THE MOLECULAR STRUCTURE OF CS_2

By C. T. ZAHN

PALMER PHYSICAL LABORATORY, PRINCETON UNIVERSITY

(Received February 20, 1930)

ABSTRACT

By the radio frequency heterodyne method previously developed measurements have been made of the dielectric constant of CS_2 at various pressures and temperatures. The molecular polarization is shown to be independent of temperature and therefore the electric moment is zero. The previous value published tentatively is shown to be in error. The structure of the CS_2 molecule can now be considered to be rectilinear and symmetrical. The value for the molecular polarization obtained is $P = 22.36$.

Comparisons with other data are given, and some convenient modifications in the experimental method and in the interpretation of dielectric constant data are described.

IN A recent article of this review Dr. J. B. Miles together with the author¹ gave values for the dielectric constant and the electric moment of CO , COS , CS_2 , and H_2S . The results then obtained indicated a small electric moment for the CS_2 molecule which seemed to be in contradiction to Williams'² results from the study of solutions. The experiments on CS_2 were accompanied by two chief difficulties. First, the apparatus was not adapted to the study of hot vapors, since part of the gas system was always at room temperature and it was therefore possible to work only at pressures below about one-third of an atmosphere. Secondly, the solubility of the CS_2 in the small amount of grease collected around the stopcocks made the results on CS_2 somewhat questionable. For these reasons the values for CS_2 were given only tentatively in the above mentioned article and it was there promised to make more conclusive measurements in the near future. Since then the apparatus has been adapted to work with hot vapors by Dr. J. B. Miles in collaboration with the author, and measurements have been made on CS_2 under excellent experimental conditions.

While this work was in progress there appeared an article by Ghosh, Mahanti, and Mukherjee³ on the dielectric constant and the molecular structure of CS_2 and N_2O , in which the moments of CS_2 and N_2O were found to be zero. The experiments described in the present article verify the conclusion that CS_2 has no appreciable electric moment but the value of the molecular polarization obtained is not in sufficiently close agreement with that of the above mentioned observers. It therefore seems worth while to give a full discussion of the present work.

EXPERIMENTAL METHOD AND MODIFICATIONS

The radio frequency heterodyne null method was used as previously described and applied to the measurement of a considerable number of gaseous substances.⁴ In the present arrangement of the apparatus there is one stopcock, which is separated from the gas system by liquid CS₂ in the manometer described,⁴ and should therefore not be so likely to introduce impurities even if grease were used in the seal. In order to make perfectly certain of this the grease was replaced by P₂O₅. The CS₂ used was taken from the same purified specimen as used before.¹

Some convenient modifications have been made in the method of interpretation of the dielectric constant data as follows. The dielectric constant should obey Debye's equation:

$$3\left(\frac{\epsilon-1}{\epsilon+2}\right)vT = AT + B$$

where ϵ is the dielectric constant, v is the specific volume referred to the *ideal* volume under S.P.T. conditions, T is the absolute temperature, and A and B are constants.

$$B = \frac{4\pi N_0}{3k} \mu^2 \text{ or } \mu = 1.099_8 \times 10^{-18} B$$

where N_0 is Loschmidt's number, the ideal number of molecules per cc under S.P.T. conditions, $2.705_6 \times 10^{19}$, k is Boltzmann's constant, $1.370_9 \times 10^{-16}$, and μ is the electric moment of the molecule.

In previous experiments it has been customary to determine the difference between the dielectric constants at atmospheric pressure and at approximate vacuum, and to determine the value of v by the van der Waal equation in its approximate form:

$$v = \frac{RT}{p} \left\{ 1 - \frac{(a/vp) - b}{v} \right\}$$

using for v on the right hand side its approximate or ideal value RT/p . This method of calculation is convenient if the dielectric constant is measured at only one pressure. A more satisfactory way to determine $(AT+B)$ is to make measurements of $\Delta\epsilon$ over the whole range of pressure available, and at the same time to test the Clausius-Mossotti relation: $(\epsilon-1)/(\epsilon+2) :: \text{density}$. At a fixed temperature the polarization would be accurately proportional to p only for an ideal gas so that plotting $3(\epsilon-1)/(\epsilon+2)$ against p would not give a straight line. If we plot against p' , the *ideal* pressure which the gas would have at the given temperature and density, we should obtain a straight line of slope $3[(\epsilon-1)/(\epsilon+2)] V/RT$. The value of p' can be

⁴ C. T. Zahn, Phys. Rev. **24**, 400 (1924); C. P. Smyth and C. T. Zahn, Jour. Amer. Chem. Soc. **47**, 2501 (1925); C. T. Zahn, Phys. Rev. **27**, 329 (1926); C. T. Zahn, Phys. Rev. **27**, 455 (1926); C. T. Zahn and J. B. Miles, Jr., Phys. Rev. **32**, 497 (1928); J. B. Miles, Jr., Phys. Rev. **34**, 964 (1929).

calculated as follows. Van der Waal's equation can be rewritten approximately:

$$v = \frac{1}{\frac{p}{RT} \left\{ 1 + \frac{p}{RT} \left(\frac{a}{RT} - b \right) \right\}} \equiv \frac{RT}{p'}$$

which defines:

$$p' = p \left\{ 1 + \frac{p}{RT} \left(\frac{a}{RT} - b \right) \right\}.$$

Hence the effect of the van der Waal constants is to introduce into the actual pressure relation a small quadratic term which can be taken into account by plotting against p' as above mentioned. The final value of $(AT+B)$ is got by multiplying the slope by RT^2 . This is done for a range of temperatures and the values plotted against T . The resulting straight line gives A as the slope and B as the intercept from which the moment is determined. If the molecule studied has no fixed moment then the values of $3(\epsilon-1)/(\epsilon+2)$ should be constant, and it is not necessary to draw the Debye line in order to determine A . It is only necessary to average the experimental values of $3[(\epsilon-1)/(\epsilon+2)]v$, which are approximately equal for the different temperatures used.

The above method of plotting has another advantage as follows. In a previous paper the author has mentioned the fact that it is impossible to make a reading for the dielectric constant at vacuum because the condenser plates are then so perfectly insulated thermally that a small but very disturbing temperature difference can be set up between them. It is then necessary to extrapolate to vacuum in order to find the actual value of $(\epsilon-1)$. The apparatus can always be so adjusted that the difference values of $(\epsilon-1)$ are approximately the actual values. These values can be divided by the corresponding approximate values of $(\epsilon+2)$ and then $3\{\Delta(\epsilon-1)/\epsilon+2\}$ can be plotted against p' . The linear extrapolation should be very accurate since the correction due to the factor $(\epsilon+2)$ is usually small and, in fact, often negligible. It is easily seen that the factor $\epsilon+2$ has the effect of introducing a small quadratic term in the value of $\epsilon-1$ as a function of the pressure since

$$3 \left\{ \frac{\epsilon-1}{\epsilon+2} \right\} :: p' \text{ or } (\epsilon-1) :: p' \left(1 + \frac{\epsilon-1}{3} \right)$$

and $(\epsilon-1)$ on the right hand side may be set proportional to p' approximately.

For a considerable number of gases there seems to be no question concerning the validity of the Clausius-Mossotti relation. On the other hand there have been performed a number of experiments⁵ in which anomalies

⁵ M. Jona, *Phys. Zeits.* 20, 14 (1919); C. T. Zahn, *Phys. Rev.* 27, 329 (1926); K. Wolf, *Phys. Zeits.* 27, 588, 830 (1926); K. Wolf, *Ann. d. Physik* 83, 884 (1927); F. Maske, *Phys. Zeits.* 28, 533 (1927); J. B. Miles, Jr., *Phys. Rev.* 34, 964 (1929).

have occurred, particularly in the case of vapors near the condensation point. These anomalies have been attributed to two causes, association and actual condensation on the condenser plates. The author has performed experiments to show that both these effects exist; for example, for water vapor. In the case of water vapor condensation on the condenser plates is accompanied by electrical conductivity which can be measured directly. The existence of such effects, whether they be due to association or condensation, or both can be detected by pressure curves such as those described above. If they are found to exist they can usually be eliminated by working at sufficiently low pressures.

EXPERIMENTAL RESULTS

In the present measurements on CS_2 complete pressure curves were obtained at four different temperatures in order to insure the absence of such effects. In Table I are shown the experimental values obtained. The fourth column contains the difference readings, $3[\Delta(\epsilon-1)/(\epsilon+2)]$, referred to a fixed point of the experimental condenser system for convenience

Fig. 1. Variation of polarization with pressure, p' .

in the calculations. The circuits are always adjusted to give the vacuum reading at approximately this fixed point, so that there is no appreciable error introduced in the value of the slope of the pressure curves. A table of calculated values or an accurately drawn chart then serves to facilitate the calculations of ϵ . The true values of $3\{\epsilon-1/\epsilon+2\}$ are measured from the zero values obtained by extrapolation on the curves. In Fig. 1 the values

of $3[\Delta(\epsilon-1)/(\epsilon+2)]$ are plotted against p' and the true values are measured from the horizontal zero lines. For the calculation of p' values of the van der Waal constants were obtained from Kaye and Laby: $a=0.02316$ and $b=0.00343$. Only two of the four sets of data are plotted here for illustration, the best and the worst. The pressure runs were always repeated in the reverse direction in order to eliminate the effect of errors caused by any drifts in the condenser system not due to the CS₂. The part of the readings for increasing pressure is marked by circles; and the part for decreasing pressure, by crosses. The line for the temperature 49.2°C is remarkably well reproduced, while that for 216.1°C shows a slight drift, which is eliminated in the drawing of the line. The strict linearity of these pressure curves indicates that there is no appreciable association or surface condensation throughout the total observed range of pressure.

The last column of Table I contains the value of the molecular polarization. P , or the total induced electric moment per gram-molecule of the substance, calculated from the mean value in the preceding column. $(\epsilon-1)/(\epsilon+2)v$ is the moment or polarization due to N_0 molecules; therefore P can be obtained from the values in the sixth column as indicated by:

$$P = (n/3N_0) \times 3 \left\{ \epsilon - 1/\epsilon + 2 \right\} v = 7.4716 \times 10^3 \times 3 \left\{ \epsilon - 1/\epsilon + 2 \right\} v$$

where n is Avogadro's number, $6.064_4 \times 10^{23}$. The values of the constants, n , N_0 , L , and k used in these calculations are those given by Birge.⁶

Since the values in the last two columns of Table I are independent of temperature within the limits of experimental error, as mentioned above it is not necessary to draw a Debye line in order to determine the constant A . The results can be summarized by: $A=0.002993$ or $P=22.36$, and $\mu=B=0$.

COMPARISONS WITH OTHER DATA

The result $\mu=0$ is in accord with the observations of Ghosh, Mahanti, and Mukherjee,⁴ but the value of A given by them is 0.002912, about three percent lower than the above value. The discrepancy may be due to a calibration error in either of the two sets of experiments. It is believed by the author that the calibration of the apparatus used for the measurements given here is accurate to a fraction of a percent. Evidence substantiating this has been pointed out by Stuart⁷ and by the author.⁸ Furthermore the value of A for air given by the above mentioned authors is 0.0005797, about one percent higher than that obtained by the author,⁹ 0.000572, and deviates in the opposite direction to that required to explain the discrepancy in the values for CS₂. A part, if not all, of the deviation could be explained by the failure of the above mentioned authors to take into account the departures of the gas from the ideal law. At atmospheric pressure this amounts

⁶ R. T. Birge, Phys. Rev. Supplement, 1, 1 (1929).

⁷ H. A. Stuart, Zeits. f. Physik 47, 457 (1928).

⁸ C. T. Zahn and J. B. Miles, Jr., Phys. Rev. 32, 497 (1928).

⁹ C. T. Zahn, Phys. Rev. 24, 400 (1924).

to about two percent in such a direction as to increase the values given. Their values of $(\epsilon - 1)$ agree remarkably well for different temperatures, but if they worked at approximately constant density of gas the above mentioned correction would probably not sensibly alter this agreement. In addition there is an unimportant error of a small fraction of a percent introduced by the neglect of the factor $(\epsilon + 2)$. They also give the value of $n_\infty^2 = 1.002956$, taken from Graetz's handbook which is *higher* than their value $\epsilon = 1.002912$. Now deviations between n_∞^2 and ϵ are usually in the opposite direction¹⁰ because the extrapolation to n_∞ is usually done from the visible spectrum neglecting the infra-red terms which have been shown to be of importance in the case of CO_2 . In the case of CO_2 the refractivity has been measured over the entire range from the ultra-violet through the infra-red. Fuchs¹¹ has extrapolated for n_∞^2 taking into account the infra-red terms and obtains a value differing from the author's value of ϵ by less than one-tenth percent. If the extrapolation had been done without considering the infra-red terms, a value too small would have been obtained. It is therefore difficult to explain experimental observations of ϵ which are smaller than the value of n_∞^2 extrapolated from the visible. In the case of CS_2 one would expect ϵ to be larger than such values of n_∞^2 all the more because it has been definitely shown to be the case for its structurally similar compound CO_2 . As additional confirmation of the value given here Williams' value of P , as given by Errera,¹⁰ is 22.2 as compared with the value of 22.36. The small deviation is in the direction to be expected from data cited by Errera.¹² For the above reasons it is believed that the above mentioned value of $\epsilon = 1.002912$ is about three percent too low.

MOLECULAR STRUCTURE

In the previously cited article¹ the authors discussed values for the electric moment of CO , CO_2 , COS , and CS_2 , with reference to molecular structure. Since in that discussion the moment for CS_2 was tentatively considered to be 0.33×10^{-18} c.g.s. e.s.u., the discussion should be somewhat modified. The moment of COS was found to be 0.65×10^{-18} ; and that of CO , 0.10×10^{-18} . Therefore one would expect the moment of CS to be of the same order as that of COS , and the value of the moment of CS_2 as there found would have to correspond to an approximately linear structure, or to a truly linear structure of the unsymmetrical type suggested by Heisenberg. Since the moment of CS_2 is now definitely proven to be zero the situation is simplified. CO_2 has been shown by Stuart⁷ to have a rectilinear structure since it has no electric moment and for other reasons which he has pointed out. The similar compound CS_2 has now been shown to have no electric moment, and we can therefore consider with a high degree of probability that its structure is rectilinear.

THE VARIATION OF DIELECTRIC CONSTANT WITH
TEMPERATURE. I. THE ELECTRIC MOMENTS OF
THE CARBON BISULPHIDE AND NITROUS
OXIDE MOLECULES*

BY CHRISTIAN H. SCHWINGEL AND JOHN WARREN WILLIAMS
LABORATORY OF PHYSICAL CHEMISTRY, UNIVERSITY OF WISCONSIN

(Received February 8, 1930)

ABSTRACT

An apparatus has been described which makes it possible to determine dielectric constants of gases and vapors and their dependence on temperature over a range of several hundred degrees. The electric moments of gaseous carbon bisulphide and nitrous oxide have been measured and found to be zero. These results indicate a linear arrangement of the three atoms forming each molecule.

IN RECENT years the study of the constitution of simple polar and non-polar molecules has attracted much attention. There have become available physical methods, among them the dipole theory of Debye,¹ which enable one to determine at least the relative positions of the atoms forming the simpler molecules, and also to say something concerning the symmetry of more complicated ones. In this connection the configuration of the carbon dioxide molecule is of interest. The results of x-ray studies on the solid² indicated without any question a linear and symmetrical arrangement of the three atoms which make up the molecule. For a long time, however it was thought that the molecule possessed a finite electric moment, suggesting a triangular arrangement of the atoms for the molecule in the gaseous condition. This conclusion appeared to be substantiated by molecular spectra data, and it was not until Stuart³ showed its electric moment to be zero that the linear and symmetrical model was accepted for the vapor as well.

There are other triatomic molecules for which electric moment data have been reported in the literature, and in certain cases where rather small values have been reported, the possibility existed that these values were indistinguishable from zero, because of experimental difficulties. Thus an electric moment of magnitude, $\mu = 0.33 \times 10^{-18}$ e.s.u., was reported by Zahn and Miles⁴ for the carbon bisulphide molecule, although liquid carbon bisulphide had previously been successfully used as a non-polar solvent for the determination of the electric moment of a number of dissolved molecules.⁵ Again,

* This paper is an abstract of a part of the thesis of C. H. Schwingel submitted in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

nitrous oxide shows such a similarity with carbon dioxide in its physical behavior⁶ that one might expect it to be non-polar in character as well.

The purpose of this article is to present the results of an experimental study of the temperature variation of the dielectric constant of the vapors of carbon bisulphide and nitrous oxide, and to show that their electric moments do not differ from zero by more than 0.05×10^{-18} in the case of N_2O and by more than 0.02×10^{-18} in the case of CS_2 .[†] The apparatus and method used are briefly described later.

RESULTS

Debye has shown how one may have a dielectric constant, or rather a portion of it that varies with the absolute temperature if it be assumed that there exist permanent electrical dipoles in the molecules. This theory has been amply verified in recent years, so it is only necessary here to give its mathematical result. The total polarization is given by the equation

$$P = \frac{\epsilon - 1}{\epsilon + 2} \cdot \frac{M}{d} = \frac{4\pi}{3} N \left[\gamma' + \frac{\mu^2}{3kT} \right] \quad (1)$$

where ϵ is the dielectric constant; M the molecular weight; d the density; N is Avogadro's number; γ' is—a constant; μ the electric moment of the molecule; k the Boltzmann constant; T the absolute temperature; $(4\pi/3) N\gamma'$ is the polarization due to deformation of the molecule and $(4\pi/3) (N\mu^2/3kT)$ is the polarization due to orientation of the molecule. In the case of gases and vapors this equation may be written with sufficient accuracy in the following form:

$$\begin{aligned} \frac{\epsilon - 1}{4\pi} \cdot \frac{M}{Nd} &= \gamma' + \frac{\mu^2}{3kT} = a + \frac{b}{T} \\ \text{i.e. } \frac{\epsilon - 1}{4\pi} \cdot \frac{m \cdot T}{d} &= aT + b = D \end{aligned} \quad (2)$$

where m = mass of the molecule in question.

In this equation the function D is a linear function of T . The slope of the line gives the polarization due to deformation, while the "y" intercept ($T=0$) gives the value of the electric moment squared divided by $3k$, that is, $b = \mu^2/3k$.

The nitrous oxide used was of hospital purity and triple distilled. It was dried thoroughly with P_2O_5 before each determination.

The carbon disulphide, Baker's C.P. analyzed, was allowed to stand over P_2O_5 for several days before use. On distillation high and low-boiling fractions were discarded. It was later distilled directly into the apparatus.

⁶ Langmuir, Jr. *Amer. Chem. Soc.* **41**, 1543 (1919).

[†] The experimental work reported herein was practically complete when an article by Ghosh, Mahanti and Mukherjee, *Zeits. f. Physik* **58**, 200 (1929) appeared in which it was found that both nitrous oxide and carbon bisulphide had zero moments. Thus the results of the two investigations are entirely in agreement.

The results of the experimental work are given by Fig. 1 which has, in turn, been constructed from the data given in Tables I and II. All measurements were made at constant pressure. The simple gas law was used to

Fig. 1.

calculate the dielectric constant of the gas at 760 mm Hg pressure. The error involved in this method of procedure was proven to be well within the limit of the experimental error of the final result for the electric moments of the molecules.

425.6	693	1.35	8.06

From equation of straight line (Fig. 1), $b = 0.007 \times 10^{-21} = \mu^2/3k$ or $\mu^2 = 3 \times 1.37 \times 0.007 \times 10^{-37} = 0.00288 \times 10^{-36}$, $\mu = 0.05 \times 10^{-18}$ e.s.u.

EXPERIMENTAL METHOD*

The method used for the determination of the dielectric constants at the various temperatures was similar to that presented by Pungs and Preuner⁷ and later improved upon by Zahn,⁸ Stuart,³ Sanger,⁹ and others.

Two loosely coupled oscillating circuits, I and II, (Fig. 2) were used to generate constant frequencies, n_1 and n_2 . These frequencies, when coupled to a detector, give the frequency $n_d = n_1 - n_2$, which may be detected in the receiver of the detector circuit.

It is evident that a variation of capacity in either circuit will change n_d . If the frequency of circuit II is kept constant, then any change in the frequency of circuit I, due to the change in capacity of C_x , can be detected in

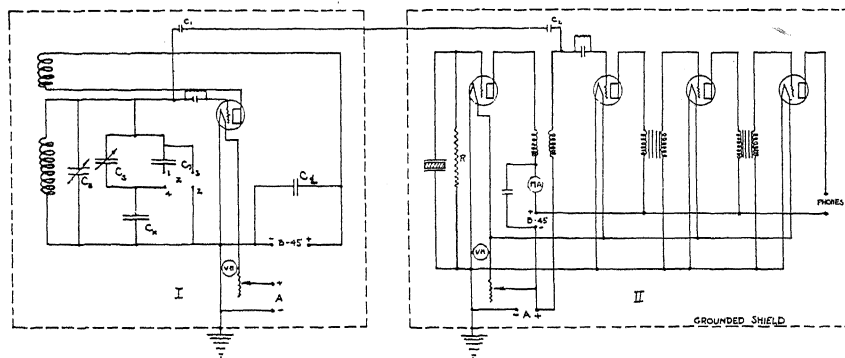

Fig. 2.

the receiver and brought back to the frequency of n_2 by means of a capacity C_s . Circuit I has in series with the gas condenser C_x , a fixed condenser C_v of much greater capacity, and a precision variable condenser C_s . The total capacity is kept constant, determined by the method of counting beats produced in the receivers of the detector circuit. The total capacity of the circuit is changed only by the change in the value of C_x , due to the admission of gases into the previously evacuated condenser; and this is compensated for by means of a change in C_s .

The following equation gives the total series capacity

$$\text{Total capacity} = (1/C_x) + (1/C_v + C_s) \quad (3)$$

If ΔC_x equals the change in capacity due to the admission of gas, and if ΔC_s is the change necessary to bring the circuit to the original frequency of circuit II, then

$$\frac{1}{C_x + \Delta C_x} + \frac{1}{C_v + C_s + \Delta C_s} = \frac{1}{C_x} + \frac{1}{C_v + C_s} \quad (4)$$

* A diagram of the apparatus without any description was included in an article submitted in June 1929 by one of us (J. W. W.) to the Fortschritte der Chemie, Physik und physikalischen Chemie as part of a discussion of this and related subjects. It is published as Band 20, Heft 5, 1930.

⁷ Pungs and Preuner, Phys. Zeits. 20, 543 (1919).

⁸ Zahn, Phys. Rev. 24, 400 (1924).

⁹ Sanger and Steiger, Helv. Phys. Acta. 1, 369 (1928), et. al.

Solving for ΔC_x , there is obtained

$$\Delta C_x = \frac{C_x^2 \cdot \Delta C_s}{(C_y + C_s)^2 + (C_y + C_s + C_x) \Delta C_s} \quad (5)$$

This can be written with sufficient accuracy

$$\Delta C_x = \frac{C_x^2 \Delta C_s}{(C_y + C_s + \frac{1}{2} \Delta C_s)^2}$$

If the condenser C_y is very large compared to C_x then a small change ΔC_x will necessitate a large change ΔC_s to bring the circuit to the initial frequency. The frequency of circuit II is kept constant by means of a thermally protected quartz plate.

The electrical connections employed are shown in the figure referred to above. The vacuum tubes were all of the UX 301 type, operated at voltages considerably below rating. It was found that a potential of 4 volts for the oscillating tubes produced the most constant conditions of frequency. The detector tube and amplifiers were operated at full rating. A plate potential of 45 volts was used in all cases. All connections were carefully soldered, and it was found advisable to remove all filament rheostats and voltmeters. The entire apparatus was fastened rigidly in place and thoroughly shielded. Separate shields were used for circuits I and II. Inductances were bakelite tubes wound with silk covered copper wire.

Capacity measurements were made at a frequency of 498.6 kilocycles, corresponding to a wave-length of approximately 600 meters. This frequency was kept constant by means of a quartz crystal, ground and calibrated at the laboratories of the General Radio Company, Cambridge, Mass. For constant conditions of operation, it was found necessary to separate the two circuits by several feet, the only coupling being the single wire as shown in the diagram. Under favorable temperature conditions in the room, the frequency would remain constant to a tenth of a scale division for several minutes, or show a regular increase of several tenths per minute and could be corrected for accordingly. The beats produced in the receiver were amplified by means of two stages of transformer coupled amplification, the zero reading being taken as twenty beats in ten seconds. Capacity C_s was a standard precision condenser of 500 $\mu\mu\text{f}$ capacity, manufactured and calibrated in the laboratories of the General Radio Company. A mica condenser, C_y was calibrated to the latter as standard. All condensers, as well as the entire apparatus, were protected from thermal fluctuations by means of proper insulation.

Gas condenser C_x , was a specially constructed fixed air condenser, made for this particular purpose by the Cardwell Manufacturing Corporation. It is shown diagrammatically in Fig. 3. The construction was of brass and heavily gold plated. The twenty-three plates, each spaced approximately 3 mm, were held in position by means of two strips of Mycalex, the strips being placed as far as possible outside the electrostatic field. The added

capacity correction is negligible, due to their size and position, amounting to not more than 0.2 percent of the total capacity.

This capacity, C_z , was mounted inside a rigidly constructed brass drum (internal diameter, six inches) one terminal of the condenser being grounded to it, and the other leading out through the central glass tube which was used for the entry and removal of gases, and which also contained the thermocouple well. The gas tight drum, containing the condenser, was bolted to the inside of an oil bath, and the capacity when assembled was approximately 444 μmf . The assembly of condenser and thermostat, consisting of (1) thermo-regulator, (2) heater, (3) gas-tight drum, (4) opening for thermocouple, (5) entrance for gas, (6 and 7) condenser terminals, and (8) stirrer, is shown in Fig. 3 and need not be detailed further.

The temperature control bath was a large galvanized iron vessel, insulated completely with "balsam wool," and filled with cotton seed oil. It was kept at constant temperature by means of a heater constructed of nichrome

Fig. 3.

wire wound on a grid of "transite." This was immersed directly in the oil. The ordinary make and break type mercury regulator was found satisfactory for keeping the temperature constant to within 0.1° for values up to 100°C , and to within 0.2° for higher temperatures. A calibrated copper-constantan couple placed in close proximity to the condenser served to determine the temperatures. It was found that the temperature became constant after about ten minutes from the time of the gas entry.

In order to evacuate the apparatus, a Hy-Vac oil pump was employed in connection with a water pump. The water pump was used only for the initial clearing out of vapors that might be absorbed by the oil in the pump. In the case of carbon disulphide vapors, and other oil soluble vapors, the system was flushed out thoroughly several times with carbon dioxide, each time evacuating to about 2 cm by means of a water pump. After several of these flushings, the Hy-Vac pump was connected and the system evacuated to 0.01 mm or better. The oil in the pump was changed at frequent intervals. For pressure measurements, a modified U-type manometer was used.

Fig. 4 shows the method used for allowing gases and vapors to enter the condenser chamber. In the case of organic liquids it was necessary to lubricate the stopcocks with a paste made of very finely precipitated silicon dioxide, phosphoric anhydride, and phosphoric acid. This mixture was found to be very satisfactory, having no appreciable vapor pressure, and lasting for the duration of a determination. Outlets *g* and *f* were attached to the oil pump and water pump respectively; and *d* was the connection to the condenser chamber. Stopcock *c* was used to allow the entrance of gases, while *a* was the bulb used for holding the liquids which were allowed to evaporate into the system. Liquids were allowed to evaporate into the system until the partial pressure, as read on the manometer, was slightly less than saturation for room temperature; consequently no condensation could take place in the system.

Fig. 4.

To determine the absolute values of the dielectric constants, it was necessary to determine the capacities of all condensers and lead wires.

The capacity of the gas condenser was determined before and after every series of measurements. This was accomplished by means of a mercury switch *z*, Fig. 2. By connecting 1 and 3, the fixed condenser C_y is short circuited. Then C_x and C_s are connected in series and C_s adjusted to fixed frequency corresponding to capacity C_s' . Then C_x was short circuited by connecting 2 and 4, and C_s adjusted to the original beat frequency, or, in other words, until the original capacity had been reached. Calling the new position C_s'' , the equation of the series capacity will be,

$$\frac{1}{C_s''} = \frac{1}{C_x + X} + \frac{1}{C_s'} \quad (6)$$

where X is the capacity of the lead wire from C_x to C_s and to z . Solving

$$C_x + X = \frac{C_s' \cdot C_s''}{C_s' - C_s''} = C. \quad (7)$$

The value for X , calculated from radio formulae was $10.6 \mu\mu f$, with a maximum variation of $2 \mu\mu f$. This amounts to not more than 0.5 percent of the total capacity.

The values for the dielectric constants were calculated according to the equation,

$$\epsilon - 1 = \frac{\Delta C_x}{C - X} \quad (8)$$

where C_x is the capacity before the admission of vapor, including X , the lead capacity.

Combining Eqs. (5), (7), and (8)

$$\epsilon - 1 = \frac{C^2}{(C_v + C_s + \frac{1}{2}\Delta C_s)^2} \cdot \frac{\Delta C_s}{C - X} \quad (9)$$

Errors in the determination of C_x amount to not more than 0.5 percent, in C_v not more than 1.5 percent, and in ΔC_x not more than 1.5 percent. Since errors in the temperature and pressure measurements are small in comparison, the total error in a dielectric constant determination will not be more than 1.5 percent.

For determining values of ΔC_s , the system was flushed out several times and evacuated. After constant temperature conditions were attained, C_s was adjusted to the beat frequency, twenty in ten seconds. Having taken the reading of C_s' , the cock was opened to allow the gas or vapor to enter the condenser chamber. When constant temperature conditions had again been attained C_s was adjusted to the capacity corresponding to the original beat frequency, C_s'' . The reading C_s' and the difference between C_s' and C_s'' or ΔC_s were substituted in formula (9), along with predetermined values of C , C_v and X . By this means $\epsilon - 1$ is evaluated directly. Any slight drift in C_s must have been predetermined, and taken into consideration.

For each temperature, five to eight readings were taken, evacuation taking place each time. The time for a single temperature measurement amounted usually to approximately eight hours.

In order thoroughly to test our apparatus the electric moment of the ethyl ether molecule was determined. The result, $\mu = 1.12 \times 10^{-18}$ e.s.u., is in perfect agreement with the recent and now commonly accepted results of Sanger¹⁰ and of Stuart.¹¹ The electric moment of carbon dioxide was also found to be zero.

CONCLUSIONS

The results of this article, with those of Ghosh, Mahanti, and Mukherjee, demonstrate that carbon bisulphide and nitrous oxide do not have finite electric moments.

To explain this fact the simplest assumption is to assign a linear and symmetrical arrangement to the three atoms which form the molecule. It is not our intention, however, to conclude that these are necessarily rigid molecules with which we are dealing. A complete knowledge of the vibration-rotation and rotation spectra of a molecule is also of particular importance in such a study, and these data are unfortunately not available at this time.

THE NUMERICAL DETERMINATION OF CHARACTERISTIC NUMBERS

BY W. E. MILNE

DEPARTMENT OF MATHEMATICS, UNIVERSITY OF OREGON

(Received February 24, 1930)

ABSTRACT

A method is developed for the numerical calculation of characteristic energy levels in cases where the wave equation contains, or can be reduced so as to contain, a single space variable. The procedure consists in the numerical integration of an auxiliary differential equation for several chosen values of the energy, after which the characteristic values are obtained by interpolation. The method is one of considerable generality so far as the form of the differential equation is concerned, and is capable of giving any preassigned degree of accuracy.

1. The entrance of wave mechanics into modern physics gives new interest to boundary value problems associated with linear differential equations, especially those problems treated by Weyl¹ and others which have to do with the Sturm-Liouville equation

$$\frac{d}{dx} \left[p(x) \frac{dy}{dx} \right] - q(x)y + \lambda \rho(x)y = 0 \quad (1)$$

in the intervals $0 < x < \infty$ or $-\infty < x < \infty$. A problem of particular physical interest is the determination of those characteristic values of λ (eigenwerte) for which (1) possesses solutions that are finite at both ends of the interval.² In several important special cases the complete analytical solution of this problem is known,³ but in other instances it is necessary to resort to approximate methods.

The object of this note is to describe a numerical procedure for obtaining the characteristic values of λ belonging to the equation

$$\frac{d^2 u}{dx^2} + G(x, \lambda)u = 0. \quad (2)$$

Equation (1) can be reduced to this form by the substitution $y = up^{-1/2}$, provided p has first and second derivatives and does not vanish in the interval.

³ Cf. e.g. Kemble, reference 2, pp. 183-186. Condon and Morse, *Quantum Mechanics*, (McGraw-Hill, 1929) Chapter II.

Equation (2) contains as a special case the wave equations of the type

$$\frac{d^2u}{dx^2} + \frac{8\pi^2\mu}{h^2} [W - V(x)]u = 0, \quad (3)$$

as is seen by setting

$$\lambda = \frac{8\pi^2\mu W}{h^2}$$

and

$$G(x, \lambda) = \lambda - \frac{8\pi^2\mu}{h^2} V(x).$$

Equation (2), however, is considerably more general than (3).

With regard to $G(x, \lambda)$ we assume that $\partial G / \partial \lambda$ exists and is positive, that $G(x, \lambda)$ is continuous in x , that when $|x|$ is sufficiently large $G(x, \lambda)$ is negative for the values of λ under consideration, and (if the interval is $0 < x < \infty$) $\lim_{x \rightarrow 0} G(x, \lambda) = -\infty$.

2. For simplicity we consider only the case in which the interval is $-\infty < x < \infty$. Let x_0 be a value of x in the interval, and let $u_1(x)$ and $u_2(x)$ be two solutions of Eq. (2) satisfying the conditions

$$\begin{aligned} u_1(x_0) &= 1, & u_2(x_0) &= 0, \\ u_1'(x_0) &= 0, & u_2'(x_0) &= a \neq 0. \end{aligned} \quad (4)$$

The constant a is arbitrary and in any particular case is to be determined so as to make the numerical work as simple as possible. These solutions satisfy the well-known identity

$$u_1(x)u_2'(x) - u_2(x)u_1'(x) \equiv a. \quad (5)$$

Let a function $w(x)$ be defined by the equation

$$w(x) = [u_1^2(x) + u_2^2(x)]^{1/2} \quad (6)$$

By differentiating this equation twice, eliminating $u_1''(x)$ and $u_2''(x)$ by means of (2), and simplifying with the aid of (5) we find that the function $w(x)$ satisfies the simple differentiation equation

$$\frac{d^2w}{dx^2} + G(x, \lambda)w - \frac{a^2}{w^3} = 0. \quad (7)$$

Now the general solution of (2) can be expressed in the form

$$u(x) = Cw(x) \sin \left\{ a \int_{x_0}^x w^{-2} dx - \alpha \right\}, \quad (8)$$

in which C and α are arbitrary constants. Since with the given hypotheses $w(x)$ does not approach zero at either end of the interval, it is clear that a solution satisfying the desired conditions at both ends of the interval can be found if and only if

$$\frac{a}{\pi} \int_{-\infty}^{\infty} w^{-2} dx = n \quad (9)$$

in which n is a positive integer.

3. Now the integral

$$N = \frac{a}{\pi} \int_{-\infty}^{\infty} w^{-2} dx \quad (10)$$

is an increasing function of λ , so that if we select k values of λ for which this integral is finite (values of λ for which N is infinite belong to the continuous spectrum and do not interest us here), say $\lambda^1 < \lambda^2 < \dots < \lambda^k$, we obtain k values of N , say $N_1 < N_2 < \dots < N_k$. If an integer n lies in the interval $N_1 < n < N_k$, we may use the method of interpolation to obtain approximately the corresponding value of λ , $\lambda = \lambda_n$, which will be precisely the n -th characteristic value of λ counted in order of magnitude.

To put this plan into execution we proceed as follows:

First, we solve Eq. (7) with the initial conditions $w(x_0) = 1$, $w'(x_0) = 0$ for each of the k values of λ , $\lambda^1, \lambda^2, \dots, \lambda^k$. For this purpose we may use any one of several well-known methods for the numerical integration of differential equations.

Second, using in turn each of the solutions now obtained, we evaluate by numerical quadrature the integral (10) and get the k values of N , N_1, N_2, \dots, N_k .

Lastly, we obtain by interpolation the values of λ corresponding to each integer in the interval N_1 to N_k .

When the characteristic value of λ has been found it is then possible to integrate (7) using this value of λ and then obtain the corresponding wave function itself by means of (8). As a matter of fact, however, it will generally be easier to obtain $w(x)$ and $\int_0^x w^{-2} dx$ by interpolation from the computations already performed.

Naturally the speed and accuracy of the method depend largely on good judgment in the selection of the trial values $\lambda^1, \lambda^2, \dots, \lambda^k$. This is perhaps best illustrated by means of an example.

4. We take as an illustrative example the differential equation

$$\frac{d^2 u}{dz^2} + \frac{8\pi^2 \mu}{h^2} [W - kz^4] u = 0,$$

which upon the substitutions

$$z = \frac{h^{1/3}}{(8\pi^2 \mu k)^{1/6}} x,$$

$$\lambda = \left[\frac{64\pi^4 \mu^2}{h^4 k} \right]^{1/3} W,$$

reduces to

$$\frac{d^2u}{dx^2} + (\lambda - x^4)u = 0.$$

For simplicity we choose $x_0 = 0$, $a = \lambda^{1/2}$, so that equation (7) becomes

$$\frac{d^2w}{dx^2} + (\lambda - x^4)w - \lambda w^{-3} = 0, \quad (11)$$

with the initial conditions $w = 1$, $w' = w'' = w^{(3)} = w^{(4)} = w^{(5)} = 0$ at $x = 0$. The desired solution is even, so that we need to compute it for positive values of x only.

The critical values of λ are evidently positive, and when n is large their order of magnitude can be obtained from the formula⁴

$$\pi n = \lambda_n^{3/4} \int_0^1 s^{1/4} (1-s)^{-1/2} ds + R_n,$$

in which R_n is bounded. This gives

$$\lambda_n = n^{4/3} [2.184 + E/n]$$

where E is bounded. It appears, therefore, that λ_1 will probably lie somewhere between 1 and 4, so we choose the four trial values $\lambda^1 = 1$, $\lambda^2 = 2$, $\lambda^3 = 3$, $\lambda^4 = 4$, and calculate the solution of (11) for each of these values. The method actually used was that described by the author elsewhere.⁵ With the aid of a calculating machine and Barlow's Tables the integration can be done rapidly. The values of $1/w^2$ and $1/w^3$ are read directly in the columns headed "square" and "cube" respectively. We retained only enough significant figures in w to give $1/w^2$ to four places of decimals. The first one of the four computations is shown below to illustrate the general method. The integrals

$$I(\lambda) = \int_{-\infty}^{\infty} w^{-2} dx = 2 \int_0^{\infty} w^{-2} dx$$

were found with the calculating machine, using Weddle's rule and were checked with Simpson's rule. They proved to be as follows:

λ	$I(\lambda)$	ΔI	$\Delta^2 I$	$\Delta^3 I$
1	3.0469			
2	3.1090	621		
3	3.1719	629	8	
4	3.2362	643	14	6

⁴ Milne, Trans. Amer. Math. Soc. 31, 907-918 (1929), see formula (25) p. 914.

⁵ Milne, Numerical Integration of Ordinary Differential Equations, Amer. Math. Monthly 33, 455 (1926).

From (8), since $a = \lambda^{1/2}$, we get

$$\lambda_n = [\pi n / I(\lambda)]^2$$

and by a few trials find from this that the values of the first two characteristic numbers are

$$\lambda_1 = 1.0605$$

$$\lambda_2 = 3.7998.$$

COMPUTATION I. $\lambda = 1$.

LETTERS TO THE EDITOR

Prompt publication of brief reports of important discoveries in physics may be secured by addressing them to this department. Closing dates for this department are, for the first issue of the month, the twenty-eighth of the preceding month; for the second issue, the thirteenth of the month. The Board of Editors does not hold itself responsible for the opinions expressed by the correspondents.

Growth of Zinc Crystals

In two recent papers by Goetz and Hasler¹ and Goetz² reference is made to a paper by Mr. A. G. Hoyem³ and myself on the growth of zinc crystals. Since certain conclusions are drawn which are based on a misconception of one point in our work I would like to point out that for crystals of the same diameter, drawn at the same rate, the height of the column of liquid zinc just below the crystal is *always the same*, regardless of the temperature of the molten zinc. It is of course obvious that the higher the latter temperature the greater the blast of cooling gas that must be used. Too feeble a gas blast for the molten zinc temperature causes an increase in the height of the liquid zinc column but also a *reduction of the diameter of the crystal*. Mr.

Hoyem and I therefore felt justified in considering the excess of temperature of molten zinc (in the crucible) above the melting point of zinc as proportional to the temperature gradient in the liquid column as long as crystals of only one diameter were grown and at a single rate. Our paper would have had little point otherwise.

The Spark Spectrum of Ruthenium

During last year we undertook the analysis of the spectrum Ru II. The fundamental multiplets were very easily discovered, but further progress was stopped by the insufficient accuracy of the measures. Accurate measures will shortly be made and the analysis extended. In the meantime it is perhaps of interest to give a table of the low terms. The table includes the electron configuration, designation and value of each low term. The odd terms are not given, but comprise $^6P^o$, D^o , F^o and $^4P^o$, D^o , $F^o(d^6p)$.

Table of low terms of Ru II.

d^7 $^4F_{4\frac{1}{2}}$	0.0
" $^4F_{3\frac{1}{2}}$	1523.0
" $^4F_{2\frac{1}{2}}$	2494.0

X-Rays Generated by Three Element Tube

The character of the x-rays generated by a specially designed three element tube was studied. This tube consisted of two filaments placed symmetrically with respect to a ring anode. The two filaments were maintained at the same potential and the electrons accelerated to the anode by a high voltage, 15,000 volts A.C. in these experiments, applied between the filaments and the anode. When the filament current was increased sufficiently, the anode current became limited by space charge and the tube started to oscillate; in this condition, the electrons oscillate back and forth through the anode.

While oscillations were present, the tube became a very efficient producer of x-rays, in the anode region. The average wave-length of these x-rays, as measured by their absorption coefficient in thin metal foils was less than 0.8Å. This indicates that either the efficiency of exciting continuous x-rays with a wave-length corresponding to the full voltage applied to the electrons is very great or that the tube can emit x-rays with a wave-length

shorter than that calculated from the voltage impressed between the anode and the filaments. The hardness of the x-rays may be due either to very high voltage oscillations in the tube which increases the energy of the electrons striking the anode or it may arise from the mutual interaction of the electron streams from the two filaments in the space surrounding the anode where the electron concentration is very high. A pin-hole picture of the source of the x-rays showed that the x-rays were generated in a space charge sheath surrounding the glass wall and extending into the space around the anode. In all these measurements, the pressure in the tube was less than 10^{-6} mm of Hg.

With one filament heated, i.e. no oscillations in the tube, no x-rays could be detected for the same anode current and voltage.

Regularities in Radioactive Nuclei

While reading an interesting paper by Barton (Phys. Rev. 35, 408 (1930)) on "A New Regularity in the List of Excited Nuclei," it occurred to us that it would be interesting to look for a similar regularity in radioactive nuclei. (The symbols we shall use in discussing this addition to his work will be those of Barton's paper, and for brevity will not be redefined here.) We plotted P against E for these nuclei assuming that the mass numbers of the actinium family are secured from those of uranium 238 by the subtraction of an integral number of α particles with mass number 4. Plotted in this way an approximate center of symmetry exists at (P, E) equal to (220, 134) which is thorium emanation. There are 34 points in this diagram, some of which are double because two radioactive nuclei fall at the same point in a number of cases. It is necessary to add 5 points to the diagram in order to complete the symmetry so that the symmetry of this "cluster" compares favorably with Barton's non-radioactive clusters. It seems, therefore, that we are justified in adding another cluster to the three which he found.

The uranium-radium-actinium family and the thorium family each form independent symmetrical clusters about the same point.

There is some uncertainty as to whether the mass number of a protactinium should be 230 as we have assumed it to be, 231, or 232. If its mass number should be 232, the actinium family and the thorium family diagrams would coincide except that (232, 141) must be added to the thorium family and (228, 140) must be added to the actinium family, and thus the actinium and thorium families would be symmetrical about the point (220, 134). The uranium-radium family would be approximately symmetrical about the point (224, 137), but the symmetry would not be so great as it is when all families are plotted together with the protactinium taken with mass number 230. If protactinium is taken with mass number 231 then the actinium family will be symmetrical about (219, 133), the thorium family would be symmetrical about (220, 134), and the uranium-radium family would have its lesser symmetry about the point (224, 137); but if all families were plotted on the same dia-

gram, the appearance of symmetry would be destroyed. It seems that all these families should be plotted on the same diagram in order to make comparisons with Barton's clusters which include all possible "radioactive families" of these non-radioactive elements.

Assuming for the sake of argument that this radioactive cluster exists, it indicates that Barton's suggested mechanism for the origin of his clusters is improbable, for his mechanism cannot be applied to the radioactive cluster. A primordial element of mass number 440 and 268 nuclear electrons cannot be postulated. Moreover, we know that the radioactive atoms do not originate by the decomposition of such a primordial element. The symmetry of this cluster is determined by regularities in the radioactive decomposition series and, therefore, the suggestion immediately arises that Barton's clusters may consist of radioactive series of nuclei with very long lives. From Aston's data (Proc. Roy. Soc. A115, 487 (1927)) on packing fractions, it is easy to see that considerable radioactivity might be possible in the (124, 72) cluster because for the general decreasing packing fractions with decreasing mass number in this region. Only a very feeble radioactivity or none at all would be possible in the (80, 45) clusters because these atoms are so near the minimum of the packing frac-

tion curve. Rubidium whose isotopes are (85, 48) and (87, 50) and belong to this cluster has been reported to be slightly radioactive. The lowest cluster with center at approximately (25, 13) could not be radioactive at all because the packing fraction curve has a negative slope. It seems to us that the symmetry of these 4 clusters is probably not due to the process of formation of the nuclei at all, but merely represents some stability relationship or some nuclear exclusion principle. At sufficiently high temperatures and pressures atoms of high packing fraction and high mass number would be stable and probably in the genesis of the elements under such conditions the possible permitted nuclei would be formed. In the radioactive cluster we merely see a spontaneous process which results in a transient excitation of these same possible permitted nuclear configurations.

It is interesting to note that the centers of these 4 clusters are at atomic numbers 12(?), 35, 52 and 86 which are very near the atomic numbers of the inert gases neon, krypton, xenon and the emanations. We have no idea whether this approximate agreement has any significance.

BOOK REVIEWS

The Kinematical Design of Couplings in Instrument Mechanisms. A. F. C. POLLARD, A. R. C. S., A. M. I. E. E., Professor of Instrument Design at the Imperial College of Science and Technology. Pp. 64, figs. 25. Adam Hilger, Ltd., London, England, 1929. Price 4s. 6d.

This book is an application to instrument design of the law of kinematics that six constraints are necessary to fix a rigid body. The author defines the terms used in the book, states the principles of kinematical design, and cites examples of the application of these principles to the design of instruments recently built by Adam Hilger Ltd., W. G. Pye and Co., Cambridge Instrument Co., E. Leitz, and others. Machine tool design of instruments depends too largely on the machines used in construction and on past experience, too little on kinematical principles, whereas kinematical design places first importance on these principles. By the latter method the forces on various members of an instrument are determined, the proper number of constraints applied, the materials decided upon, the so-called point contacts on the guiding surfaces expanded to withstand the pressures involved, and the allowable fits or clearances determined. This results in a stable instrument, in a reduction of variance in the instrument, in simpler and more economical manufacture because the workmanship is expended in the production of accurate geometrical forms rather than accurate fits, and permits the introduction of small adjustments which are often of great importance. Though this book is not intended as a complete text, it adequately sets forth the principles of the subject. It should be of great value to those who construct, repair, or use precision instruments.

Since reading the book this reviewer has applied these principles to the design of a comparator and an adjustable lamp support for the recording galvanometer of a microphotometer. A study of some of our present apparatus indicates that changes indicated by kinematical design would be very desirable. Accurate steel balls, which are easily and cheaply procurable, are widely used in these designs.

C. W. GARTLEIN

Handbuch der Experimentalphysik, Vol. IX, Part 1. High and Low Temperature by H. VON WARTENBERG; Liquefaction of Gases by H. LENZ; Heat Conduction by OSCAR KNOBLAUCH and H. REIHER; Heat Radiation by W. WIEN and C. MÜLLER. Pp. 484, figs. 50. Akademische Verlagsgesellschaft, Leipzig, 1929. Price, bound RM 44.60.

The first section by Wartenberg is a detailed listing of the means for obtaining and methods of measuring high and low temperatures.

The second section by Lenz on the liquefaction of gases is a very excellent discussion, both qualitative and quantitative, of the whole problem. The thermodynamic aspect of the fundamental gas theory is given in detail. The literature of the experimental side of the theory is completely given with interesting abstract and comment. The experimental work and data for air are given particular attention and their application to the liquefier problems carried right through. The writer knows of no such treatment anywhere in English.

The various technical methods used for liquefying air are described in their physical, not their engineering aspect. The liquefaction of H and He are described in connection with the actual installation at the few places where they have been carried out.

A short treatment on separation or purification of gases by fractional distillation—oxygen and nitrogen from air, hydrogen from various mixtures, helium from natural gas—completes the section.

The section on heat transfer is opened by Oscar Knoblauch with a discussion on heat conduction. After a brief introduction to the analytical situation, the experimental methods with some results are described for the metals especially with reference to the Wiedeman and Franz relation; for poorly conducting bodies with special reference to economically important materials; for single crystals, for liquids and for gases.

The second part, heat transfer by convection (Reiher), covers the very complex and important subject especially in its engineering aspect of the transfer of heat between solid bodies by a moving fluid. Both the analytical and experimental aspects are given in considerable detail, especially the case of transfer through tubing in various arrangements.

The third part discusses radiation as a means of heat transfer without duplication seriously of the later section. The fourth part discusses some important applications of the previous discussion.

The third and final section of the volume is by W. Wien and C. Müller on heat radiation, of which Wien writes the larger part. They cover the general theory, thermodynamical and statistical; experimental technique, sources, measuring instruments, units, black body, light pressure; experimental test of the theory and measurement of the radiation constants; energy distribution in the spectrum. The mass of references seems to cover all the important work.

J. R. ROEBUCK

Wave Mechanics, Being One Aspect of the New Quantum Theory. H. T. FLINT. Pp. ix+117. E. P. Dutton, New York. Price, \$1.25.

This little book, which has just (March 1930) been received for review has a preface dated December 1928. It is probably the poorest of the books which have appeared on this subject. It is of about the scope of Biggs' little book on wave mechanics.

Chapter 1 and 2 present the analogy between optics and mechanics and arrive at the wave equation in much the same way as Schrödinger did in the second of his famous series of *Annalen der Physik* papers.

The Schrödinger relativistic equation is given and the erroneous formula for the hydrogen fine structure to which it leads is presented. Then the author says, "It is apparently of no purpose to discuss the accuracy of the formula just obtained . . ." and does not tell the reader that the formula is wrong and how the electron spin hypothesis corrects it and improves Sommerfeld's original theory of the fine structure!

Chapter 4 purporting to review the diffraction by crystals and gases of electron waves, is very bad. Three of the book's 19 figures are devoted to the old uncertain results of Davisson and Kunsman while not a single mention is made of the work of Davisson and Germer! Then three more figures are devoted to Dymond's work on scattering in helium although Harnwell had shown that these results were due to secondary effects and published his work during 1928. Then follow about ten pages about G. P. Thomson's electron diffraction work still with no reference to the earlier work of Davisson and Germer.

The last fifth of the book is devoted to an account of attempts to connect Ψ with the general relativity theory which are certainly among the least important of the recent developments especially since they were carried out without reference to the electron spin problem which Dirac showed (winter, 1927) was inseparably connected with relativistic effects. I can find no mention of electron spin in the whole book.

Now the reason for setting these things out so fully is this: The publishers wrote to me a year ago for criticism of this book and paid me well for it. I told them much the same as I have written here and recommended that the book be revised before being issued in this country. But I suppose that was too much trouble so they prefer to offer to the physicists of America, at a price of more than 1 cent per 8×14 cm type page, a book which is very much out of date, misleading in spots, and ignores completely one of the finest pieces of experimental work done in the past decade.

E. U. CONDON

Bandenspektren auf experimenteller Grundlage. RICHARD RUEDY. Pp. vi+124, figs. 62. Sammlung Vieweg, Heft 101/102, 1930. Price RM 9.60.

Progress in the field of band spectra, since the publication, in 1926, of the National Research Council Bulletin "Molecular Spectra in Gases," has been both extensive and important. As a result, there is a real demand for an up-to-date account, but the knowledge and the time required to prepare a really adequate monograph on this very complex subject are

so great that even the leading workers in the field have shrunk from the task. The volume under review cannot be said to satisfy the demand. It is written in text book style,—that is, categorically, with no references to original literature, save for a brief list on the last two pages, of which no mention is made elsewhere. The reviewer feels that the subject is still too new for this style of treatment, and that the general reader is likely to get a false impression from it. A large portion of the volume is devoted to a detailed description of the fine structure, of various types of bands. This will be of interest mainly to the prospective research worker but the precise definitions and directions, so necessary for successful work, are in general not included. The most valuable feature of the book is the many diagrams, mainly taken with more or less adaptation from the original literature.

The nomenclature of band spectra is now undergoing a complete revision, and preliminary evidences appear in this volume, where two different symbols for the same quantity are sometimes used indiscriminately. In this matter of nomenclature, just one point will be mentioned. It has recently been agreed to use v as the vibrational quantum number (the former n). Professor Mulliken and the reviewer are now suggesting the use of $u = v + 1/2$, so that $u = 0$, or $v = -1/2$, for the hypothetical state of zero vibration. Ruedy retains n with its former meaning, and defines $v = n + 1/2$, so that his v is our u . He then makes the error of defining *his* v as the vibrational quantum number.

RAYMOND T. BIRGE

Handbuch der Experimental Physik, Band VIII, 2. Teil. Wärmeausdehnung, Zustandsgrößen und Theorien der Wärme. Pp. xii+766, 17.1×24.1 cm, Akademische Verlagsgesellschaft M. b. H., Leipzig, 1929. Price, bound RM 76.

Not much more can be attempted in a necessarily short review of a book of this character and extent than a summary of the nature of the contents.

The thermal expansion of solids and liquids is treated in 72 pages by Valentiner. Not only are the conventional experimental methods described with the aid of a number of diagrams but the theoretical significance of such measurements is made plainer by a discussion of the laws of expansion proposed by Debye and Grüneisen.

The thermal parameters (Thermische Zustandsgrößen) of gases at moderate and low pressures are discussed by Otto in an article of 161 pages. This includes a discussion of the experimental methods of determining the p - v - t relations for gases, together with the experimental results, dealing particularly with the experiments of Amagat. There is a very useful section on equations of state, with a reproduction of the 56 most important such equations that have been proposed. A very short section is given on gaseous mixtures.

The thermal parameters of liquids, solids and gases under high pressures are treated in 155 pages in an article written by myself and translated by Lenz. This article is by intention mostly concerned with my own experiments, and deals with the compressibility of liquids, gases, and solids as a function of pressure and temperature, melting phenomena and polymorphic transitions under high pressure. There is a short concluding section on the absorption of gases by liquids at pressures of a few hundred kg/cm².

Adsorption phenomena of gases and vapors on solid surfaces are treated in 100 pages by Glaser. Not only is the experimental material presented, but there is a welcome discussion of the thermodynamics of adsorption.

Vapor pressure measurements are discussed in 76 pages by Harteck. This includes the conventional material, and also such recent material as methods of determining the vapor pressure of involatile substances like tungsten or carbon. There is a section on hygrometry, which perhaps might not be looked for under the general heading.

The kinetic theory of gases and vapors is treated in 144 pages of Przibram. Such an article on a theoretical subject might perhaps not be expected in a Handbuch ostensibly devoted to experimental topics, but the emphasis is throughout on the experimental aspects, and for this reason it will be found to be a most useful supplement to the ordinary theoretical discussions by statistical methods. The discussions of recent direct methods of determining the actual velocity of gas molecules and demonstrating the Maxwellian velocity distribution are to be especially commended.

The concluding article is a short one of 22 pages by Herzfeld on certain consequences for physical chemistry of Nernst's heat theorem, dealing mostly with transition and reaction phenomena, with a discussion of the chemical constant.

P. W. BRIDGMAN

Molecular Spectra and Molecular Structure. A General Discussion held by the Faraday Society, September 1929. Price 15/6.

This volume consists of a collection of forty papers on molecular spectra and molecular structure given before the Faraday Society, September 1929, at the University of Bristol. The contributions are grouped into three parts, Band Spectra in the Visible and Ultra-Violet Regions, The Raman Effect and Infra-Red Spectra which latter part is subdivided into sections dealing with Solid Bodies, Liquids and Gases. Each division is opened by an introductory paper which presents the subject and gives something of the historical development. This is then followed by a series of original papers dealing with researches on particular phases of the problem.

It is difficult to summarize the individual papers since the problems they treat are so diversified. The reviewer can only call attention to some few which appear to him to be more outstanding. In the first section we find an attempt to provide a uniform Nomenclature for Diatomic Molecular Spectra introduced by O. W. Richardson, Band Spectra and Atomic Nuclei by R. S. Mulliken, a paper on Chemical Binding by F. Hund, a general paper on the Electronic Structure of Diatomic Molecules by J. E. Lennard-Jones and papers describing particular diatomic molecules by R. C. Johnson, O. W. Richardson, and W. E. Curtis. R. T. Birge contributes two papers, The Determination of Heats of Dissociation by Means of Band Spectra and Recent Work on Isotopes in Band Spectra.

The second part is opened with a paper by Professor Sir, C. V. Raman and is followed among others by articles by R. W. Wood and J. C. McLennan. The section on Infra-Red Spectra is well represented by some thirteen papers including, On the Infra-Red Spectra of Gases under High Dispersion by E. F. Barker and C. F. Meyer, and The Absorption Spectrum of Ammonia Gas in the Near Infra-Red by R. Mecke and R. M. Badger.

This volume issued by the Faraday Society will prove useful in three ways. The introductory articles are for the most part excellent and serve as a survey of the whole field of molecular spectra. The original contributions are valuable as such and give a good account of the most recent work on the subject. All the papers seem to be well supplied with citations of earlier work and since there are so many of them, on so many different phases, the whole collection may profitably be used for purposes of reference.

DAVID M. DENNISON

The Science of Voice. DOUGLAS STANLEY. Pp. 327, Carl Fisher Inc., 430 S. Wabash Avenue, Chicago. 1929.

This book was apparently written principally for the use of teachers and students of singing and speaking. It is divided into three parts. First, a physical introduction written in rather elementary form and in such a way that teachers and students with a moderate understanding and interest in physical principles might profit by it. The second part called "Vocal Technic" contains a description in physical terms of what the author considers to be a mechanism of the various terms used in vocal art. For a physicist without musical experience who is interested in the meaning attached by musicians to such terms as "register," "breath control," "the vibrato," "slur," "shakes," "staccato," etc., this second section is very suggestive in a manner which seems to be unique in such treatises. The third section on "musicianship and interpretation" is addressed almost entirely to musicians.

R. L. WEGEL

THE PHYSICAL REVIEW

ON THE USE OF THE ENERGY-MOMENTUM PRINCIPLE IN GENERAL RELATIVITY

BY RICHARD C. TOLMAN

NORMAN BRIDGE LABORATORY, CALIFORNIA INSTITUTE OF TECHNOLOGY,
PASADENA, CALIFORNIA

(Received December 20, 1930)

ABSTRACT

The primary purpose of this article is to obtain from the general relativity form of the energy-momentum principle certain new consequences which are needed for later work that the author has in mind. In addition, it is the intention to give at the same time a somewhat comprehensive and coherent treatment of the principle and its consequences, which it is hoped will increase the confidence and facility of physicists in the use of this important part of the general theory of relativity. In carrying out the investigation, it has seemed desirable for English readers, to take Eddington's "Mathematical Theory of Relativity" as a starting point, and this has incidentally led to a new form of deduction for certain consequences of the energy-momentum principle that were already known.

After presenting the energy-momentum principle in the form discovered by Einstein and showing its application to the case of the conservation of energy in an isolated system, an important expression is derived which gives the total densities of energy and momentum in the form of a divergence. This expression is equivalent to one previously obtained by Einstein but on account of the starting point adopted is derived and expressed in terms of the quantities $g^{\mu\nu}$ and $g_{\alpha}^{\mu\nu}$ instead of the $g^{\mu\nu}$ and $g_{\alpha}^{\mu\nu}$. Following this, the limiting values at large distances from an isolated material system are obtained for the quantities $g^{\alpha\beta}\partial\mathcal{E}/\partial g_{\gamma}^{\alpha\beta}$ and $g^{\alpha\beta}\partial\mathcal{E}/\partial g_{\gamma}^{\alpha\beta}$. These values, which have considerable use, have not previously received explicit expression. This is followed by a deduction from our present starting point of Einstein's famous relation $U=m$ between the energy and gravitational producing mass of an isolated system. An important expression is then obtained which gives the energy of a quasi-static isolated system in the form of an integral which has to be extended only over the portion of space actually occupied by matter or radiation. This expression has not previously received a satisfactory derivation. The result is used to obtain an expression for the energy of a spherical distribution of a perfect fluid, and it is then shown that this expression, in the case of a sphere of ordinary material, approaches in a sufficiently weak field to the classical expression for energy including the potential gravitational energy. This result is not only intrinsically useful, but also shows for a particular case that a higher order of approximation to the general relativity value for total energy is obtained by including the classical gravitational energy than by going at once to flat space-time as is often done. Finally, a general consideration is given to the problem of determining the conditions imposed on those changes from one static state to another which could occur in a non-isolated system forming part

of a larger static system, without changing the distribution of matter and radiation outside the boundary and without contravening the energy-momentum principle as applied to the system as a whole.

§1. INTRODUCTION

IN ACCORDANCE with Einstein's development of the general theory of relativity, the relativity analogues of the classical principles of the conservation of energy and momentum are to be obtained with the help of integration from the well-known differential equation¹

$$\frac{\partial}{\partial x_\nu}(\mathfrak{T}_\mu^\nu + t_\mu^\nu) = 0 \quad (1)$$

where \mathfrak{T}_μ^ν is the tensor density of material energy and momentum and t_μ^ν is the pseudo-tensor density of potential gravitational energy and momentum. Considering x_4 to be the time-like coordinate, equation (1) leads to the three equations for the conservation of momentum with $\mu = 1, 2, 3$, and leads to the equation for the conservation of energy with $\mu = 4$.

Taking for illustration the latter case, multiplying the equation by $dx_1 dx_2 dx_3$, and integrating over the system of interest, we obtain with some rearrangement of terms

$$\begin{aligned} \frac{\partial}{\partial x_4} \iiint (\mathfrak{T}_4^4 + t_4^4) dx_1 dx_2 dx_3 \\ = - \iiint \left[\frac{\partial}{\partial x_1} (\mathfrak{T}_4^1 + t_4^1) + \frac{\partial}{\partial x_2} (\mathfrak{T}_4^2 + t_4^2) + \frac{\partial}{\partial x_3} (\mathfrak{T}_4^3 + t_4^3) \right] dx_1 dx_2 dx_3 \end{aligned}$$

and by performing the indicated integrations on the right hand side this can be rewritten in the form

$$\begin{aligned} \frac{\partial}{\partial x_4} \iiint (\mathfrak{T}_4^4 + t_4^4) dx_1 dx_2 dx_3 \\ = - \iint \left| \mathfrak{T}_4^1 + t_4^1 \right|_{x_1}^{x_1'} dx_2 dx_3 - \iint \left| \mathfrak{T}_4^2 + t_4^2 \right|_{x_2}^{x_2'} dx_1 dx_3 - \iint \left| \mathfrak{T}_4^3 + t_4^3 \right|_{x_3}^{x_3'} dx_1 dx_2 \quad (2) \end{aligned}$$

where the limits of integration are denoted by x_1, x_1' etc. The result states that the rate of change with the time (x_4) in the value of the integral on the left hand side of the equation can be calculated from the conditions prevailing at the boundary of the system of interest as given by the right hand side of the equation. The equation can thus be regarded as a statement of the energy principle provided we define the energy of the system by the expression

$$U = \iiint (\mathfrak{T}_4^4 + t_4^4) dx_1 dx_2 dx_3. \quad (3)$$

And a similar treatment for the components of momentum can be obtained by taking $\mu = 1, 2, 3$.

¹ See for example Eddington, "The Mathematical Theory of Relativity." Cambridge 1923, equations (59.2) and (59.3).

Owing to the fact that equations (1) and (2) are not tensor equations and that the quantity t_μ^ν is not a true tensor density, considerable doubt as to the validity of the above formulation of the energy principle was at one time expressed² and perhaps to some extent still exists.³ It can be shown, nevertheless, that the equations have the necessary fundamental property of being true in all sets of coordinates, and a completely satisfactory justification of the formulation was finally given by Einstein in 1918.⁴

Since that time, however, the interest of mathematical physicists has been largely turned to other matters, and the methods and results of applying the energy-momentum principle have not been particularly investigated. It is the purpose of the present article to consider some of these methods and results not only because of their intrinsic importance, but also because of certain further applications which the writer has in mind.

In carrying out the investigation we shall use, as far as may be, the notation adopted by Eddington in his "Mathematical Theory of Relativity", and shall base our deductions on equations given by him. This choice of starting point necessitates some duplication of results which have previously been obtained by other methods, but seems desirable owing to the familiarity of English readers with Eddington's treatise and owing to the excellence of the detailed and coherent treatment which he has given.

In the immediately following section, §2, we shall first give Einstein's method of applying the above energy principle to an isolated material system. In §3 we shall then obtain a very useful formula which expresses the total density of energy and momentum as an ordinary divergence; the formula is equivalent in import to one already obtained by Einstein but because of our choice of starting point differs in method of derivation and form of expression. Following this, in §4, we shall deduce the limiting values at large distances from such an isolated system of certain functions of the gravitational field; these values are necessary for our further work and have not previously received explicit expression. In §5 we shall then be able to give a deduction from our present basis of Einstein's relation between the total energy and gravitational mass of an isolated material system. In §6 we shall deduce an extremely important equation expressing the total energy of an isolated system by an integral which has to be extended only over that portion of space which is actually occupied by matter or radiation; this equation

² Schroedinger, *Phys. Zeits.* 19, 4 (1918); Bauer, *ibid.* 19, 163 (1918).

³ Thus, for example, Eddington (reference 1, pp. 135-136) objects to the fundamental significance of the equation $\partial/\partial x_\nu (\mathfrak{T}_\mu^\nu + t_\mu^\nu) = 0$ on the ground that t_μ^ν is not a true tensor density, and appears to regard the introduction of the equation as an unfortunate pandering to an immoral desire to obtain by hook or crook some kind of conservation laws in the mechanics of general relativity. It should be remarked, however, that the appropriate criterion for the fundamental significance of equations should not be that they are written in tensorial form but that they are written in covariant form so as to be true in all sets of coordinates. All tensor equations are indeed covariant equations, but this does not exclude the possibility of covariant equations, such as the one above, which are not tensorial. To assume the contrary would be the fallacy of the Dormouse in Alice in Wonderland, who said:—"I breathe when I sleep" is the same thing as "I sleep when I breathe."

⁴ Einstein, *Berl. Ber.* 1918, p. 448.

has not previously received a satisfactory derivation. In the following section, §7, we shall use this equation to obtain an expression for the total energy of a distribution of perfect fluid having spherical symmetry. And in §8 we shall show that, on making the gravitational field weaker, the above expression approaches the classical expression for the energy of such a sphere including the classical value for its potential gravitational energy; the result is an intrinsically useful one and also shows for a particular case that a higher order of approximation to the general relativity value for total energy is obtained by including the classical gravitational energy than by neglecting the gravitational energy entirely as has hitherto often been done. Finally in §§9, 10 we shall consider the application of the general energy-momentum principle to changes occurring within a region which forms part of a larger system, and in §11 shall make some concluding remarks.

§2. THE CONSERVATION OF ENERGY IN AN ISOLATED SYSTEM

Let us now first consider the application of the energy principle to those changes which can take place within a limited system without producing any changes in the gravitational field outside of a sufficiently distant boundary located in the free space surrounding the system. Such a system will be called an isolated one. In this case, we can easily show that the general energy principle, as given by equation (2), can be interpreted as leading to the conservation of energy within the boundary taken.

For the tensor density of matter and energy \mathfrak{T}_μ^ν , occurring in equation (2), we can write from the equation of definition⁵

$$\mathfrak{T}_\mu^\nu = \sqrt{-g} g_{\alpha\mu} T^{\alpha\nu} = \sqrt{-g} g_{\alpha\mu} \rho_0 \frac{dx_\alpha}{ds} \frac{dx_\nu}{ds} \quad (4)$$

where ρ_0 is the proper density of matter. And since we take the boundary which encloses the system as located in free space the density ρ_0 will there be zero, so that it is evident that the quantities \mathfrak{T}_4^1 , \mathfrak{T}_4^2 and \mathfrak{T}_4^3 , occurring on the right hand side of equation (2), will themselves have the value zero at the boundary.

Furthermore, the pseudo-tensor density of potential energy is defined in terms of the Lagrangian function \mathfrak{L} and the cosmological constant Λ by the equation⁶

$$t_\mu^\nu = \frac{1}{16\pi} \left\{ g_\mu^\nu \mathfrak{L} - g_\mu^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g^{\alpha\beta}} \right\} + \frac{\Lambda}{8\pi} g_\mu^\nu \sqrt{-g}. \quad (5)$$

The quantity g_μ^ν , however, is equal to zero with $\mu \neq \nu$, and the symbol $g_4^{\alpha\beta}$ is a short hand for $\partial(g^{\alpha\beta}\sqrt{-g})/\partial x_4$ and hence is equal to zero at the boundary enclosing our system, if the gravitational field at that boundary is not changing with the time as postulated. Hence the quantities t_4^1 , t_4^2 , and t_4^3 ,

⁵ See Eddington, reference 1, equation (53.1).

⁶ See Eddington, reference 1, equation (59.4). The additional term in Λ , when the cosmological term is not neglected, can easily be shown necessary. Compare Einstein, reference 4, equation (18).

occurring on the right hand side of equation (2), will also be zero at the boundary with which we have enclosed the system.

Hence using a system of coordinates such that the limits of integration coincide with the boundary enclosing the system,⁷ it is evident that the terms on the right hand side of equation (2) will all of them become zero and the energy principle for this particular case will reduce to the conservation of energy

$$\frac{\partial}{\partial x_4} \iiint (\mathfrak{T}_4^4 + t_4^4) dx_1 dx_2 dx_3 = 0$$

or

$$U = \iiint (\mathfrak{T}_4^4 + t_4^4) dx_1 dx_2 dx_3 = \text{const.} \quad (6)$$

§3. THE DENSITIES OF MOMENTUM AND ENERGY EXPRESSED AS DIVERGENCES

In order to make use of this interesting result, it will now be necessary to make a rather lengthy digression by deducing certain useful lemmas in this and in the following section. In the present section we shall show the possibility of expressing the total density of momentum or energy as an ordinary divergence in accordance with the equation⁸

$$8\pi(\mathfrak{T}_\mu^\nu + t_\mu^\nu) = \frac{\partial}{\partial x_\gamma} \left(-g^{\alpha\nu} \frac{\partial \mathfrak{L}}{\partial g_\gamma^{\mu\alpha}} + \frac{1}{2} g_\mu^\nu g^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g_\gamma^{\alpha\beta}} \right). \quad (7)$$

To prove this equation will be a very tiresome business, justified only by the importance of the result. To carry out the demonstration we shall have to make use of a large number of well established results which we shall now give.

For the density of material energy and momentum we shall use the fundamental equation connecting it with the metrical properties of the field⁹

$$-8\pi\mathfrak{T}_\mu^\nu = \mathfrak{G}_\mu^\nu - \frac{1}{2} g_\mu^\nu \mathfrak{G} + \Lambda g_\mu^\nu \quad (8)$$

where \mathfrak{G}_μ^ν is the tensor density corresponding to the contracted Riemann-Christoffel tensor and Λ the cosmological constant. For the density of potential energy and momentum we shall use the equation of definition already given above

$$16\pi g_\mu^\nu = g_\mu^\nu \mathfrak{L} - g_\mu^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g_\nu^{\alpha\beta}} + 2\Lambda g_\mu^\nu \quad (9)$$

⁷ With a system of coordinates chosen so that some of the limits of integration do not fall on the boundary, the quantities $[\mathfrak{T}_4^4 + t_4^4]_{x_4}$ etc. will not necessarily be zero. Compare §9.

⁸ This equation is equivalent in import to equation (18) given by Einstein, *Berl. Ber.* 1916, p. 1115. It differs in form since we are regarding \mathfrak{L} as a function of the $g^{\mu\nu}$ and $g_\alpha^{\mu\nu}$ instead of as a function of the $g^{\mu\nu}$ and $g_\alpha^{\mu\nu}$.

⁹ See Eddington, reference 1, equation (54.71).

where the Lagrangian function \mathfrak{L} is defined in terms of the Christoffel symbols by the equation¹⁰

$$\mathfrak{L} = \sqrt{-g} g^{\alpha\beta} \left(\{ \alpha\gamma, \epsilon \} \{ \beta\epsilon, \gamma \} - \{ \alpha\beta, \gamma \} \{ \gamma\epsilon, \epsilon \} \right). \quad (10)$$

In accordance with this definition it is possible to show that \mathfrak{L} can also be expressed as a function of the quantities

$$g^{\alpha\beta} = g^{\alpha\beta} \sqrt{-g} \quad \text{and} \quad g_{\gamma}^{\alpha\beta} = \frac{\partial}{\partial x_{\gamma}} (g^{\alpha\beta} \sqrt{-g}) \quad (11)$$

and will then have the differential coefficients¹¹

$$\frac{\partial \mathfrak{L}}{\partial g^{\alpha\beta}} = - \left(\{ \alpha\gamma, \epsilon \} \{ \beta\epsilon, \gamma \} - \{ \alpha\beta, \gamma \} \{ \gamma\epsilon, \epsilon \} \right) \quad (12)$$

and¹²

$$\frac{\partial \mathfrak{L}}{\partial g_{\gamma}^{\alpha\beta}} = - \{ \alpha\beta, \gamma \} + \frac{1}{2} g_{\alpha}^{\gamma} \{ \beta\epsilon, \epsilon \} + \frac{1}{2} g_{\beta}^{\gamma} \{ \alpha\epsilon, \epsilon \}. \quad (13)$$

Further important properties of the Lagrangian function, relating it to the metrical properties of the field, are given by the equation¹³

$$G_{\mu\nu} = \frac{\partial}{\partial x_{\gamma}} \frac{\partial \mathfrak{L}}{\partial g_{\gamma}^{\mu\nu}} - \frac{\partial \mathfrak{L}}{\partial g^{\mu\nu}} \quad (14)$$

and¹⁴

$$\mathfrak{G} = \frac{\partial}{\partial x_{\gamma}} \left(g^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g_{\gamma}^{\alpha\beta}} \right) - \mathfrak{L}. \quad (15)$$

Finally, the quantity $g_{\gamma}^{\alpha\beta}$ may be expressed in terms of the Christoffel symbols by the equation¹⁵

$$g_{\gamma}^{\alpha\beta} = \sqrt{-g} \left(- \{ \delta\gamma, \alpha \} g^{\delta\beta} - \{ \delta\gamma, \beta \} g^{\delta\alpha} + \{ \gamma\delta, \delta \} g^{\alpha\beta} \right). \quad (16)$$

We are now ready to proceed to the derivation of equation (7). Combining equations (8) and (9) we have

$$8\pi(\mathfrak{T}_{\mu}^{\nu} + t_{\mu}^{\nu}) = - \mathfrak{G}_{\mu}^{\nu} + \frac{1}{2} g_{\mu}^{\nu} \mathfrak{G} + \frac{1}{2} g_{\mu}^{\nu} \mathfrak{L} - \frac{1}{2} g_{\mu}^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g_{\nu}^{\alpha\beta}}$$

¹⁰ See Eddington, reference 1, equation (58.1).

¹¹ See Eddington, reference 1, equation (58.51).

¹² See Eddington, reference 1, equation (58.52). We have written the expression in a symmetrical form which is equivalent to Eddington's unsymmetrical form.

¹³ See Eddington, reference 1, equation (58.6).

¹⁴ See Eddington, reference 1, equation (58.8).

¹⁵ See Eddington, reference 1, the equation immediately following (58.72).

Substituting (14) and (15) we obtain

$$8\pi(\mathfrak{T}_\mu^\nu + t_\mu^\nu) = -g^{\alpha\nu} \frac{\partial}{\partial x_\gamma} \frac{\partial \mathfrak{L}}{\partial g^{\mu\alpha}} + g^{\alpha\nu} \frac{\partial \mathfrak{L}}{\partial g^{\mu\alpha}} + \frac{1}{2} g_\mu^\nu \frac{\partial}{\partial x_\gamma} \left(g^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g^{\alpha\beta}} \right) - \frac{1}{2} g_\mu^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g^{\alpha\beta}}$$

and this can evidently be rewritten in the form

$$8\pi(\mathfrak{T}_\mu^\nu + t_\mu^\nu) = \frac{\partial}{\partial x_\gamma} \left(-g^{\alpha\nu} \frac{\partial \mathfrak{L}}{\partial g^{\mu\alpha}} + \frac{1}{2} g_\mu^\nu g^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g^{\alpha\beta}} \right) + g_\gamma^{\alpha\nu} \frac{\partial \mathfrak{L}}{\partial g^{\mu\alpha}} + g^{\alpha\nu} \frac{\partial \mathfrak{L}}{\partial g^{\mu\alpha}} - \frac{1}{2} g_\mu^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g^{\alpha\beta}}. \quad (17)$$

Comparing this result with equation (7), we see that our deduction will be completed if we can now show that the sum of the last three terms is equal to zero. To accomplish this we must substitute for the quantities occurring in these three terms their explicit values in terms of the Christoffel symbols as given by equations (12), (13) and (16). Doing so we obtain

$$\begin{aligned} & g_\gamma^{\alpha\nu} \frac{\partial \mathfrak{L}}{\partial g^{\mu\alpha}} + g^{\alpha\nu} \frac{\partial \mathfrak{L}}{\partial g^{\mu\alpha}} - \frac{1}{2} g_\mu^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g^{\alpha\beta}} \\ &= \sqrt{-g} [-\{ \delta\gamma, \alpha \} g^{\delta\nu} - \{ \delta\gamma, \nu \} g^{\delta\alpha} + \{ \gamma\delta, \delta \} g^{\alpha\nu}] [-\{ \mu\alpha, \gamma \} + \frac{1}{2} g_\mu^\gamma \{ \alpha\epsilon, \epsilon \} + \frac{1}{2} g_\alpha^\gamma \{ \mu\epsilon, \epsilon \}] \\ &\quad + \sqrt{-g} g^{\alpha\nu} [-\{ \alpha\gamma, \epsilon \} \{ \mu\epsilon, \gamma \} + \{ \alpha\mu, \gamma \} \{ \gamma\epsilon, \epsilon \}] \\ &\quad - \frac{1}{2} \sqrt{-g} [-\{ \delta\mu, \alpha \} g^{\delta\beta} - \{ \delta\mu, \beta \} g^{\delta\alpha} + \{ \mu\delta, \delta \} g^{\alpha\beta}] [-\{ \alpha\beta, \nu \} + \frac{1}{2} g_\alpha^\nu \{ \beta\epsilon, \epsilon \} \\ &\quad + \frac{1}{2} g_\beta^\nu \{ \alpha\epsilon, \epsilon \}] \\ &= \sqrt{-g} [\{ \delta\gamma, \alpha \} \{ \mu\alpha, \gamma \} g^{\delta\nu} - \frac{1}{2} \{ \delta\mu, \alpha \} \{ \alpha\epsilon, \epsilon \} g^{\delta\nu} - \frac{1}{2} \{ \delta\alpha, \alpha \} \{ \mu\epsilon, \epsilon \} g^{\delta\nu} \\ &\quad + \{ \delta\gamma, \nu \} \{ \mu\alpha, \gamma \} g^{\delta\alpha} - \frac{1}{2} \{ \delta\mu, \nu \} \{ \alpha\epsilon, \epsilon \} g^{\delta\alpha} - \frac{1}{2} \{ \delta\alpha, \nu \} \{ \mu\epsilon, \epsilon \} g^{\delta\alpha} \\ &\quad - \{ \gamma\delta, \delta \} \{ \mu\alpha, \gamma \} g^{\alpha\nu} + \frac{1}{2} \{ \mu\delta, \delta \} \{ \alpha\epsilon, \epsilon \} g^{\alpha\nu} + \frac{1}{2} \{ \alpha\delta, \delta \} \{ \mu\epsilon, \epsilon \} g^{\alpha\nu} \\ &\quad - \{ \alpha\gamma, \epsilon \} \{ \mu\epsilon, \gamma \} g^{\alpha\nu} + \{ \alpha\mu, \gamma \} \{ \gamma\epsilon, \epsilon \} g^{\alpha\nu} \\ &\quad - \frac{1}{2} \{ \delta\mu, \alpha \} \{ \alpha\beta, \nu \} g^{\delta\beta} + \frac{1}{4} \{ \delta\mu, \nu \} \{ \beta\epsilon, \epsilon \} g^{\delta\beta} + \frac{1}{4} \{ \delta\mu, \alpha \} \{ \alpha\epsilon, \epsilon \} g^{\delta\nu} \\ &\quad - \frac{1}{2} \{ \delta\mu, \beta \} \{ \alpha\beta, \nu \} g^{\delta\alpha} + \frac{1}{4} \{ \delta\mu, \beta \} \{ \beta\epsilon, \epsilon \} g^{\delta\nu} + \frac{1}{4} \{ \delta\mu, \nu \} \{ \alpha\epsilon, \epsilon \} g^{\delta\alpha} \\ &\quad + \frac{1}{2} \{ \mu\delta, \delta \} \{ \alpha\beta, \nu \} g^{\alpha\beta} - \frac{1}{4} \{ \mu\delta, \delta \} \{ \beta\epsilon, \epsilon \} g^{\delta\nu} - \frac{1}{4} \{ \mu\delta, \delta \} \{ \alpha\epsilon, \epsilon \} g^{\alpha\nu}] \\ &= 0 \end{aligned}$$

where the value zero arises, after some changes in dummy suffixes, from the mutual cancellation of all terms, as can easily be verified by noting that the terms have been labelled in such a way that those which destroy each other are given the same number.

Combining this result with equation (17), we now complete the derivation of the original equation (7), which it was the purpose of this section to prove.

§4. THE LIMITING VALUES OF CERTAIN QUANTITIES AT LARGE DISTANCES FROM AN ISOLATED MATERIAL SYSTEM

As a further preparation for our later considerations we shall now obtain the limiting values at large distances from an isolated material system for the quantities $g^{ab}(\partial\mathfrak{L}/\partial g^{ab})$ and $g^{a4}(\partial\mathfrak{L}/\partial g^{a4})$ which occur on the right hand side of equation (7). To do this we recall that we have defined an isolated system in §2, in such a way that the changes taking place within the system do not produce changes in the gravitational field outside of a sufficiently distant boundary. Therefore, at a sufficient distance from an isolated system the gravitational field will be static and spherically symmetrical, and we can use for it the well known Schwarzschild solution. Hence placing the system in the neighborhood of the origin of a set of coordinates x, y, z, t , which approach Galilean coordinates at large distances we can write for the line element the approximate Schwarzschild expression¹⁶

$$ds^2 = -(1+2m/r)(dx^2+dy^2+dz^2) + (1-2m/r)dt^2$$

where the constant m is the mass of the system and r is an abbreviation for $(x^2+y^2+z^2)^{1/2}$.

Since the above expression gives the form taken by the Schwarzschild solution in a particular kind of quasi-Galilean coordinates, it is evident that later results, which are dependent on the present section, will also be originally derived in the form which they assume in these particular coordinates, and their translation into the language of other systems of coordinates must be undertaken with due cognizance of their method of derivation. Furthermore, the above expression is an approximate one, valid at distances large enough so that terms of the order $(m/r)^2$ can be neglected, and yet at the same time small enough so that the curvature of the universe as a whole, as given by the cosmological term, can be neglected. Hence those later considerations which are dependent on this section will primarily apply only to systems which are small compared to the total dimensions of the universe, even though of course still very large compared with ordinary terrestrial dimensions.

Returning to our approximate expression for the Schwarzschild line element we may now write for the components of the fundamental metrical tensor, the values

$$\begin{aligned} g_{11} &= g_{22} = g_{33} = -[1+2m/r] & g_{44} &= [1-2m/r] \\ g^{11} &= g^{22} = g^{33} = -\frac{1}{[1+2m/r]} & g^{44} &= \frac{1}{[1-2m/r]} \\ g_{\mu\nu} &= g^{\mu\nu} = 0 \quad (\mu \neq \nu) & \sqrt{-g} &= [1+2m/r]^{3/2} [1-2m/r]^{1/2} \end{aligned} \quad (18)$$

To calculate the desired quantities from these expressions for the metrical tensor, we shall first need the values of the Christoffel symbols. These are defined by the equation¹⁷

¹⁶ See Eddington, reference 1, equation (46.15).

¹⁷ See Eddington, reference 1, equation (27.2).

$$\{\mu\nu, \sigma\} = \frac{1}{2} g^{\sigma\lambda} \left(\frac{\partial g_{\mu\lambda}}{\partial x_\nu} + \frac{\partial g_{\nu\lambda}}{\partial x_\mu} - \frac{\partial g_{\mu\nu}}{\partial x_\lambda} \right)$$

which evidently reduces under our circumstances to

$$\{\mu\nu, \sigma\} = \frac{1}{2} g^{\sigma\sigma} \left(\frac{\partial g_{\mu\sigma}}{\partial x_\nu} + \frac{\partial g_{\nu\sigma}}{\partial x_\mu} - \frac{\partial g_{\mu\nu}}{\partial x_\sigma} \right) \quad (\text{not summed})$$

and taking μ, ν , and σ as *different* indices we obtain the four cases

$$\begin{aligned} \{\mu\mu, \mu\} &= \frac{1}{2} g^{\mu\mu} \frac{\partial g_{\mu\mu}}{\partial x_\mu} \\ \{\mu\mu, \nu\} &= -\frac{1}{2} g^{\nu\nu} \frac{\partial g_{\mu\mu}}{\partial x_\nu} \\ \{\nu\mu, \mu\} &= \{\mu\nu, \mu\} = \frac{1}{2} g^{\mu\mu} \frac{\partial g_{\mu\mu}}{\partial x_\nu} \\ \{\mu\nu, \sigma\} &= 0. \end{aligned} \tag{19}$$

We are now ready to proceed to our calculations. Under our circumstances we may evidently write

$$g^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g_1^{\alpha\beta}} = \sqrt{-g} \left(g^{11} \frac{\partial \mathfrak{L}}{\partial g_1^{11}} + g^{22} \frac{\partial \mathfrak{L}}{\partial g_1^{22}} + g^{33} \frac{\partial \mathfrak{L}}{\partial g_1^{33}} + g^{44} \frac{\partial \mathfrak{L}}{\partial g_1^{44}} \right).$$

Substituting the values given by equation (13), this becomes

$$\begin{aligned} g^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g_1^{\alpha\beta}} &= \sqrt{-g} \left(-g^{11} \{11, 1\} + \frac{1}{2} g^{11} \{1\epsilon, \epsilon\} + \frac{1}{2} g^{11} \{1\epsilon, \epsilon\} \right. \\ &\quad \left. - g^{22} \{22, 1\} - g^{33} \{33, 1\} - g^{44} \{44, 1\} \right) \end{aligned}$$

and introducing the values of the Christoffel symbols given by equations (19) it reduces to

$$\begin{aligned} g^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g_1^{\alpha\beta}} &= \frac{1}{2} \sqrt{-g} \left(g^{11} g^{22} \frac{\partial g_{22}}{\partial x} + g^{11} g^{33} \frac{\partial g_{33}}{\partial x} + g^{11} g^{44} \frac{\partial g_{44}}{\partial x} \right. \\ &\quad \left. + g^{22} g^{11} \frac{\partial g_{22}}{\partial x} + g^{33} g^{11} \frac{\partial g_{33}}{\partial x} + g^{44} g^{11} \frac{\partial g_{44}}{\partial x} \right). \end{aligned}$$

Finally, substituting the values for the components of the metrical tensor given by equations (18), and, because of the large distances under consideration, neglecting quantities of the order m/r in comparison with unity, we easily obtain

$$g^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g_1^{\alpha\beta}} = -2 \frac{\partial}{\partial x} \left(\frac{2m}{r} \right) + \frac{\partial}{\partial x} \left(\frac{2m}{r} \right) = \frac{2m}{r^2} \frac{\partial r}{\partial x}.$$

From considerations of symmetry it is evident that we shall also have similar expressions in y and z , and introducing the direction cosines for the radius vector we may evidently write

$$g^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g^{\alpha\beta}_1} = \frac{2m}{r^2} \cos(nx), \quad g^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g^{\alpha\beta}_2} = \frac{2m}{r^2} \cos(ny), \quad g^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g^{\alpha\beta}_3} = \frac{2m}{r^2} \cos(nz) \quad (20)$$

while the value of the fourth quantity $g^{\alpha\beta}(\partial \mathfrak{L} / \partial g^{\alpha\beta}_4)$ will not be needed for our later work.

Turning now to the second of the quantities of interest mentioned at the beginning of this section, we may evidently write with the help of equations (18), (13) and (19)

$$g^{\alpha 4} \frac{\partial \mathfrak{L}}{\partial g^{\alpha 4}_1} = \sqrt{-g} g^{44} \frac{\partial \mathfrak{L}}{\partial g^{44}_1} = -\sqrt{-g} g^{44} \{44, 1\} = \frac{1}{2} \sqrt{-g} g^{44} g^{11} \frac{\partial g^{44}}{\partial x}$$

or, to the same order of approximation as before, we obtain

$$g^{\alpha 4} \frac{\partial \mathfrak{L}}{\partial g^{\alpha 4}_1} = -\frac{m}{r^2} \cos(nx), \quad g^{\alpha 4} \frac{\partial \mathfrak{L}}{\partial g^{\alpha 4}_2} = -\frac{m}{r^2} \cos(ny), \quad g^{\alpha 4} \frac{\partial \mathfrak{L}}{\partial g^{\alpha 4}_3} = -\frac{m}{r^2} \cos(nz). \quad (21)$$

§5. RELATION BETWEEN THE ENERGY AND MASS OF AN ISOLATED SYSTEM

We are now ready to return to our discussion of the energy principle by giving a deduction from our present basis of Einstein's relation between the energy and mass of an isolated material system. Using the quasi-Galilean coordinates described in the last section, we may write for the energy of the system, in accordance with equation (6),

$$U = \iiint (\mathfrak{T}_4^4 + t_4^4) dx dy dz$$

and this quantity will be constant independent of the time t as shown in §2, provided the boundary of the region of integration is taken sufficiently distant from the system. Substituting the value for total energy density given by equation (7), we can now rewrite our expression for the energy in the form

$$U = \frac{1}{8\pi} \iiint \frac{\partial}{\partial x_\gamma} \left(-g^{\alpha 4} \frac{\partial \mathfrak{L}}{\partial g^{\alpha 4}_\gamma} + \frac{1}{2} g^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g^{\alpha\beta}_\gamma} \right) dx dy dz.$$

Taking the boundary of the region of integration as a sphere with its center at the origin of coordinates, using Gauss's theorem to transform to a surface integral, and substituting at the distant boundary the three values for the term in parenthesis found in the previous section as given by equations (20) and (21), this can evidently be rewritten in the form

$$U = \frac{1}{8\pi} \iint \frac{2m}{r^2} [\cos^2(nx) + \cos^2(ny) + \cos^2(nz)] dS \\ + \frac{1}{8\pi} \frac{\partial}{\partial t} \iiint \left(-g^{\alpha 4} \frac{\partial \mathfrak{L}}{\partial g^{\alpha 4}_4} + \frac{1}{2} g^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g^{\alpha\beta}_4} \right) dx dy dz.$$

Since, however, both U and the surface integral on the right hand side of the equation are constants independent of the time,¹⁸ it is evident that the second term on the right hand side of the equation must be zero, as the volume integral in the second term could not continue to change permanently at a constant rate with the time. Hence evaluating the surface integral, we easily obtain for an isolated system the simple relation

$$U = m \quad (22)$$

where U is Einstein's expression for the energy of the system, and m is the mass which must be substituted into the Schwarzschild solution to give the gravitational field at large distances. This appropriate result is itself no mean justification for Einstein's formulation of the energy principle.

§6. THE ENERGY OF A QUASI-STATIC ISOLATED SYSTEM EXPRESSED BY AN INTEGRAL EXTENDING ONLY OVER THE OCCUPIED SPACE

For certain purposes both of the expressions for the energy of an isolated system, $\iiint (\mathfrak{T}_4^4 + t_4^4) dx dy dz$ and m , are sometimes unsatisfactory, the first because the integration has to be extended over a region large compared with the actual system, owing to the fact that t_4^4 is in general not zero in free space, and the second because it gives no method of computing the energy from the actual distribution of matter or radiation within the system. For a particular class of systems, which we shall call quasistatic, a more usable expression can be obtained.

Starting once more with our fundamental equation (6) for the energy of an isolated system, we write

$$U = \iiint (\mathfrak{T}_4^4 + t_4^4) dx dy dz$$

where we again use the quasi-Galilean coordinates defined in §4. Substituting the expression for the density of potential energy t_4^4 given by equation (9) this can be rewritten in the form¹⁹

$$U = \iiint \left(\mathfrak{T}_4^4 + \frac{\mathfrak{L}}{16\pi} - \frac{1}{16\pi} g^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g^{\alpha\beta}} \right) dx dy dz$$

and introducing the expression for \mathfrak{L} given by equation (15) this becomes

$$U = \iiint \left[\mathfrak{T}_4^4 - \frac{\mathfrak{G}}{16\pi} + \frac{1}{16\pi} \frac{\partial}{\partial x_\gamma} \left(g^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g^{\alpha\beta}} \right)_\gamma - \frac{1}{16\pi} g^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g^{\alpha\beta}} \right] dx dy dz.$$

¹⁸ The quantity m must be a constant, since it determines the gravitational field at the distant boundary, and by our definition an isolated system produces a constant gravitational field at the distant boundary.

¹⁹ We omit the cosmological term in the expressions for t_4^4 and \mathfrak{T} since our present considerations already contain the assumption that the system is small compared with the total dimensions of the universe.

Substituting now for \mathcal{G} the well-known expression¹⁹

$$\mathcal{G} = 8\pi\mathfrak{T} = 8\pi(\mathfrak{T}_1^1 + \mathfrak{T}_2^2 + \mathfrak{T}_3^3 + \mathfrak{T}_4^4)$$

writing the third term of the integrand out in full, and combining with the last term, we then easily obtain

$$\begin{aligned} U = & \frac{1}{2} \iiint (\mathfrak{T}_4^4 - \mathfrak{T}_1^1 - \mathfrak{T}_2^2 - \mathfrak{T}_3^3) dx dy dz \\ & + \frac{1}{16\pi} \iiint \left[\frac{\partial}{\partial x} \left(g^{\alpha\beta} \frac{\partial \mathfrak{Q}}{\partial g^{\alpha\beta}_1} \right) + \frac{\partial}{\partial y} \left(g^{\alpha\beta} \frac{\partial \mathfrak{Q}}{\partial g^{\alpha\beta}_2} \right) + \frac{\partial}{\partial z} \left(g^{\alpha\beta} \frac{\partial \mathfrak{Q}}{\partial g^{\alpha\beta}_3} \right) \right] dx dy dz \quad (23) \\ & + \frac{1}{16\pi} \iiint g^{\alpha\beta} \frac{\partial}{\partial t} \left(\frac{\partial \mathfrak{Q}}{\partial g^{\alpha\beta}_4} \right) dx dy dz. \end{aligned}$$

The second integral on the right hand side of this equation can be evaluated, however, by taking the boundary of the region of integration as a sphere, transforming to a surface integral and substituting at the distant boundary the values given by equations (20). We thus easily obtain $m/2$ as the value of the second integral and since for an isolated system this is itself equal by equation (22) to $U/2$ as shown in the preceding section, we can rewrite equation (23) in the form

$$U = \iiint (\mathfrak{T}_4^4 - \mathfrak{T}_1^1 - \mathfrak{T}_2^2 - \mathfrak{T}_3^3) dx dy dz + \frac{1}{8\pi} \iiint g^{\alpha\beta} \frac{\partial}{\partial t} \left(\frac{\partial \mathfrak{Q}}{\partial g^{\alpha\beta}_4} \right) dx dy dz \quad (24)$$

Finally, let us now define a quasi-static system as one in which changes with the time are taking place sufficiently slowly so that the last term in this equation can be neglected in comparison with the others, as will of course be exactly true in case we are only interested in the energy of the system at times when it is in a quiescent state of temporary or permanent equilibrium. We can then write as the desired expression²⁰ for the energy of an isolated quasi-static system

$$U = \iiint (\mathfrak{T}_4^4 - \mathfrak{T}_1^1 - \mathfrak{T}_2^2 - \mathfrak{T}_3^3) dx dy dz \quad (25)$$

²⁰ This expression for energy was first given by Nordström, *Proc. Amster. Acad.* **202**, 1080 (1918). The derivation given for the expression, however, was unsatisfactory since it was made to depend on an equation which the author ascribed to von Laue without any citation of the place of publication nor statement as to its range of validity. I have myself not been able to find the source of this expression and Professor von Laue has informed me by letter that he has been unable to find such an expression in the second volume of his book on relativity, does not know how he could have arrived at such an equation, now where else he might have set it forth, and is inclined to believe that Nordström must have been in error concerning the reference. Attention should also be called in this connection to the limited range as to the nature of the system and the choice of coordinates which will make equation (25) valid.

where it is evident from the equation of definition

$$T^{\mu\nu} = \rho_0 \frac{dx_\mu}{ds} \frac{dx_\nu}{ds}$$

that the integration has to be extended only over the region actually occupied by matter or radiation.

§7. ENERGY OF A SPHERE OF PERFECT FLUID.

We may now use equation (25) to calculate the energy of a spherical distribution of perfect fluid in a static state of stable or metastable equilibrium.

Continuing to use our quasi-Galilean coordinates x, y, z, t , we may evidently write the line element for our spherically symmetrical and static system in the form

$$ds^2 = -e^\mu (dx^2 + dy^2 + dz^2) + e^\nu dt^2 \quad (26)$$

where μ and ν are functions of $r = (x^2 + y^2 + z^2)^{1/2}$ and independent of t . In accordance with this line element we have for the components of the fundamental metrical tensor

$$\begin{aligned} g_{11} = g_{22} = g_{33} &= -e^\mu & g_{44} &= e^\nu \\ g^{11} = g^{22} = g^{33} &= -e^{-\mu} & g^{44} &= e^{-\nu} \\ g_{\rho\sigma} = g^{\rho\sigma} &= 0 \quad (\rho \neq \sigma) & \sqrt{-g} &= e^{\frac{3\mu+\nu}{2}}. \end{aligned} \quad (27)$$

For the tensor of energy and momentum for a perfect fluid we have the well known equation²¹

$$T^{\rho\sigma} = (\rho_{00} + p_0) \frac{dx_\rho}{ds} \frac{dx_\sigma}{ds} - g^{\rho\sigma} p_0 \quad (28)$$

where ρ_{00} and p_0 are the proper *macroscopic* density and proper pressure of the fluid as measured by local observers, and the quantities (dx_ρ/ds) are *macroscopic* velocities. For our case the macroscopic velocities will all be zero except for the case $\rho = \sigma = 4$ and we shall then have

$$\left(\frac{dt}{ds} \right)^2 = g^{44} = e^{-\nu}$$

so that the surviving components of the energy tensor will be

$$T^{11} = T^{22} = T^{33} = e^{-\mu} p_0 \quad T^{44} = e^{-\nu} \rho_{00}$$

or lowering suffixes

$$T_1^1 = T_2^2 = T_3^3 = -p_0 \quad T_4^4 = \rho_{00} \quad (29)$$

Multiplying these results by $\sqrt{-g}$ to change to tensor densities and substituting in equation (25), we now obtain for the energy of a steady spherical distribution of perfect fluid

²¹ See Eddington, reference 1, equations (54.81) and (54.82).

$$U = \iiint (\rho_{00} + 3p_0) e^{\frac{3\mu+p}{2}} dx dy dz. \quad (30)$$

We also have, moreover, the general relation

$$dV_0 ds = \sqrt{-g} dx_1 dx_2 dx_3 dx_4$$

where dV_0 is the element of proper three dimensional volume, and in our case this reduces to

$$dV_0 = e^{\frac{3\mu+p}{2}} dx dy dz \frac{dt}{ds} = e^{3\mu/2} dx dy dz$$

so that equation (30) can be rewritten in the extremely simple form

$$U = \int (\rho_{00} + 3p_0) e^{\nu/2} dV_0 = \int (\rho_{00} + 3p_0) \sqrt{g_{44}} dV_0. \quad (31)$$

§8. APPROXIMATE EXPRESSION FOR THE ENERGY OF A SPHERE OF FLUID IN A WEAK GRAVITATIONAL FIELD

We shall now investigate the value of this expression, for the energy of a sphere of perfect fluid, under circumstances where the gravitational field is weak enough so that the Newtonian theory of gravitation is approximately valid. Such a condition can of course be achieved by taking the quantity of matter in the sphere sufficiently small.

Under these circumstances the line element will approach that for flat space-time and we may write the components of the metrical tensor in the form

$$g_{\mu\nu} = \delta_{\mu\nu} + h_{\mu\nu} \quad (32)$$

where the quantities $\delta_{\mu\nu}$ are the Galilean values for the components of the metrical tensor, ± 1 or 0 , and the quantities $h_{\mu\nu}$ are *small* deviations therefrom. With these values for the components of the metrical tensor, however, we may easily obtain a well-known relation between h_{44} and the Newtonian gravitational potential Ψ .

To do this let us consider the behavior of a test particle placed at the point of interest and then allowed to move freely under the action of the gravitational field. In accordance with the theory of relativity the motion of this free particle must correspond to a geodesic in space-time and hence be governed by the equation²²

$$\frac{d^2 x_\alpha}{ds^2} + \{\mu\nu, \alpha\} \frac{dx_\mu}{ds} \frac{dx_\nu}{ds} = 0. \quad (33)$$

Since the particle starts from rest, however, the initial "velocities" dx_μ/ds and dx_ν/ds will all be zero except with μ or $\nu = 4$, and taking first the case of $\alpha = 1$, the above equation will reduce at the beginning of the motion to

²² See Eddington, reference 1, equation (49.42).

²³ See Eddington, reference 1, equation (28").

$$\frac{d^2x}{ds^2} + \{44, 1\} \left(\frac{dt}{ds} \right)^2 = 0. \quad (34)$$

Furthermore, we have for a particle at rest

$$ds^2 = g_{44} dt^2 = (1 + h_{44}) dt^2 \approx dt^2 \quad (35)$$

and in general

$$\{44, 1\} = \frac{1}{2} g^{\lambda 1} \left(\frac{\partial g_{4\lambda}}{\partial x_4} + \frac{\partial g_{4\lambda}}{\partial x_4} - \frac{\partial g_{44}}{\partial x_\lambda} \right)$$

which for our case reduces with sufficient approximation to

$$\{44, 1\} = \frac{1}{2} \frac{\partial g_{44}}{\partial x} = \frac{\partial}{\partial x} \left(\frac{h_{44}}{2} \right). \quad (36)$$

So that substituting (35) and (36) in (34) and writing the analogous equations with $\alpha = 2$ and 3 , we easily obtain for the initial acceleration of the test particle the equations

$$\frac{d^2x}{dt^2} = -\frac{\partial}{\partial x} \left(\frac{h_{44}}{2} \right), \quad \frac{d^2y}{dt^2} = -\frac{\partial}{\partial y} \left(\frac{h_{44}}{2} \right), \quad \frac{d^2z}{dt^2} = -\frac{\partial}{\partial z} \left(\frac{h_{44}}{2} \right). \quad (37)$$

We note at once that $(h_{44}/2)$ satisfies the same differential equations of motion as the gravitational potential Ψ in the ordinary Newtonian theory, and since h_{44} tends to zero at large distances may now write

$$\frac{h_{44}}{2} = \Psi \quad (38)$$

provided we make the usual convention that the gravitational potential shall be zero at infinity. This equation connects the relativity and Newtonian methods of treatment, providing the gravitational field is weak enough to permit the use of the older method.

In addition to this equation, we shall also need to use a value for a certain integral which was known in the Newtonian theory but is sufficiently unfamiliar so that we shall now derive it. The integral in question is $3 \int p dV$, where p is the pressure within the fluid and the integration is to be taken over the volume V of the whole sphere. We write

$$3 \int p dV = 3 \int_0^R 4\pi r^2 p dr$$

where R is the radius of the sphere, and by partial integration obtain

$$\begin{aligned} 3 \int p dV &= 4\pi r^3 p \Big|_0^R - \int_0^R 4\pi r^3 dp \\ &= - \int_0^R 4\pi r^3 dp \end{aligned}$$

where the first term has been dropped since r is zero at one limit and p at the other. It is evident, however, that the quantity $-4\pi r^2 dp$ is the total radial force acting outwards on the spherical shell of material dM_r lying between the radii r and $r+dr$ and hence can be equated to the gravitational attraction acting on this shell which gives us

$$3 \int p dV = \int_0^R \frac{M_r}{r} dM_r.$$

Moreover, the quantity on the right hand side of this equation is obviously the work that would be necessary to remove the material of the sphere to infinity and hence the negative of its potential energy. So that we can finally write

$$3 \int p dV = - \int \frac{\rho \Psi}{2} dV \quad (39)$$

where the integral on the right hand side of the equation is a well-known expression for potential energy, ρ being the density of material and Ψ the gravitational potential.

We are now ready to return to equation (31) which gave as an exact expression for the total energy of the sphere

$$U = \int (\rho_{00} + 3p_0) \sqrt{g_{44}} dV_0.$$

In accordance with equations (32) and (38) we can write as approximately valid in the case of a weak field

$$\sqrt{g_{44}} = (1 + h_{44})^{1/2} \approx 1 + \frac{h_{44}}{2} = 1 + \Psi.$$

And this can be substituted above to give

$$U = \int \rho_{00} dV_0 + \int \rho_{00} \Psi dV_0 + 3 \int p_0 dV_0 + 3 \int p_0 \Psi dV_0.$$

In the case of a weak gravitational field, however, the potential Ψ is everywhere small compared with unity and for the case of ordinary matter in a weak gravitational field²⁴ p_0 is small compared with ρ_{00} . Hence the last term in the above expression may be dropped entirely and the next two preceding terms simplified by omitting the subscripts $(_0)$ which specify a proper system of coordinates for the measuring of quantities. The result then becomes

$$U = \int \rho_{00} dV_0 + \int \rho \Psi dV + 3 \int p dV$$

²⁴ This is not true for radiation where $p_0 = \rho_{00}/3$, so that our present considerations apply to a sphere in which the density of ordinary matter is large compared with that of radiation, which is of course the case for which the Newtonian potential energy was known.

and introducing the value of $3\int p dV$ given by equation (39), we finally obtain as an approximate expression for the energy of a sphere of perfect fluid in a weak gravitational field

$$U = \int \rho_{00} dV_0 + \int \frac{\rho \Psi}{2} dV. \quad (40)$$

In satisfactory agreement with older theory, the energy thus consists of two parts,—the first being the total proper energy of the material out of which the sphere is composed, and the second the well-known Newtonian expression for its potential gravitational energy.

As far as the writer is aware, this is the first case in which it has been shown that Einstein's exact relativity expression for the energy of a system is more closely approximated by including the Newtonian potential energy than by going at once to flat space-time. It is hoped that the reasonableness of this result will lead to increased confidence in the use of the energy-momentum principle in general relativity.

§9. THE INTERPRETATION AND USE OF THE ENERGY-MOMENTUM PRINCIPLE IN THE CASE OF NON-ISOLATED SYSTEMS

So far, the applications of the energy-momentum principle, which we have considered in the foregoing, have dealt with the conservation of energy for an isolated system enclosed within a distant boundary located in the free space surrounding the system, and these applications have been made largely in order to illustrate the reasonableness of Einstein's formulation of the principle. In applying the theory of relativity to the phenomena of nature, however we may often be interested in using the energy-momentum principle to give us information as to the changes which could take place within a limited region which forms part of a larger system. Hence in the present section we shall consider the interpretation and use of the energy-momentum principle when applied to such non-isolated systems, and in the following section we shall discuss specifically the changes which the energy-momentum principle would allow in the distribution of matter within a certain kind of non-isolated system.

Let us return to the fundamental differential equation, true in all sets of coordinates, which was given in §1

$$\frac{\partial}{\partial x_\mu} (\mathfrak{T}_\mu^\nu + t_\mu^\nu) = 0 \quad (41)$$

where \mathfrak{T}_μ^ν is the tensor density of material energy and momentum and t_μ^ν the pseudo-tensor density of potential gravitational energy and momentum. Taking x_4 to be the time like coordinate, this equation will lead to the momentum principles with $\mu = 1, 2, 3$ and to the energy principle with $\mu = 4$. For our present purposes, however, we shall leave μ unspecified since the following considerations are general enough to apply to the energy-momentum principle as a whole.

Multiplying the above equation by $dx_1 dx_2 dx_3$, and integrating over the system of interest we obtain with some rearrangement of terms

$$\begin{aligned} & \frac{\partial}{\partial x_4} \iiint (\mathfrak{T}_\mu^4 + t_\mu^4) dx_1 dx_2 dx_3 \\ &= - \iiint \left[\frac{\partial}{\partial x_1} (\mathfrak{T}_\mu^1 + t_\mu^1) + \frac{\partial}{\partial x_2} (\mathfrak{T}_\mu^2 + t_\mu^2) + \frac{\partial}{\partial x_3} (\mathfrak{T}_\mu^3 + t_\mu^3) \right] dx_1 dx_2 dx_3 \end{aligned}$$

and, by performing the indicated integrations on the right hand side, this can be rewritten in the form

$$\begin{aligned} & \frac{\partial}{\partial x_4} \iiint (\mathfrak{T}_\mu^4 + t_\mu^4) dx_1 dx_2 dx_3 \\ &= - \iint \left[\mathfrak{T}_\mu^1 + t_\mu^1 \right]_{x_1}^{x_1'} dx_2 dx_3 - \iint \left[\mathfrak{T}_\mu^2 + t_\mu^2 \right]_{x_2}^{x_2'} dx_1 dx_3 - \iint \left[\mathfrak{T}_\mu^3 + t_\mu^3 \right]_{x_3}^{x_3'} dx_1 dx_2 \end{aligned} \quad (42)$$

where the limits of integration for the spatial variables x_1, x_2, x_3 are to be chosen so as to include the system of interest.

Equation (42) as written is true in all sets of coordinates, owing to its immediate dependence on the covariant equation (41). The interpretation and use of the equation, however, are often simplified if we choose coordinates in such a way that the limits of integration which must be taken in order to include the system of interest actually lie on the boundary surface which separates the region in question from its surroundings. Thus for example quasi-Galilean coordinates x, y, z with the limits of integration x to x' , y to y' , and z to z' lying on the boundary of the system, are usually preferable for our present purposes to polar coordinates r, θ, ϕ , with the origin inside the system and the limits of integration 0 to r , 0 to π and 0 to 2π , in which case r is the only limit actually lying on the boundary. The increased simplicity of the properly chosen coordinates arises from the fact that the right hand side of equation (42) is then completely determined solely by the values assumed at the boundary by the quantities $\mathfrak{T}_\mu^i, t_\mu^i$ etc. and is not dependent on their values within the system.

Having chosen coordinates in the way suggested, the interpretation of equation (42) becomes very simple. The equation now states that the rate of change with time x_4 of the volume integral on the left hand side of the equation is equal to the quantity on the right hand side, whose value is entirely determined by the conditions prevailing at the boundary of the system. The left hand side of the equation can then be interpreted as the rate of change with the time of a component of the total momentum of the system, with $\mu = 1, 2, 3$, or the rate of change of the energy of the system, with $\mu = 4$; and the right hand side of the equation can be interpreted as the flux of momentum or energy through the boundary.

The use of equation (42) will also be facilitated by the suggested choice of coordinates, when we are interested in some process which takes place within our system under circumstances such that we have definite information as to

the values of the quantities $\mathfrak{T}_\mu^1, t_\mu^1$ etc. at the boundary of the system, but do not have definite information as to the values they may assume in the interior of the system during the course of the process which interests us. In the following section we shall use coordinates of the kind suggested without further remark.

§10. APPLICATION OF THE ENERGY-MOMENTUM PRINCIPLE TO THE STATIC STATES OF A SYSTEM

Having thus obtained an indication as to the interpretation and use of the energy-momentum principle in the case of non-isolated systems, we shall now apply the principle to determine what restriction it would impose on the form of line element within a system which could exist in different static states. To solve this problem we apply the energy-momentum principle to the following process.

We start with a non-isolated system which together with its surroundings is originally in some given static state such that none of the components of the metrical tensor are changing with the time x_4 . Without altering the metric or the distribution of matter and radiation outside of the system, we then assume a change to take place in the distribution of matter and energy inside the system in such a way that the system ultimately arrives in some new possible static state. In the absence of the detailed knowledge, which would permit us to describe the exact mechanism of the internal process that takes place, we now inquire into the restrictions which the energy-momentum principle, as applied to the system as a whole, would impose on the changes in the form of line element inside the system which could accompany such a process.

The first condition on the possible changes in the line element is imposed by the hypothesis that the metric and the distribution of matter and radiation outside the system are not to be changed by the process, this hypothesis being introduced since our interest will lie in those changes which could take place solely within the system without affecting anything in the outside surroundings. As an immediate result of the assumption that the metric is not to be changed outside of the system, it is at once evident that the process must produce no change in the values at the boundary of the components $g_{\mu\nu}$ of the metrical tensor and their first differential coefficients $\partial g_{\mu\nu}/\partial x_\alpha$. And as a result of the assumption that the distribution of matter and radiation is not to be changed outside of the system, it is evident that the energy-momentum tensor $T^{\mu\nu}$ will remain unchanged at the boundary since it is completely determined by the distribution of matter and radiation in accordance with the equation of definition

$$T^{\mu\nu} = \rho_0 \frac{dx_\mu}{ds} \frac{dx_\nu}{ds}. \quad (43)$$

The second condition on the possible changes in the line element is imposed by the requirement that the process taking place within the system shall agree with the energy-momentum principle as applied to the system as a whole. This condition is given by our previous equation

$$\begin{aligned} & \frac{\partial}{\partial x_4} \iiint (\mathfrak{T}_\mu^4 + t_\mu^4) dx_1 dx_2 dx_3 \\ &= - \iint \left| \mathfrak{T}_\mu^1 + t_\mu^1 \right|_{x_1}^{x_1'} dx_2 dx_3 - \iint \left| \mathfrak{T}_\mu^2 + t_\mu^2 \right|_{x_2}^{x_2'} dx_1 dx_3 - \iint \left| \mathfrak{T}_\mu^3 + t_\mu^3 \right|_{x_3}^{x_3'} dx_1 dx_2. \end{aligned} \quad (44)$$

To apply this equation, we note that at the start of the process when the system is in its original static state, the left hand side of the equation is obviously equal to zero since none of the quantities involved can be changing with the time. Thus at the start of the process the values at the boundary of the quantities $\mathfrak{T}_\mu^1 \cdots t_\mu^3$ must be such as to make the right hand side also equal to zero. The quantities \mathfrak{T}_μ^1 , \mathfrak{T}_μ^2 and \mathfrak{T}_μ^3 , however, are determined by the $g_{\mu\nu}$ and $T^{\mu\nu}$ and the quantities t_μ^1 , t_μ^2 and t_μ^3 by the $g_{\mu\nu}$ and $\partial g_{\mu\nu}/\partial x_\alpha$, and hence in accordance with the last paragraph the values which they assume at the boundary will not change during the process. The result is that both sides of equation (44) remain equal to zero throughout the process, and the condition imposed by the energy-momentum principle reduces to the requirement of constant energy and components of momentum for the system as given by the equation

$$\iiint (\mathfrak{T}_\mu^4 + t_\mu^4) dx_1 dx_2 dx_3 = \text{const.} \quad (45)$$

To investigate the effect of this condition on the possible changes in line element which could occur, we shall now reexpress the integrand by substituting for it the expression given by equation (7) in §3. We thus obtain

$$\iiint \frac{\partial}{\partial x_\gamma} \left(-g^{\alpha 4} \frac{\partial \mathfrak{L}}{\partial g^{\mu\alpha}} + \frac{1}{2} g_\mu^4 g^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g^{\alpha\beta}} \right) dx_1 dx_2 dx_3 = \text{const.} \quad (46)$$

In this equation, however, the suffix γ is a dummy and the term with $\gamma=4$ will be zero at the beginning and end of our process, since by hypothesis the system is at these times a static one and the rate of change of all quantities with respect to the time x_4 is zero. Hence, writing the summation out in full and performing the possible integrations with respect to x_1 , x_2 and x_3 which are indicated, we can now express the condition imposed on the form of the line element by stating that for the static states at the beginning and end of the process we must have the relation

$$\begin{aligned} & \iint \left| -g^{\alpha 4} \frac{\partial \mathfrak{L}}{\partial g^{\mu\alpha}} + \frac{1}{2} g_\mu^4 g^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g^{\alpha\beta}} \right|_{x_1}^{x_1'} dx_2 dx_3 \\ &+ \iint \left| -g^{\alpha 4} \frac{\partial \mathfrak{L}}{\partial g^{\mu\alpha}} + \frac{1}{2} g_\mu^4 g^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g^{\alpha\beta}} \right|_{x_2}^{x_2'} dx_1 dx_3 \\ &+ \iint \left| -g^{\alpha 4} \frac{\partial \mathfrak{L}}{\partial g^{\mu\alpha}} + \frac{1}{2} g_\mu^4 g^{\alpha\beta} \frac{\partial \mathfrak{L}}{\partial g^{\alpha\beta}} \right|_{x_3}^{x_3'} dx_1 dx_2 = \text{const.} \end{aligned} \quad (47)$$

where the limits of integration x_1, x_1' etc. lie on the boundary of the system. The quantities occurring in the integrands of this equation, however, are completely determined by the values of the components $g_{\mu\nu}$ of the metrical tensor and their first differential coefficients, as can be verified from equations already given in this article. Hence the condition imposed by the energy-momentum principle has already been met by our previous requirement necessary to preserve the metric outside that the values at the boundary for the $g_{\mu\nu}$ and their first differential coefficients should not be changed by the process.

Hence, noting the restriction given in §9 as to the kind of coordinate systems that we employ, we can now state the following otherwise general conclusion. Let us start with a non-isolated system, which together with its surroundings is originally in some given static state, and consider that some process then takes place which leaves the metric and the distribution of matter and radiation outside the system unaltered but changes the matter and radiation inside the system in such a way that we finally arrive in some new static state. Assuming no detailed knowledge as to the nature of the internal process that has occurred, but applying the energy-momentum principle to the system as a whole, we then find that the requirements imposed by the energy-momentum principle on the possible changes in line element within the system are to be met by the condition that the components $g_{\mu\nu}$ of the metrical tensor and their first differential coefficients $\partial g_{\mu\nu}/\partial x_a$ are to retain their values unaltered at the boundary.²⁵

§11. CONCLUSION

This concludes the material which it was desired to present in the present article. It is hoped that the general coherence of the treatment and the specific satisfactory result, as to the inclusion of the ordinary Newtonian expression for potential gravitational energy in the case of a fluid sphere in a weak gravitational field, will increase the confidence with which the energy principle is used in general relativity.

Some apology should perhaps be offered for the great length of the two preceding sections on the application of the energy principle to the changes that may take place within a limited region which forms part of a larger system. There are, however, a number of points connected with the development which have seemed puzzling enough to warrant a detailed exposition and the final conclusion is one of considerable usefulness.

It should perhaps also be remarked that we have not treated in the foregoing any questions which involve the energy of the closed universe as a whole since these deserve separate consideration.²⁶

²⁵ In connection with the formulation of this section, I have been greatly helped by discussions with my colleague Dr. J. Robert Oppenheimer, for which I wish to thank him, also in this place.

ON THE USE OF THE ENTROPY PRINCIPLE
IN GENERAL RELATIVITY

BY RICHARD C. TOLMAN

NORMAN BRIDGE LABORATORY, CALIFORNIA INSTITUTE OF TECHNOLOGY, PASADENA

(Received December 30, 1929)

ABSTRACT

The main purpose of this article is to use the extension of thermodynamics to general relativity, previously proposed by the author, to obtain expressions which will give the criteria for the thermodynamic equilibrium of a static gravitating system in a readily applicable mathematical form. After restating the principle chosen by the author as the general relativity analogue of the second law of thermodynamics, and showing once more that it is a natural covariant generalization of the ordinary second law of thermodynamics, the principle is then applied to finite systems in general and to adiabatic systems having no flux of matter or heat at the boundary. The mathematical conditions for thermodynamic equilibrium are then obtained for the case of any finite static system, and a specially useful form for these conditions is obtained for the case that the system has spherical symmetry.

§1. INTRODUCTION

IN SEVERAL previous articles, I have attempted an extension of thermodynamics to general relativity¹ and have tried to make certain applications of this extension.² The main purpose of the present article is to prepare for certain further applications which I propose to make.

The postulate, which must be taken in work of this kind as the general relativity analogue of the ordinary first law of thermodynamics, is evidently Einstein's generalized energy-momentum principle, which reduces in flat space-time to the ordinary laws of the conservation of energy and momentum, and is a principle which certainly must not be violated by any thermodynamic changes which may take place. The use of this principle has already been discussed in some detail in the preceding article in this journal,³ and, those conclusions drawn from it, which will be necessary for the present considerations.

The postulate which was chosen as the general relativity analogue of the second law of thermodynamics was a new one, which was justified, so far as may be, by showing it to be a natural covariant generalization of the ordinary second law of thermodynamics in flat space-time. In the present article we shall be especially interested in the method of applying this principle to determine the equilibrium conditions for a finite system in a static state.

⁴ See reference (3) last paragraph of §10.

In the immediately following section, §2, we shall again state the postulate chosen as the general relativity analogue of the second law of thermodynamics in the form which it assumes for an infinitesimal region, and show again by way of review that it is a natural covariant generalization of the ordinary second law of thermodynamics valid in flat space-time. In §3, we shall obtain by integration the form taken by the principle in the case of a finite system in general, and then more especially in the case of an adiabatic system having no flux of matter or heat at the boundary. Following this we shall consider, in §4, the conditions for thermodynamic equilibrium in the case of a finite static system, and finally, in §5, we shall consider a specific form in which these conditions for equilibrium can be put in case the system under consideration has spherical symmetry.

§2. THE GENERALIZED SECOND LAW OF THERMODYNAMICS

To state the postulate which was taken as the general relativity analogue of the second law of thermodynamics, we shall first define the *entropy vector* at a given point in space-time, by the equation

$$S^\mu = \phi_0 \frac{dx_\mu}{ds} \quad (1)$$

where ϕ_0 is the *proper density of entropy* at the point in question as measured by a local observer, and dx_μ/ds is the *macroscopic velocity* of matter at that point. Corresponding to this vector, we also have the *entropy vector density* given by the equation

$$\mathfrak{S}^\mu = S^\mu \sqrt{-g} = \phi_0 \sqrt{-g} \frac{dx_\mu}{ds} \quad (2)$$

The second law postulate can then be stated in the form

$$\frac{\partial \mathfrak{S}^\mu}{\partial x_\mu} dx_1 dx_2 dx_3 dx_4 \geq \frac{dQ_0}{T_0} \quad (3)$$

where dQ_0 is the *heat measured in proper coordinates* flowing through the boundary into the infinitesimal region and during the infinitesimal time denoted by $dx_1 dx_2 dx_3 dx_4$, and T_0 is the *proper temperature* at the boundary.

To show that expression (3) is covariant, we rewrite it by a well-known transformation in the form

$$(S^\mu)_\mu \sqrt{-g} dx_1 dx_2 dx_3 dx_4 \geq \frac{dQ_0}{T_0} \quad (4)$$

The quantity $(S^\mu)_\mu$, however, is the contracted covariant derivative of S^μ and is known to be an invariant, while $\sqrt{-g} dx_1 dx_2 dx_3 dx_4$ and dQ_0/T_0 are also obviously invariants so that both sides of expression (4) are tensors of rank zero, and the requirement of covariance is met in the simplest possible way.

To show that expression (3) reduces to the ordinary requirements of the second law in the limiting case of flat space-time, we first rewrite it with the help of (2) in the form

$$\frac{\partial}{\partial x_\mu} \left(\phi_0 \sqrt{-g} \frac{dx_\mu}{ds} \right) dx_1 dx_2 dx_3 dx_4 \geq \frac{dQ_0}{T_0}. \quad (5)$$

In flat space-time, however, using Galilean coordinates x, y, z and t , we shall have $\sqrt{-g}=1$, and writing out the indicated summation in full, we obtain with some rearrangement in the order of terms

$$\begin{aligned} \frac{\partial}{\partial t} \left(\phi_0 \frac{dt}{ds} \right) dx dy dz dt \\ \geq - \left[\frac{\partial}{\partial x} \left(\phi_0 \frac{dx}{ds} \right) + \frac{\partial}{\partial y} \left(\phi_0 \frac{dy}{ds} \right) + \frac{\partial}{\partial z} \left(\phi_0 \frac{dz}{ds} \right) \right] dx dy dz dt + \frac{dQ_0}{T_0} \end{aligned}$$

and this can evidently be rewritten as

$$\begin{aligned} \frac{\partial}{\partial t} \left(\phi_0 \frac{dt}{ds} \right) dx dy dz dt \\ \geq \left[\frac{\partial}{\partial x} \left(\phi_0 \frac{dt}{ds} \frac{dx}{dt} \right) + \frac{\partial}{\partial y} \left(\phi_0 \frac{dt}{ds} \frac{dy}{dt} \right) + \frac{\partial}{\partial z} \left(\phi_0 \frac{dt}{ds} \frac{dz}{dt} \right) \right] dx dy dz dt + \frac{dQ_0}{T_0}. \quad (6) \end{aligned}$$

In accordance, however, with the special theory of relativity, valid in flat space-time, entropy is an invariant for the Lorentz transformation, so that entropy density will be affected by the Lorentz-Fitzgerald factor of contraction ds/dt in such a way that we can make the substitution

$$\phi = \phi_0 \frac{dt}{ds} \quad (7)$$

where ϕ is the density of entropy in the particular set of Galilean coordinates that are being used. Furthermore, since heat and temperature have the same transformation factors on the basis of the special theory, we may also substitute

$$\frac{dQ}{T} = \frac{dQ_0}{T_0}. \quad (8)$$

Hence, using u, v, w to denote the components of ordinary velocity dx/dt etc. we can finally rewrite expression (6) in the form

$$\frac{\partial \phi}{\partial t} dx dy dz dt \geq - \left[\frac{\partial}{\partial x} (\phi u) + \frac{\partial}{\partial y} (\phi v) + \frac{\partial}{\partial z} (\phi w) \right] dx dy dz dt + \frac{dQ}{T}. \quad (9)$$

This expression, however, evidently states the essence of the ordinary second law of thermodynamics, since it requires that the actual increase of entropy occurring in the time dt in the infinitesimal volume $dx dy dz$ cannot be less

than the total entropy brought in from the outside by the flux of matter and the flow of heat.

Our postulate as to the general relativity analogue of the second law has thus been justified both by the fact of its expression in covariant form and by its reduction in the limiting case of flat space-time to the ordinary second law of thermodynamics. The justification, thus presented, is of course in no sense a complete proof of the validity of the postulate taken. Covariance and agreement with the form of the second law valid in the special theory of relativity are necessary but not sufficient requirements for determining the new form of the second law. The new postulate must be regarded as a real generalization containing an element not present in the special theory of relativity, and the ultimate complete justification of the postulate must be dependent on the agreement between the conclusions that can be drawn from it and actual experimental or observational facts.

§3. APPLICATION OF THE ENTROPY PRINCIPLE TO FINITE SYSTEMS

To apply the new principle to the changes taking place in a finite system, let us start with the principle in the form given by expression (5), and taking x_1 , x_2 and x_3 as being the space-like coordinates, integrate over the spatial region of interest. If we carry out such an integration, using coordinates such that the limits of integration necessary to include the whole system fall on the actual boundary which separates the system from its surroundings, it is evident that the summation of dQ_0/T_0 over the interior of the system will cancel out, since any heat entering a given element of volume is abstracted from neighboring elements, so that we shall only have to consider the heat entering the system from its surroundings. Hence dividing equation (5) through by dx_4 , writing out the indicated summation, and performing the suggested integration, we obtain with some rearrangement in the order of terms

$$\begin{aligned} \frac{\partial}{\partial x_4} \iiint \left(\phi_0 \sqrt{-g} \frac{dx_4}{ds} \right) dx_1 dx_2 dx_3 \\ \cong - \iiint \left[\frac{\partial}{\partial x_1} \left(\phi_0 \sqrt{-g} \frac{dx_1}{ds} \right) + \frac{\partial}{\partial x_2} \left(\phi_0 \sqrt{-g} \frac{dx_2}{ds} \right) \right. \\ \left. + \frac{\partial}{\partial x_3} \left(\phi_0 \sqrt{-g} \frac{dx_3}{ds} \right) \right] dx_1 dx_2 dx_3 + \sum \left(\frac{1}{T_0} \frac{dQ_0}{dx_4} \right)_{\text{Boundary}}. \end{aligned}$$

The last term on the right hand side of this expression is the total value taken over the boundary of the system of the quantity $(1/T_0) (dQ_0/dx_4)$, and by performing the indicated integrations the other terms on this side of the expression can also be seen to depend solely on quantities whose values are determined by conditions at the boundary, provided we continue to use, as suggested above, a set of coordinates so chosen that the limits of integration necessary to include the whole of the system actually lie on the boundary. We obtain

$$\begin{aligned}
\frac{\partial}{\partial x_4} \iiint \left(\phi_0 \sqrt{-g} \frac{dx_4}{ds} \right) dx_1 dx_2 dx_3 \geq & \int \int \left| \phi_0 \sqrt{-g} \frac{dx_1}{ds} \right|_{x_1}^{x_1'} dx_2 dx_3 \\
& - \int \int \left| \phi_0 \sqrt{-g} \frac{dx_2}{ds} \right|_{x_2}^{x_2'} dx_1 dx_3 - \int \int \left| \phi_0 \sqrt{-g} \frac{dx_3}{ds} \right|_{x_3}^{x_3'} dx_1 dx_2 \\
& + \sum \left(\frac{1}{T_0} \frac{dQ_0}{dx_4} \right)_{\text{Boundary}}
\end{aligned} \tag{10}$$

where the limits of integration at the boundary of the system are denoted by x_1, x_1' etc.

This expression (10) may be regarded as a general statement of the second law of thermodynamics as applied to finite systems, and defining the entropy of the system by the equation

$$S = \iiint \left(\phi_0 \sqrt{-g} \frac{dx_4}{ds} \right) dx_1 dx_2 dx_3 \tag{11}$$

the expression can be interpreted as giving the relation which must hold between the rate at which the entropy of a finite system is changing with the "time" x_4 , and those conditions existing at the boundary which determine the flux of matter and the flow of heat.

For the case of an adiabatic system with no flow of heat through the boundary, and in addition with the quantities dx_1/ds , dx_2/ds and dx_3/ds equal to zero at the boundary, so that there is no flux of matter between the system and its surroundings, expression (10) reduces to

$$\frac{\partial}{\partial x_4} \iiint \left(\phi_0 \sqrt{-g} \frac{dx_4}{ds} \right) dx_1 dx_2 dx_3 \geq 0. \tag{12}$$

In accordance with this expression, the entropy of an adiabatic system of the kind described can only increase or remain constant with increases in the time x_4 .

§4. THERMODYNAMIC EQUILIBRIUM IN A STATIC SYSTEM

We shall now investigate the conditions for thermodynamic equilibrium in a static system. To do this we must examine the changes which could take place from one static state to another without violating either the energy-momentum principle or the entropy principle as applied to the system as a whole.

Consider a system which together with its surroundings is originally in some given static state, such that none of the components $g_{\mu\nu}$ of the metrical tensor are changing with the time, and furthermore such that there is no flow of heat nor macroscopic flux of matter or radiation at any point. Without alteration in the metric or the distribution of matter and radiation outside of the system we then assume some change to take place in the distribution of matter and radiation inside the boundary in such a way that the system ultimately arrives in some new possible static state. Assuming no detailed

knowledge of the exact nature of the internal process which occurs, we now inquire into the restrictions which the energy-momentum principle and the entropy principle applied to the system as a whole would impose on the change in state.

In accordance with a conclusion obtained in my previous article on the energy-momentum principle,⁴ the restrictions imposed by this principle on the possible changes in line element within the system are to be met by the condition that the components $g_{\mu\nu}$ of the metrical tensor and their first differential coefficients $\partial g_{\mu\nu}/\partial x_\alpha$ are to retain their values unaltered at the boundary. These restrictions, coming from considerations of the energy-momentum principle, must be applied as part of the thermodynamic criteria for determining the possible changes in state.

Turning now to the entropy principle, we note that the process under consideration has been so chosen that the change is an adiabatic one of the kind described in the preceding section, since by hypothesis the flow of heat and macroscopic flux of matter are everywhere zero at the start and remain so at the boundary while the process is under way; hence we can at once apply expression (12) to the process. We thus obtain as the restriction imposed by the entropy principle the requirement that the entropy as defined by equation (11) shall not be decreased by the process. This restriction must be applied as giving the remaining thermodynamic criteria for determining the possible changes in state.

The considerations of the last two paragraphs immediately make it evident that the condition for the thermodynamic equilibrium of a static system, with no flow of heat or flux of matter at any point, is that the entropy of the system as given by equation (11) shall be the maximum that can be obtained without violating the boundary conditions furnished from considerations of the energy-momentum principle. Stating this conclusion more specifically by the use of the calculus of variations, we may now give as the condition of thermodynamic equilibrium in a static system of the kind described above

$$\delta \iiint \phi_0 \sqrt{-g} \frac{dx_1}{ds} dx_2 dx_3 = 0 \quad (13)$$

under the subsidiary condition holding *at the boundary of the system*

$$\delta g_{\mu\nu} = \delta \left(\frac{\partial g_{\mu\nu}}{\partial x_\alpha} \right) = 0 \quad (14)$$

where it is to be remembered that the conclusions have been derived using a system of coordinates such that the limits of integration necessary to include the whole of the system of interest fall on the actual boundary which separates the system from its surroundings.

§5. EQUILIBRIUM IN A STATIC SYSTEM HAVING SPHERICAL SYMMETRY

As just mentioned the conditions given by equations (13) and (14) have been derived using a system of coordinates such that the limits of integration

necessary to include the whole of the system fall on the actual boundary separating it from its surroundings. In the case of a system having spherical symmetry, it is possible, however, to translate these results into a system of polar coordinates, and thus put them into a more convenient form for use.

Let us take a static system of the kind discussed above, with no flow of heat nor macroscopic flux of matter or radiation at any point, and having spherical spatial symmetry, and let us initially make use of a set of coordinates x, y, z, t with the center of symmetry at the origin of the three equivalent spatial axes x, y and z . Such a set of coordinates is of the kind used in deriving the restrictions given by equations (13) and (14).

The line element for our system in these coordinates can evidently be written in the form

$$ds^2 = -e^\mu (dx^2 + dy^2 + dz^2) + e^\nu dt^2 \quad (15)$$

where the exponents μ and ν are independent of the time t , and on account of the spherical symmetry depend on the coordinates x, y and z in such a way that they are expressible as functions of $(x^2 + y^2 + z^2)^{1/2}$.

In accordance with this line element we have

$$g_{11} = g_{22} = g_{33} = -e^\mu \quad g_{44} = e^\nu$$

$$\sqrt{-g} = e^{\frac{3\mu + \nu}{2}} \quad (16)$$

and since there is no macroscopic flux of matter or radiation, we have the value zero for all the macroscopic velocities dx_μ/ds except for the case $\mu = 4$, and then have

$$\frac{dx_4}{ds} = \frac{dt}{ds} = e^{-\nu/2}. \quad (17)$$

Substituting the values given by equations (16) and (17) into equations (13) and (14) we then have as the requirement for thermodynamic equilibrium in our present coordinates

$$\delta \iiint \phi_0 e^{3\mu/2} dx dy dz = 0 \quad (18)$$

under the subsidiary condition holding at the boundary of the system

$$\delta\mu = \delta \left(\frac{\partial\mu}{\partial x_\alpha} \right) = \delta\nu = \delta \left(\frac{\partial\nu}{\partial x_\alpha} \right) = 0. \quad (19)$$

These requirements, however, can now easily be translated into polar coordinates r, θ and ϕ by setting

$$\begin{aligned} x &= r \sin \theta \cos \phi \\ y &= r \sin \theta \sin \phi \\ z &= r \cos \theta \end{aligned} \quad (20)$$

and noting that the condition of spherical symmetry makes it possible to take μ and ν as functions of r alone

$$\mu = \mu(r) \quad \nu = \nu(r). \quad (21)$$

The requirements for thermodynamic equilibrium then evidently become

$$\delta \iiint \phi_0 e^{3\mu/2} r^2 \sin \theta dr d\theta d\phi = 0 \quad (22)$$

under the subsidiary condition

$$\delta\mu = \delta\mu' = \delta\nu = \delta\nu' = 0 \quad (23)$$

where the primes indicate differentiation with respect to r , and the limitation given by (23) is to be applied at the actual boundary separating the system from its surroundings rather than at the limits of integration which must be given to the new variables in order to include the region of interest.

Finally if we take the region of interest as being a spherical shell contained between the constant radii r_1 and r_2 , we can evidently rewrite equations (22) and (23) in the form

$$\delta \left[4\pi \int_{r_1}^{r_2} \phi_0 e^{3\mu/2} r^2 dr \right] = 0 \quad (24)$$

under the subsidiary condition

$$\delta\mu = \delta\mu' = \delta\nu = \delta\nu' = 0 \quad (\text{at } r_1 \text{ and } r_2). \quad (25)$$

It is believed that this form of the conditions of equilibrium will be found an easy and useful one to employ.

ON THE WEIGHT OF HEAT AND THERMAL EQUILIBRIUM IN GENERAL RELATIVITY

BY RICHARD C. TOLMAN

NORMAN BRIDGE LABORATORY, CALIFORNIA INSTITUTE OF TECHNOLOGY,
PASADENA, CALIFORNIA

(Received December 30, 1929)

ABSTRACT

In accordance with the special theory of relativity all forms of energy, including heat, have inertia and hence in accordance with the equivalence principle also have weight. The purpose of the present article is to investigate the thermodynamic implications of the idea that heat has weight. In particular an investigation is made to see if a temperature gradient is a necessary accompaniment of thermal equilibrium in a gravitational field, in order to prevent the flow of heat from regions of higher to those of lower gravitational potential.

A preliminary non-rigorous treatment of this problem is first given by attempting to modify the classical thermodynamics only to the extent of associating with each intrinsic quantity of energy an additional amount of potential gravitational energy. In this way an expression is obtained for increase in equilibrium temperature with decrease in gravitational potential which, however, could in any case only be correct as a first approximation in a weak gravitational field. A discussion of the uncertainties and lack of rigor of this preliminary treatment is then given and the necessity pointed out for a rigorous treatment based on the principles of general relativity.

A rigorous relativistic treatment is then undertaken using the extension of thermodynamics to general relativity previously presented by the author. The system to be treated is taken as a static spherical distribution of perfect fluid which has come to gravitational and thermodynamic equilibrium. The principles of relativistic mechanics are first applied to such a system in order to obtain results needed in the later work. And it is then shown that these *mechanical* principles themselves are sufficient to determine the temperature distribution as a function of potential in the simple case of black-body radiation. The principles of relativistic thermodynamics are then applied to this same case of pure black-body radiation and the same expression for temperature as a function of potential obtained by the *thermodynamic* as by the mechanical treatment. This may be regarded as giving some measure of check on the validity of the proposed relativistic thermodynamics.

Following this, a thermodynamic treatment is given for the temperature distribution in the more general case of matter and radiation and a result found which harmonizes with that for radiation alone. A treatment is then given to the distribution of a perfect monatomic gas in a gravitational field both on the assumption that the total number of atoms must remain constant and on the assumption of the ready interconvertibility of matter and radiation. In the latter case the same dependence of concentration on temperature is obtained as was found by Stern and by the author for the case of flat space-time.

Using a system of coordinates such that the line element for the sphere of fluid takes the form

$$ds^2 = -e^u(dr^2 + r^2 d\theta^2 + r^2 \sin^2 \theta d\phi^2) + e^v dt^2$$

the general result for the relation between gravitational potential and equilibrium temperature T_0 as measured by a local observer in proper coordinates can be given by the equation

$$\frac{d \ln T_0}{dr} = - \frac{1}{2} \frac{dv}{dr}$$

This equation reduces in the case of a weak field to that obtained by the preliminary non-rigorous treatment, and gives a very small change of temperature with position in fields of ordinary intensity. The result, however, is one of great theoretical interest, since constant temperature throughout any system which has come to thermal equilibrium has hitherto been regarded as an inescapable thermodynamic conclusion. It is also not out of the question that the effect might sometime be of experimental or observational importance.

§1. INTRODUCTION

ONE of the most important results of the special theory of relativity was the relation between the total energy of a system U and its inertial mass m , given by Einstein's equation

$$U = mc^2 \quad (1)$$

where c is the velocity of light. In accordance with this equation we must ascribe the property of inertia to energy. For ordinary matter, however, we are in the possession of very exact experimental results showing a proportionality between inertia and weight, and hence the question at once arises whether we must also ascribe to energy the property of weight.

As early as 1911, in developing those ideas which finally led to the general theory of relativity, Einstein¹ considered this question, as to the weight of energy, and showed by a simple application of the equivalence hypothesis that the property of weight must indeed also be ascribed to energy if we are to maintain the postulated equivalence between behavior in a homogeneous gravitational field and behavior with reference to a set of uniformly accelerated axes. The later more complete developments of the general theory of relativity have shown that the Newtonian concept of the weight of a body as a force acting on it when placed in a gravitational field, is an idea which is only suitable for the treatment of slow-moving particles in weak gravitational fields. Nevertheless, these more complete developments of the general theory of relativity have completely confirmed the fundamental nature of the idea that weight must be ascribed to energy, since they have shown in any case that all forms of energy will be subject to the same gravitational action when placed under the same conditions in a gravitational field. Furthermore, in the case of weak enough fields and slow enough motions so that the Newtonian concepts may still be taken as approximately valid, the general theory of relativity has shown that the gravitational force F acting on any quantity of energy U will be given as would be expected by the simple equation

¹ Einstein, *Ann. d. Physik* **35**, 898 (1911).

$$F = (U/c^2)g \quad (2)$$

where g is the acceleration due to gravity.

If we accept the conclusion that energy has weight, it is evident that we must also ascribe weight to energy in the form of heat, and hence must expect to find thermodynamic consequences of the new idea. Thus considering for example cases where the Newtonian approximation is valid, we might expect the flow of heat from a place of higher to a place of lower gravitational potential to be accompanied by a decrease in potential energy, and this in turn would lead us to suspect that the condition of thermal equilibrium in a gravitational field might involve higher temperatures at the lower gravitational levels in order to prevent any thermal flow. It is the purpose of the present article to investigate the thermodynamic consequences of this idea that heat has weight, making use of principles obtained in an extension of thermodynamics to general relativity which I have already given.²

In the immediately following section, §2, we shall first consider a preliminary treatment of temperature equilibrium in the case of a system in such a weak gravitational field that we shall feel warranted in trying to apply the Newtonian concept of gravitation as a first approximation. And in §3, we shall examine the inadequacies of this preliminary treatment and show the necessity for the more rigorous treatments to follow. In §4, we shall then prepare for the rigorous general relativity treatment by applying the principles of relativistic mechanics to a spherical distribution of perfect fluid to obtain results which will be needed in the later developments. And in §5, we shall show that these purely mechanical results are alone sufficient to determine the temperature distribution in the simple case of a spherical distribution of pure radiation. In §6, we shall then briefly restate that result of the earlier extension of thermodynamics to general relativity which is necessary for our present considerations and then apply it in §7 to this same special case of pure radiation, and show that the same results are also obtained from the thermodynamic as from the purely mechanical treatment; this may be regarded as furnishing a partial confirmation of the correctness of the new system of relativistic thermodynamics. Following this, in §8, we shall use our relativistic thermodynamics to obtain a general equation for the distribution of temperature in any spherical mass of gravitating fluid, which has come to equilibrium. In §9, we shall then consider the equilibrium distribution of matter in a gravitational sphere of fluid; in particular the cases of a perfect monatomic gas, both when in equilibrium with radiation and when the total number of atoms is constant, will be treated. Finally in §10, we shall make some concluding remarks.

§2. PRELIMINARY TREATMENT OF TEMPERATURE EQUILIBRIUM IN A WEAK GRAVITATIONAL FIELD

To obtain a preliminary non-rigorous treatment of the temperature equilibrium in a weak gravitational field, we shall endeavor to apply the

² Tolman, Proc. Nat. Acad. 14, 268 (1928); *ibid.* 14, 701 (1928); This Journal, 896, *ibid.*

principles of the classical thermodynamics, modified only by assuming that the force of gravity will act on any quantity of energy U as though it had a weight, in the Newtonian sense, corresponding to its inertial mass U/c^2 . Under these circumstances a quantity of energy which has the intrinsic magnitude U , when measured at the zero of gravitational potential at a great distance from bodies producing a gravitational field, will be assumed to have associated with it the potential energy $U\Psi/c^2$ when brought to a point where the gravitational potential has the value Ψ .

Consider now an isolated sphere of material which is held together by its own gravitational attraction, but has a small enough mass so that the gravitational field is everywhere weak. In accordance with the classical thermodynamics, this system should be in equilibrium provided it has the maximum entropy S consistent with its total energy U . To determine the temperature distribution which corresponds to these conditions, let us then consider a small variation in temperature distribution, leaving unaltered, however, the amount of substance of each component in each element of volume dV . For the variation in total entropy we shall write

$$\delta S = \int \frac{\delta u}{T} dV \quad (3)$$

where T is the temperature at the point where the element of volume dV is located, δu is the change in the intrinsic energy density at that point produced by the variation in temperature, and the integration is to be taken over the whole volume of the system. On the other hand for the variation in the total energy of the system, we shall write

$$\delta U = \int \left(1 + \frac{\Psi}{c^2} \right) \delta u dV \quad (4)$$

where Ψ is the gravitational potential at the point in question.

Setting equation (3) equal to zero as the condition that the entropy be a maximum, and equation (4) equal to zero as the subsidiary condition of constant energy, and combining by the method of Lagrange, we obtain

$$\int \left[\frac{1}{T} - \lambda \left(1 + \frac{\Psi}{c^2} \right) \right] \delta u dV = 0 \quad (5)$$

where λ is a constant undetermined multiplier, and this equation can only be true for arbitrary variations δu , if we have

$$\frac{1}{T} = \lambda \left(1 + \frac{\Psi}{c^2} \right) \quad (6)$$

which is the desired expression giving the distribution of the temperature T throughout the system as a function of the gravitational potential Ψ .

Differentiating this equation with respect to the radius r , to obtain an expression for the rate of change of the temperature with distance from the center of the gravitating sphere, we have

$$-\frac{1}{T^2} \frac{dT}{dr} = \frac{\lambda}{c^2} \frac{d\Psi}{dr}$$

and substituting the expression for λ which can be obtained from (6), we obtain

$$\frac{d \ln T}{dr} = -\frac{(1/c^2)(d\Psi/dr)}{1+\Psi/c^2} = -\frac{d}{dr} \ln \left(1 + \frac{\Psi}{c^2} \right) \quad (7)$$

or since by hypothesis the field is weak enough so that Ψ/c^2 is small compared with unity we have approximately

$$\frac{d \ln T}{dr} = -\frac{1}{c^2} \frac{d\Psi}{dr} = -\frac{g}{c^2} \quad (8)$$

where g is the acceleration due to gravity.

For the case of a field of vanishing gravitational intensity with g negligible, the result degenerates into the usual condition for thermal equilibrium, $T = \text{constant}$. Furthermore, owing to the magnitude of the velocity of light the percentage change in temperature with height would be very small in fields of any ordinary intensity. Thus in a gravitational field having the strength of that at the surface of the earth we should have approximately

$$\frac{d \ln T}{dr} = -10^{-17} \text{ cm}^{-1}.$$

§3. INADEQUACY OF THE PRELIMINARY TREATMENT

The foregoing treatment contains of course many inadequacies and uncertainties, which can only be removed by a rigorous treatment of the problem from the point of view of general relativity. In the first place, in accordance with the classical thermodynamics, we have assumed maximum entropy and constant energy as the criteria of equilibrium for an isolated system, without any certain knowledge as to the form or even the validity of such principles in the presence of a gravitational field. Equation (3) for the entropy assumes it to depend on what we have called the intrinsic energy but the justification for this is by no means clear. Equation (4) for the energy, on the other hand, even if satisfactory for the case of weak gravitational fields,³ can certainly not be regarded as correct in general when we recall the great modifications in the nature of the energy principle which have to be introduced in the theory of general relativity. Furthermore, it should be noted that we have given no very clear definition of the quantities temperature T and intrinsic energy density u which occur in the equations, although we might perhaps guess that we should take the values of these quantities as measured by local observers using proper coordinates. In addition, even the interpretation of the quantity dV appears dubious when we recall the differences between pro-

³ See §8 in the article already referred to, This Journal, 888, for a satisfactory approximate treatment of the energy of a sphere of perfect fluid in a weak gravitational field.

per volume and coordinate volume which occur in the general theory of relativity.

It is hence abundantly evident that we cannot regard the results of the preceding section as having any certainty of validity, unless indeed we can show them to be an approximation in weak fields for conclusions which can be obtained from a more rigorous general relativity treatment. In what follows we shall now turn our attention to the general relativity treatment of the distribution of temperature and matter in a sphere of gravitating fluid which has come to thermodynamic equilibrium.

§4. THE RELATIVITY MECHANICS OF A SPHERICAL DISTRIBUTION OF PERFECT FLUID

As a preparation for our later work we must first consider the application of the mechanics of general relativity to a static distribution of perfect fluid having spherical symmetry. For a sufficiently general line element for such a system we may evidently write

$$ds^2 = -e^\mu (dr^2 + r^2 d\theta^2 + r^2 \sin^2 \theta d\phi^2) + e^\nu dt^2 \quad (9)$$

where the conditions that the system is to be static and spherically symmetrical are fulfilled if μ and ν can be taken as functions of r alone.

The components of the metrical tensor corresponding to this line element are evidently

$$\begin{aligned} g_{11} &= -e^\mu, & g_{22} &= -e^\mu r^2, & g_{33} &= -e^\mu r^2 \sin^2 \theta, & g_{44} &= e^\nu \\ g^{11} &= -e^{-\mu}, & g^{22} &= -\frac{e^{-\mu}}{r^2}, & g^{33} &= -\frac{e^{-\mu}}{r^2 \sin^2 \theta}, & g^{44} &= e^{-\nu} \\ g_{\rho\sigma} &= g^{\rho\sigma} = 0 \quad (\rho \neq \sigma) & \sqrt{-g} &= e^{\frac{3\mu+\nu}{2}} r^2 \sin \theta \end{aligned} \quad (10)$$

and the components of the contracted Riemann-Christoffel tensor corresponding to this metrical tensor have already been worked out and are known to have the values⁴

$$\begin{aligned} G_{11} &= \mu'' + \frac{\nu''}{2} + \frac{\mu'}{r} - \frac{\mu'\nu'}{4} + \frac{\nu'^2}{4} \\ G_{22} &= \frac{3}{2} r\mu' + \frac{r\nu'}{2} + \frac{r^2\mu''}{2} + \frac{r^2\mu'^2}{4} + \frac{r^2\mu'\nu'}{4} \\ G_{33} &= G_{22} \sin^2 \theta \\ G_{44} &= -e^{\nu-\mu} \left[\frac{\nu''}{2} + \frac{\nu'}{r} + \frac{\mu'\nu'}{4} + \frac{\nu'^2}{4} \right] \\ G_{\rho\sigma} &= 0 \quad (\rho \neq \sigma) \end{aligned} \quad (11)$$

⁴ See Eddington, "The Mathematical Theory of Relativity," Cambridge 1923. The results in question can be obtained by setting $\lambda = \mu$ in Eddington's equations (43.5).

where the primes indicate differentiation with respect to r . Raising suffixes with the help of the values of the metrical tensor (10), and substituting into the fundamental equation

$$-8\pi T_\sigma^\sigma = G_\sigma^\sigma - \frac{1}{2}g^\sigma_\sigma G \quad (12)$$

which connects the energy-momentum tensor T_σ^ρ with the metric we can then obtain, after a simple calculation, for the separate components of T_σ^ρ

$$\begin{aligned} -8\pi T_1^1 &= e^{-\mu} \left[\frac{\mu' + \nu'}{r} + \frac{\mu' \nu'}{2} + \frac{\mu'^2}{4} \right] \\ -8\pi T_2^2 &= -8\pi T_3^3 = e^{-\mu} \left[\frac{\mu'' + \nu''}{2} + \frac{\mu' + \nu'}{2r} + \frac{\nu'^2}{4} \right] \\ -8\pi T_4^4 &= e^{-\mu} \left[\mu'' + \frac{2\mu'}{r} + \frac{\mu'^2}{4} \right]. \end{aligned} \quad (13)$$

On the other hand in the case of a perfect fluid the energy tensor is known to depend on the properties of the fluid in accordance with the equation⁵

$$T_{00} = (\rho_{00} + p_0) \frac{dx_\rho}{ds} \frac{dx_\sigma}{ds} - g^{\rho\sigma} p_0 \quad (14)$$

where ρ_{00} is the proper *macroscopic* density of energy in the fluid, p_0 its proper pressure and the quantities dx_ρ/ds are *macroscopic* "velocities." Since we assume a static condition in our fluid, these "velocities" will all be zero except for the case ρ or $\sigma = 4$, and in accordance with the line element (9) will then have the value $dx_4/ds = e^{-\nu/2}$. Hence noting the values for $g^{\rho\sigma}$ given by equations (10) we obtain for the separate components of $T^{\rho\sigma}$

$$T^{11} = e^{-\mu} p_0, \quad T^{22} = \frac{e^{-\mu}}{r^2} p_0, \quad T^{33} = \frac{e^{-\mu}}{r^2 \sin^2 \theta} p_0, \quad T^{44} = e^{-\nu} \rho_{00} \quad (15)$$

or lowering suffixes with the help of the metrical tensor (10) we have

$$T_1^1 = T_2^2 = T_3^3 = -p_0 \quad T_4^4 = \rho_{00}. \quad (16)$$

Comparing these results with those given by equations (13) we can now write

$$p_0 = \frac{e^{-\mu}}{8\pi} \left[\frac{\mu' + \nu'}{r} + \frac{\mu' \nu'}{2} + \frac{\mu'^2}{4} \right] \quad (17)$$

$$p_0 = \frac{e^{-\mu}}{8\pi} \left[\frac{\mu'' + \nu''}{2} + \frac{\mu' + \nu'}{2r} + \frac{\nu'^2}{4} \right] \quad (18)$$

$$\rho_{00} = -\frac{e^{-\mu}}{8\pi} \left[\mu'' + \frac{2\mu'}{r} + \frac{\mu'^2}{4} \right] \quad (19)$$

⁵ See Eddington, reference 4, equations (54.81) and (54.82).

as expressions connecting the proper pressure p_0 and proper macroscopic density ρ_{00} with the metric. The reason that we obtain two separate expressions (17) and (18) connecting the pressure with the metric lies in the fact that the line element (9) with which we have started is sufficiently general to apply to any static distribution having spherical symmetry, while our later assumption of a perfect fluid involves at each point of the fluid an equality between the stresses in the radial and tangential directions.

Adding equations (17), (19), and (18) taken twice we obtain

$$(\rho_{00} + 3p_0) = \frac{e^{-\mu}}{8\pi} \left(v'' + \frac{2v'}{r} + \frac{\mu'v'}{2} + \frac{v'^2}{2} \right)$$

and this can be rewritten in a form which will later prove useful

$$8\pi(\rho_{00} + 3p_0)e^{\frac{3\mu+\nu}{2}}r^2 = e^{\frac{\mu+\nu}{2}} \left(v'' + \frac{2v'}{r} + \frac{\mu'v'}{2} + \frac{v'^2}{2} \right) r^2 = \frac{d}{dr} (e^{\frac{\mu+\nu}{2}} v' r^2). \quad (20)$$

We are now ready to apply the principles of mechanics to our system, in accordance with the fundamental equation of relativity mechanics which can be written in the form.⁶

$$\frac{\partial \mathfrak{T}_\sigma^\rho}{\partial x_\rho} - \frac{1}{2} \mathfrak{T}^{\alpha\beta} \frac{\partial g_{\alpha\beta}}{\partial x_\sigma} = 0 \quad (21)$$

Considering first the case $\sigma = 1$, substituting values for the tensor *densities* of energy and momentum obtained from (15) and (16) through multiplication by $\sqrt{-g}$, and substituting for $g_{\alpha\beta}$ from (10), we can write

$$\begin{aligned} \frac{\partial}{\partial r} (-p_0 \sqrt{-g}) - \frac{1}{2} (e^{-\mu} p_0 \sqrt{-g}) \frac{\partial}{\partial r} (-e^\mu) - \frac{1}{2} \left(\frac{e^{-\mu}}{r^2} p_0 \sqrt{-g} \right) \frac{\partial}{\partial r} (-e^\mu r^2) \\ - \frac{1}{2} \left(\frac{e^{-\mu}}{r^2 \sin^2 \theta} p_0 \sqrt{-g} \right) \frac{\partial}{\partial r} (-e^\mu r^2 \sin^2 \theta) - \frac{1}{2} (e^{-\nu} \rho_{00} \sqrt{-g}) \frac{\partial}{\partial r} (e^\nu) = 0 \end{aligned}$$

and substituting the value $\sqrt{-g} = r^2 \sin \theta e^{\frac{3\mu+\nu}{2}}$ given in (10), this is easily found to reduce to the form

$$\frac{\partial p_0}{\partial r} = -\frac{\rho_{00} + p_0}{2} \frac{\partial \nu}{\partial r} \quad (22)$$

which furnishes us with a very simple and useful expression for the change in pressure with radius. The equation may be regarded as the general relativity analogue of the Newtonian equation

$$\frac{dp}{dr} = -\rho \frac{d\Psi}{dr}$$

where ρ is now expressed in terms of mass per unit volume, and indeed can be shown to reduce to this in case the gravitational field is weak and the sys-

⁶ See Eddington, reference 4, equation (55.6).

tem consists of ordinary matter with the pressure p_0 negligible compared with the density ρ_{00} .

It is also of interest to note that equation (22) can alternatively be derived by combining equations (17), (18) and (19), without the use of the mechanical principle given by equation (21). The mechanical principle and the equality of the two different expressions for pressure thus imply the same restrictions on the pressure distribution within the sphere.

Returning now to the mechanical equation (21) and considering the cases $\sigma=2$ and $\sigma=3$, it is easy to show by a similar method to the one just used that we obtain the results

$$\frac{\partial p_0}{\partial \theta} = \frac{\partial p_0}{\partial \phi} = 0 \quad (23)$$

as was to be expected.

Finally, considering the case $\sigma=4$, we obtain by substitution into (21)

$$\frac{\partial}{\partial t}(\rho_{00} \sqrt{-g}) - \frac{1}{2} \mathfrak{T}^{\alpha\beta} \frac{\partial g_{\alpha\beta}}{\partial t} = 0$$

and since by our hypothesis of a static system the $g_{\alpha\beta}$ are independent of the time t , we have the result

$$\frac{\partial \rho_{00}}{\partial t} = 0 \quad (24)$$

the proper density remaining constant with time at each point in the distribution, in complete agreement with our original assumption of a static system

§5. MECHANICAL TREATMENT OF TEMPERATURE DISTRIBUTION IN THE CASE OF RADIATION

In the case of a spherical distribution of pure black-body radiation such as might surround a gravitating sphere of denser matter, relativistic mechanics without a resort to relativistic thermodynamics will be sufficient to determine the temperature distribution. This arises because of the simple relations in the case of black-body radiation directly connecting the thermodynamic quantity temperature with the mechanical quantities energy density and pressure.

For the energy density and pressure of black-body radiation we can evidently write in accordance with well known equations

$$\rho_{00} = aT_0^4 \quad (25)$$

and

$$p_0 = \frac{1}{3} aT_0^4 \quad (26)$$

where a is the Stefan-Boltzmann constant and T_0 is the *proper* temperature, as measured by a local observer, located at a point where ρ_{00} and p_0 are the proper macroscopic energy density and proper pressure of the radiation.

Substituting these expressions into our mechanical equation (22), we at once obtain as exact relativistic expressions for the temperature distribution within a field of radiation

$$\frac{d \ln T_0}{dr} = -\frac{1}{2} \frac{d\nu}{dr} \quad (27)$$

or

$$T_0 = C e^{-\nu/2} \quad (28)$$

where C is a constant of integration. Furthermore, in the case of weak enough fields so that the Newtonian theory of gravitation is a sufficient approximation, equation (27) can be shown to reduce to

$$\frac{d \ln T_0}{dr} = -\frac{1}{c^2} \frac{d\Psi}{dr} = -\frac{g}{c^2} \quad (29)$$

in agreement with equation (8) obtained by our preliminary treatment. The qualitative nature of this result is entirely reasonable since it is evident that the pressure of radiation must increase as we go to lower gravitational levels in order to support the increasing amount of the radiation above, and in the case of pure radiation such an increase in pressure can only be the result of an increase in temperature.

It is a matter of great interest that we have thus been able to determine, by a straightforward application of relativity mechanics without any resort to the new relativistic thermodynamics, the effect of gravity on temperature distribution in the particular case of a field of pure radiation. We have thus obtained in a rather unimpeachable manner a justification in at least one case for our original general idea, as expressed in §1, that the condition of thermodynamic equilibrium under the action of gravitation would involve higher temperatures at lower gravitational levels in order to prevent the downward flow of heat, and shall be ready to expect similar effects of gravitational action on temperature in more complicated cases whose solution will involve our new system of relativistic thermodynamics.

§6. THE THERMODYNAMIC CONDITIONS FOR EQUILIBRIUM

To prepare for our thermodynamic treatment, we may now restate the conditions for equilibrium in a static system obtained in the previous development of relativistic thermodynamics.⁷ Using the polar coordinates adopted in §4 of this article, these conditions took the form that the general relativity expression for the entropy of the system lying within the spherical shell between the constant radii r_1 to r_2 should be a maximum in accordance with the variational equation

$$\delta \left[4\pi \int_{r_1}^{r_2} \phi_0 e^{3\nu/2} r^2 dr \right] = 0 \quad (30)$$

under the subsidiary condition coming from consideration of the energy-momentum principle

⁷ See in particular §5 in the article in *This Journal*.

$$\delta\mu = \delta\mu' = \delta\nu = \delta\nu' = 0 \quad (\text{at } r_1 \text{ and } r_2) \quad (31)$$

where μ and ν are the exponents occurring in our expression for the line element, and the quantity ϕ_0 occurring in equation (30) is the proper density of entropy.

§7. THERMODYNAMIC TREATMENT OF TEMPERATURE DISTRIBUTION IN THE CASE OF RADIATION

Let us now make use of the thermodynamic method to obtain a treatment of temperature distribution in the case of radiation. To do this we can re-express the entropy density ϕ_0 occurring in equation (30) in terms of energy density ρ_{00} , and by means of our previous relation connecting energy density with the metric can obtain the condition for maximum entropy in a form in which it depends explicitly on the metrical variable μ and its differential coefficients. The variation indicated in equation (30) can then be performed and the subsidiary conditions imposed by equation (31) on the variable μ easily introduced.

For the proper density of entropy ϕ_0 in terms of the proper temperature T_0 we can evidently write in accordance with the well known properties of black-body radiation

$$\phi_0 = \frac{4}{3} a T_0^3 \quad (32)$$

where a is the Stefan-Boltzmann constant. Combining this with equation (25), connecting the energy density with temperature, we obtain

$$\phi_0 = \frac{4}{3} a^{1/4} \rho_{00}^{3/4} \quad (33)$$

and using equation (19) which connects the energy density with the metric we can write

$$\phi_0 = -\frac{4a^{1/4}}{24\pi} e^{-3\mu/4} \left[\mu'' + \frac{2\mu'}{r} + \frac{\mu'^2}{4} \right]^{3/4}. \quad (34)$$

Substituting this into equation (30) and dividing out the constant factors, we finally obtain as the condition of maximum entropy in terms of the metrical variable μ

$$\delta \int_{r_1}^{r_2} \left(\mu'' + \frac{2\mu'}{r} + \frac{\mu'^2}{4} \right)^{3/4} e^{3\mu/4} r^2 dr = 0 \quad (35)$$

under the condition

$$\delta\mu = \delta\mu' = 0 \quad (\text{at } r_1 \text{ and } r_2). \quad (36)$$

Performing the variation indicated in equation (35) we obtain

$$\begin{aligned} \int_{r_1}^{r_2} \left[\frac{3}{4} \left(\mu'' + \frac{2\mu'}{r} + \frac{\mu'^2}{4} \right)^{-1/4} \left(\delta\mu'' + \frac{2}{r} \delta\mu' + \frac{\mu'}{2} \delta\mu' \right) e^{3\mu/4} \right. \\ \left. + \frac{3}{4} \left(\mu'' + \frac{2\mu'}{r} + \frac{\mu'^2}{4} \right)^{3/4} e^{3\mu/4} \delta\mu \right] r^2 dr = 0 \quad (37) \end{aligned}$$

and resubstituting the expression for energy density given by equation (19) this can be rewritten in the simpler form

$$\int_{r_1}^{r_2} \left[\frac{e^{(\mu/2)} r^2}{\rho_{00}^{1/4}} \left(\delta\mu'' + \frac{2}{r} \delta\mu' + \frac{\mu'}{2} \delta\mu' \right) - 8\pi \rho_{00}^{3/4} e^{3\mu/2} r^2 \delta\mu \right] dr = 0$$

Noting, however, in accordance with equation (36) that $\delta\mu'$ and $\delta\mu$ are equal to zero at the limits r_1 and r_2 this can evidently be transformed in the usual manner with the help of partial integrations, dropping terms that become zero at the limits, to the following form containing $\delta\mu$ alone.

$$\int_{r_1}^{r_2} \left[\frac{d^2}{dr^2} \left(\frac{e^{\mu/2} r^2}{\rho_{00}^{1/4}} \right) - 2 \frac{d}{dr} \left(\frac{e^{\mu/2} r}{\rho_{00}^{1/4}} \right) - \frac{d}{dr} \left(\frac{e^{\mu/2} r^2}{\rho_{00}^{1/4}} \frac{\mu'}{2} \right) - 8\pi \rho_{00}^{3/4} e^{3\mu/2} r^2 \right] \delta\mu dr = 0. \quad (38)$$

This equation, however, can be true for arbitrary variations $\delta\mu$ only if the quantity in the square brackets is equal to zero, and this can evidently be rewritten to give us

$$\frac{d}{dr} \left\{ e^{\mu/2} r^2 \frac{d}{dr} \left(\frac{1}{\rho_{00}^{1/4}} \right) \right\} = 8\pi \rho_{00}^{3/4} e^{3\mu/2} r^2. \quad (39)$$

And substituting the relation between energy density ρ_{00} and temperature T_0 given by equation (25), this becomes

$$\frac{d}{dr} \left\{ e^{\mu/2} r^2 \frac{d}{dr} \left(\frac{1}{T_0} \right) \right\} = 8\pi \frac{\rho_{00}}{T_0} e^{3\mu/2} r^2. \quad (40)$$

To solve this equation for T_0 as a function of r , we note that in the case of radiation we have $8\pi\rho_{00}=4\pi(\rho_{00}+3p_0)$ and substituting equation (20) we can then rewrite (40) in the form

$$\frac{d}{dr} \left\{ e^{\mu/2} r^2 \frac{d}{dr} \left(\frac{1}{T_0} \right) \right\} = \frac{e^{-\nu/2}}{T_0} \frac{d}{dr} \left\{ e^{\mu/2} r^2 \frac{d}{dr} (e^{\nu/2}) \right\}$$

or

$$\left(\frac{1}{T_0} \right)^{-1} \frac{d}{dr} \left\{ e^{\mu/2} r^2 \frac{d}{dr} \left(\frac{1}{T_0} \right) \right\} = (e^{\nu/2})^{-1} \frac{d}{dr} \left\{ e^{\mu/2} r^2 \frac{d}{dr} (e^{\nu/2}) \right\}. \quad (41)$$

Postponing a more general discussion of the solution of this equation until the next section, §8, where the equation again occurs, we note at once that a particular solution of the equation is given by

$$T_0 = C e^{-\nu/2} \quad (42)$$

where C is a constant of integration and this equation for the temperature distribution in a field of radiation which has come to equilibrium under the action of gravity is exactly the same as equation (28) which we obtained in §5. Hence in this simple case of radiation, where a mechanical treatment can be given, the thermodynamic and the mechanical treatment of temperature

distribution under the action of gravity lead to the same result. This can be regarded as some confirmation of the validity of the system of relativistic thermodynamics which I have proposed.

§8. TEMPERATURE DISTRIBUTION IN THE GENERAL CASE OF ANY PERFECT FLUID

Let us now consider the application of our condition for a maximum of the relativistic expression for entropy

$$\delta \left[4\pi \int_{r_1}^{r_2} \phi_0 e^{3\mu/2} r^2 dr \right] = 0 \quad (43)$$

to a determination of the temperature distribution in the general case of any perfect fluid. To apply this equation it will be convenient to note that $4\pi e^{3\mu/2} r^2 dr$ is evidently the *proper* spatial volume lying in the spherical shell between r and $r+dr$. This can be seen from the general relation for the element of proper spatial volume

$$dV_0 ds = \sqrt{-g} dx_1 dx_2 dx_3 dx_4$$

which, in the case of our system and line element (9), gives

$$dV_0 = e^{\frac{3\mu+\nu}{2}} r^2 \sin \theta dr d\theta d\phi \frac{dt}{ds} = e^{3\mu/2} r^2 \sin \theta dr d\theta d\phi.$$

And if we integrate this over all values of θ and ϕ , we obtain

$$V_0 = 4\pi e^{3\mu/2} r^2 dr \quad (44)$$

for the proper spatial volume lying between r and $r+dr$, where V_0 is of course an infinitesimal quantity.

Under these circumstances, since ϕ_0 is the proper density of entropy, we may evidently write

$$S_0 = 4\pi \phi_0 e^{3\mu/2} r^2 dr \quad (45)$$

as an expression for the entropy, as measured in proper coordinates, associated with the material lying between r and $r+dr$. As this quantity of entropy is measured in proper coordinates, it will evidently obey the classical laws of thermodynamics and may be taken as a function of temperature T_0 , volume V_0 and number of molecules $N_1, N_2 \dots N_n$ of the n different components which are necessary to specify the composition, in the way ordinarily employed in thermodynamics.

We are now ready to investigate the temperature distribution in our fluid. To do this let us consider the effect of a variation in the temperature T_0 and volume V_0 associated with the shell r to $r+dr$, keeping the composition of the material in this shell unaltered, that is holding $N_1 \dots N_n$ constant. Under these conditions, we shall have in accordance with the principles of ordinary thermodynamics

$$\delta S_0 = \frac{\delta U_0}{T_0} + \frac{p_0}{T_0} \delta V_0 \quad (46)$$

and in accordance with equations (44) and (45) this can evidently be written in the form

$$\delta(4\pi \phi_0 e^{3\mu/2} r^2 dr) = \frac{\delta(4\pi \rho_{00} e^{3\mu/2} r^2 dr)}{T_0} + \frac{p_0}{T_0} \delta(4\pi e^{3\mu/2} r^2 dr). \quad (47)$$

Substituting this in equation (43) for the maximum of the relativistic expression for entropy we now obtain

$$4\pi \int_{r_1}^{r_2} \left[\frac{\delta(\rho_{00} e^{3\mu/2})}{T_0} + \frac{p_0}{T_0} \delta(e^{3\mu/2}) \right] r^2 dr = 0 \quad (48)$$

which gives the condition for a maximum of the relativistic entropy in a form which can be made to depend solely on the variation of the metrical variable μ and its derivatives, by substituting for the energy density ρ_{00} its values as given by equation (19). Doing so we obtain

$$\int_{r_1}^{r_2} \left[-\frac{1}{2T_0} \delta \left\{ e^{\mu/2} \left(\mu'' + \frac{2\mu'}{r} + \frac{\mu'^2}{4} \right) \right\} + \frac{4\pi p_0}{T_0} \delta(e^{3\mu/2}) \right] r^2 dr = 0 \quad (49)$$

Performing the indicated variations, we have

$$\begin{aligned} \int_{r_1}^{r_2} \left[-\frac{e^{\mu/2}}{2T_0} \left(\delta\mu'' + \frac{2\delta\mu'}{r} + \frac{\mu'}{2} \delta\mu' \right) - \frac{e^{\mu/2}}{4T_0} \left(\mu'' + \frac{2\mu'}{r} + \frac{\mu'^2}{4} \right) \delta\mu \right. \\ \left. + \frac{12\pi p_0}{2T_0} e^{3\mu/2} \delta\mu \right] r^2 dr = 0. \end{aligned}$$

Noting, however, that the variations are to be carried out in accordance with equation (31) which gives $\delta\mu' = \delta\mu = 0$ at r_1 and r_2 , the first term in the integrand can evidently be transformed in the usual manner with the help of partial integrations, dropping terms that become zero at the limits, to a form depending on $\delta\mu$ alone; and the second term in the integrand can be simplified by resubstituting equation (19) for the energy density ρ_{00} . We thus obtain

$$\int_{r_1}^{r_2} \left[\frac{d^2}{dr^2} \left(\frac{e^{\mu/2} r^2}{T_0} \right) - 2 \frac{d}{dr} \left(\frac{e^{\mu/2} r}{T_0} \right) - \frac{d}{dr} \left(\frac{e^{\mu/2} r^2}{T_0} \frac{\mu'}{2} \right) - \frac{4\pi(\rho_{00} + 3p_0)}{T_0} e^{3\mu/2} r^2 \right] \delta\mu dr = 0.$$

This equation can be true, however, for arbitrary variations $\delta\mu$ only if the term in square brackets is equal to zero, and this can evidently be rewritten to give us

$$\frac{d}{dr} \left\{ e^{\mu/2} r^2 \frac{d}{dr} \left(\frac{1}{T_0} \right) \right\} = \frac{4\pi(\rho_{00} + 3p_0)}{T_0} e^{3\mu/2} r^2 \quad (50)$$

and substituting equation (20), we finally obtain as an expression connecting T_0 with the coordinate r and the metrical variables μ and ν

$$\frac{d}{dr} \left\{ e^{\mu/2} r^2 \frac{d}{dr} \left(\frac{1}{T_0} \right) \right\} = \frac{e^{-\nu/2}}{T_0} \frac{d}{dr} \left\{ e^{\mu/2} r^2 \frac{d}{dr} (e^{\nu/2}) \right\}. \quad (51)$$

This differential equation for T_0 is the same as equation (41) which we got when we applied the thermodynamic method to pure radiation. A first integral for this equation can be written in the form

$$\frac{d \ln T_0}{dr} = -\frac{1}{2} \frac{d\nu}{dr} + \frac{B e^{-\frac{\mu+\nu}{2}}}{r^2} T_0 \quad (52)$$

where B is a constant of integration, and substituting equation (22) this can be written as

$$\frac{d \ln T_0}{dr} = \frac{1}{\rho_{00} + p_0} \frac{dp_0}{dr} + \frac{B e^{-\frac{\mu+\nu}{2}}}{r^2} T_0.$$

If, however, we now assume on physical grounds that at the center of the sphere $r=0$, we have dT_0/dr and dp_0/dr equal to zero, T_0 not equal to zero and the other functions of r finite, it is evident that the constant of integration B must be equal to zero.⁸ Under these circumstances the second integral of our equation is then easily seen to be

$$T_0 = C e^{-\nu/2} \quad (53)$$

where C is a second constant of integration.

This result is exactly of the same form as that obtained for radiation alone and that is a satisfactory outcome since our method of derivation did not involve the assumption that any matter at all was necessarily present. The equation gives a definite relation connecting the equilibrium temperature in a gravitational field with the variable ν which is itself determined in a known way by the gravitational field. The general nature of the result can perhaps be more easily appreciated by redifferentiating equation (53) with respect to r and substituting equation (22). We then obtain

$$\frac{d \ln T_0}{dr} = -\frac{1}{2} \frac{d\nu}{dr} = \frac{1}{\rho_{00} + p_0} \frac{dp_0}{dr} \quad (54)$$

and can at once see that temperature and pressure will increase together as we go towards the center of the sphere. It is also of interest to note once more the approximation

$$\frac{d \ln T_0}{dr} = -\frac{1}{c^2} \frac{d\Psi}{dr} = -\frac{g}{c^2}$$

⁸ It would be interesting to investigate the possibility of solutions of physical interest with $B \neq 0$.

valid in weak enough fields so that the Newtonian method is applicable, and this is the same equation as was obtained in our preliminary non-rigorous treatment.⁹

§9. THE DISTRIBUTION OF MATTER IN A SPHERE OF PERFECT FLUID

The principles of relativistic thermodynamics which we have used in the preceding section should be sufficient to give us information not only as to the temperature distribution in a sphere of fluid but also as to the equilibrium distribution of matter. To obtain such information let us return once more to our condition for a maximum of the relativistic expression for entropy

$$\delta \left[4\pi \int_{r_1}^{r_2} \phi_0 e^{3\mu/2} r^2 dr \right] = 0. \quad (55)$$

In using this equation to determine the distribution of temperature, we considered the result of varying the temperature as a function of r , holding constant the number of molecules $N_1 \cdots N_n$ of each of the different components of the system in each spherical shell lying between r and $r+dr$. To determine the distribution of matter, on the other hand, we may hold the temperature constant and consider the result of varying the composition of the layers. As simple illustrations, we shall apply this method to a system consisting of a mixture of a perfect monatomic gas and radiation, both on the assumption that radiation and matter are interconvertible, and on the assumption that the total number of molecules in the system cannot be varied.

For the proper density of entropy of a mixture of perfect monatomic gas and radiation, we may evidently write in accordance with well known equations

$$\phi_0 = N_0 k \ln \frac{CT_0^{3/2}}{N_0} + \frac{4}{3} a T_0^3 \quad (56)$$

where N_0 is the number of molecules in unit volume as measured in proper coordinates by a local observer, T_0 is the proper temperature, k and a are respectively the Boltzmann constant and Stefan constant, and C is a constant so chosen that the starting points for the measurement of the entropy of matter and radiation will be in agreement.

If now we vary the proper concentration of molecules N_0 holding the temperature T_0 constant, we obtain

$$\delta \phi_0 = \left(k \ln \frac{CT_0^{3/2}}{N_0} - k \right) \delta N_0. \quad (57)$$

On the other hand for the proper density of energy we evidently have

$$\rho_{00} = N_0 m c^2 + \frac{3}{2} N_0 k T_0 + a T_0^4 \quad (58)$$

⁹ As a justification for the results of this section, my colleague Dr. J. Robert Oppenheimer has kindly pointed out to me that the relation which I have obtained between temperature and gravitational potential is a necessary one if the Planck radiation law is to hold at different gravitational levels.

where m is the rest mass of one molecule and c the velocity of light, $-mc^2$ thus being the internal energy and $(3/2)kT_0$ the average kinetic energy per molecule. Hence, holding the temperature constant as before, and varying N_0 we obtain

$$\delta\rho_{00} = (mc^2 + \frac{3}{2}kT_0)\delta N_0 \quad (59)$$

and by combining equations (57) and (59) we can express the variation in the density of entropy in terms of the variation in density of energy in the form

$$\delta\phi_0 = \frac{k \ln CT_0^{3/2}/N_0 - k}{mc^2 + 3/2kT_0} \delta\rho_{00}$$

or

$$\delta\phi_0 = f(N_0, T_0) \delta\rho_{00} \quad (60)$$

where for simplification we have written $f(N_0, T_0)$ as an abbreviation for the coefficient of $\delta\rho_{00}$.

Since $\delta\rho_{00}$, however, can be expressed as a function of the metrical variable μ , we can now return to our equation (55) for maximum entropy and write as a condition for equilibrium

$$4\pi \int_{r_1}^{r_2} [\delta\phi_0 e^{3\mu/2} + \frac{3}{2}\phi_0 e^{3\mu/2} \delta\mu] r^2 dr = 0$$

or substituting equation (60)

$$4\pi \int_{r_1}^{r_2} [f(N_0, T_0) e^{3\mu/2} \delta\rho_{00} + \frac{3}{2}\phi_0 e^{3\mu/2} \delta\mu] r^2 dr = 0 \quad (61)$$

and substituting in turn the value of ρ_{00} in terms of the metrical variable give by equation (19) we obtain

$$\begin{aligned} \int_{r_1}^{r_2} \left[-\frac{1}{2}f(N_0, T_0)e^{\mu/2} \left(\delta\mu'' + \frac{2}{r}\delta\mu' + \frac{\mu'}{2}\delta\mu' \right) \right. \\ \left. + \frac{1}{2}f(N_0, T_0)e^{\mu/2} \left(\mu'' + \frac{2\mu'}{r} + \frac{\mu'^2}{4} \right) \delta\mu + 4\pi\frac{3}{2}\phi_0 e^{3\mu/2} \delta\mu \right] r^2 dr = 0. \end{aligned}$$

Noting as in previous sections, however, that the variations are to be carried out in accordance with equation (31) which gives $\delta\mu' = \delta\mu = 0$ at r_1 and r_2 , the first term in the integrand can evidently be transformed in the usual manner with the help of partial integrations, dropping terms that become zero at the limits, to a form depending on $\delta\mu$ alone; and the second term in the integrand can be simplified by resubstituting equation (19) for the energy density ρ_{00} . We thus obtain

$$\begin{aligned} \int_{r_1}^{r_2} \left[\frac{d^2}{dr^2} \{ f(N_0, T_0) e^{\mu/2} r^2 \} - 2 \frac{d}{dr} \{ f(N_0, T_0) e^{\mu/2} r \} \right. \\ \left. - \frac{d}{dr} \left\{ f(N_0, T_0) e^{\mu/2} r^2 \frac{\mu'}{2} \right\} + 4\pi \{ 2f(N_0, T_0)\rho_{00} - 3\phi_0 \} e^{3\mu/2} r^2 \right] \delta\mu dr = 0 \end{aligned}$$

and combining the first three terms this can be rewritten in the form

$$\int_{r_1}^{r_2} \left[\frac{d}{dr} \left\{ e^{\mu/2} r^2 \frac{d}{dr} f(N_0, T_0) \right\} + 4\pi \{ 2f(N_0, T_0) \rho_{00} - 3\phi_0 \} e^{3\mu/2} r^2 \right] \delta\mu dr = 0. \quad (62)$$

This equation has resulted from an application of the condition for maximum relativistic entropy under the subsidiary condition, given by equation (31), which satisfies the requirements of the energy-momentum principle. In case we assume the ready interconvertibility of matter and radiation no further subsidiary conditions need be introduced. On the other hand, if we are interested in what might be only a temporary condition of equilibrium reached in a length of time such that the total number of molecules could not change, we must evidently add as a further subsidiary condition

$$\delta \left[4\pi \int_{r_1}^{r_2} N_0 e^{3\mu/2} r^2 dr \right] = 0 \quad (63)$$

where N_0 is the proper concentration of molecules and as we saw above $4\pi e^{3\mu/2} r^2 dr$ is the proper volume in the spherical shell lying between r and $r+dr$.

Performing the indicated variation, keeping of course the temperature constant as in the previous variation, and substituting the value for δN_0 given by equation (58), we obtain

$$4\pi \int_{r_1}^{r_2} \left[\frac{e^{3\mu/2}}{mc^2 + (3/2)kT_0} \delta\rho_{00} + \frac{3}{2} N_0 e^{3\mu/2} \delta\mu \right] r^2 dr = 0.$$

This equation, however, is of the same general form as (61) above, and can be treated by the same methods which led from (61) to (62), and will then evidently reduce to

$$\int_{r_1}^{r_2} \left[\frac{d}{dr} \left\{ e^{\mu/2} r^2 \frac{d}{dr} \left(\frac{1}{mc^2 + (3/2)kT_0} \right) \right\} + 4\pi \left\{ \frac{2\rho_{00}}{mc^2 + (3/2)kT_0} - 3N_0 \right\} e^{3\mu/2} r^2 \right] \delta\mu dr = 0. \quad (64)$$

Equations (64) and (62) may now be combined by the method of Lagrange to give us a single condition

$$\int_{r_1}^{r_2} \left[\frac{d}{dr} \left\{ e^{\mu/2} r^2 \frac{d}{dr} \left(f(N_0, T_0) + \frac{\lambda}{mc^2 + (3/2)kT_0} \right) \right\} + 4\pi \left\{ 2 \left(f(N_0, T_0) + \frac{\lambda}{mc^2 + (3/2)kT_0} \right) \rho_{00} - 3\phi_0 - 3\lambda N_0 \right\} e^{3\mu/2} r^2 \right] \delta\mu dr = 0$$

where λ is a constant undetermined multiplier, whose value will be zero in case equilibrium between matter and radiation is established, since the additional condition (63) will then not be needed. This equation, however, can only be true for arbitrary variations $\delta\mu$, if the quantity in square brackets

is equal to zero. Hence, resubstituting the value of $f(N_0, T_0)$ given by equation (60) we have as our final differential equation

$$\frac{d}{dr} \left\{ e^{\mu/2} r^2 \frac{d}{dr} \frac{k \ln CT_0^{3/2}/N_0 - k + \lambda}{mc^2 + (3/2)kT_0} \right\} = 4\pi \left\{ 3\phi_0 + 3\lambda N_0 - 2 \frac{k \ln CT_0^{3/2}/N_0 - k + \lambda}{mc^2 + (3/2)kT_0} \rho_{00} \right\} e^{3\mu/2} r^2 \quad (65)$$

where $\lambda=0$ in case the equilibrium between matter and radiation is established.

We have thus obtained a second order differential equation connecting the thermodynamic quantities concentration N_0 and temperature T_0 with the coordinate r . We have already found in the previous section, §8, however, equations for T_0 as a function of r , and hence the present equation requires that N_0 be such a function of T_0 as not to disagree with the previous results. We shall then suggest as an expression for the dependence of N_0 on T_0 and hence implicitly on r

$$k \ln \frac{CT_0^{3/2}}{N_0} - k + \lambda = \frac{mc^2}{T_0} + \frac{3}{2}k \quad (66)$$

or

$$N_0 = C e^{\lambda/k - 5/2} T_0^{3/2} e^{-mc^2/kT_0}$$

and test the suggestion by substituting into (65). Doing so, we obtain

$$\frac{d}{dr} \left\{ e^{\mu/2} r^2 \frac{d}{dr} \left(\frac{1}{T_0} \right) \right\} = 4\pi \left\{ 3\phi_0 + 3\lambda N_0 - \frac{2\rho_{00}}{T_0} \right\} e^{3\mu/2} r^2.$$

Comparing the first form of equation (66), however, with the expression for ϕ_0 given by (56), and introducing the expression for ρ_{00} given by (58), we obtain

$$\begin{aligned} \frac{d}{dr} \left\{ e^{\mu/2} r^2 \frac{d}{dr} \left(\frac{1}{T_0} \right) \right\} &= 4\pi \left\{ \frac{3N_0 mc^2}{T_0} + \frac{15}{2} N_0 k - 3\lambda N_0 + 4a T_0^3 \right. \\ &\quad \left. + 3\lambda N_0 - 2 \frac{N_0 mc^2}{T_0} - 3N_0 k - 2a T_0^3 \right\} e^{3\mu/2} r^2 \\ &= 4\pi \left\{ \frac{N_0 mc^2 + (3/2)N_0 k T_0 + a T_0^4 + 3(N_0 k T_0 + (a/3)T_0^4)}{T_0} \right\} e^{3\mu/2} r^2 \\ &= 4\pi \frac{(\rho_{00} + 3p_0)}{T_0} e^{3\mu/2} r^2 \end{aligned} \quad (67)$$

since the gas pressure is evidently $N_0 k T_0$ and the radiation pressure $\frac{1}{3}aT_0^4$. And this equation is exactly the same as our general equation (50) for the dependence of temperature on the coordinate and metric as obtained in the previous section §8. Hence our suggested expression equation (66) for the dependence of the concentration on temperature can be accepted as

satisfying the information previously obtained as to the dependence of temperature on the metric, and thus as a satisfactory solution of the problem of the distribution of a perfect monatomic gas in a gravitational field.

It is also significant to point out that equation (66) can be subjected to another test, since this expression for the proper concentration of the gas makes it possible to calculate the partial pressure of the gas and by combining with the partial pressure of radiation, then examine the dependence of total pressure on the radius r to see if it agrees with the purely mechanical equation $dp_0/dr = -(\rho_{00} + p_0)v'/2$, obtained in §4. And as a matter of fact equation (66) does lead to this result.¹⁰

Finally, it is interesting to compare the dependence of proper concentration on proper temperature given by equation (66) with the result obtained for the equilibrium concentration in flat space-time by Stern¹¹ and myself.¹² Taking the case where equilibrium between matter and radiation has been established, we have $\lambda = 0$ and equation (66) can be written

$$N_0 = (Ce^{5/2}) T_0^{3/2} e^{-mc^2/kT_0}$$

which agrees with my previous result as it stands, and agrees with the Stern result if we assign to the constant term $(Ce^{5/2})$ the not necessarily correct value which Stern obtained for it. Hence the conclusion can again be stated, owing to the great magnitude of the negative exponent for reasonable values of m and T , that the equilibrium concentration would be extremely small unless the constant term could be shown to have an enormous magnitude.

§10. CONCLUSION

In accordance with the special theory of relativity and the equivalence principle all forms of energy, including heat, must be regarded as having both inertia and weight, and the purpose of the present article has been to investigate, in as consequent a manner as may be, the thermodynamic implications of the notion that heat has weight. The most striking result of the investigation has been the discovery of a definite relation connecting gravitational potential with the distribution of temperature throughout a system which has come to thermodynamic equilibrium.

Qualitatively, the increase in equilibrium temperature which was found to accompany decrease in gravitational potential, may be regarded as due to the necessity of having a temperature gradient to prevent the flow of heat from places of higher to those of lower potential energy; and quantitatively, a first approximation to the magnitude of this temperature gradient was

¹⁰ It may seem strange that this purely mechanical equation holding within the interior of the system should be derivable from the application of thermodynamics to the system as a whole. The result, however, is the relativity analogue to the equation for change in pressure with height obtained by Gibbs ("Scientific Papers," Longmans, Green 1906, equation 230, p. 145) in his thermodynamic treatment of the conditions of equilibrium under the influence of gravity. Indeed the whole treatment of this article may be regarded as the relativistic extension of this part of Gibbs' work.

¹¹ Stern, *Zeits. f. Elektrochem.* **31**, 448 (1925); *Trans. Farad. Soc.* **21**, 477 (1925-26).

¹² Tolman, *Proc. Nat. Acad.* **12**, 670 (1926).

obtained by modifying the classical thermodynamics merely by ascribing to each given intrinsic quantity of energy the right additional quantity of potential gravitational energy. For a rigorous treatment, however, it was obviously necessary to investigate the whole problem from the standpoint of general relativity, and this was done using the extension of thermodynamics to general relativity which I have previously given. In this way it was possible to obtain what appears to be a rigorous equation connecting equilibrium temperature with gravitational potential. In addition in the case of black-body radiation it was possible to test the thermodynamic method, since the same temperature distribution in the case of this simple system was also obtained by the use of relativistic mechanics, without the necessity for the use of the new relativistic thermodynamics.

This discovery of a dependence of equilibrium temperature on gravitational potential must be regarded as something essentially new in thermodynamics, since uniform temperature throughout any system which has come to equilibrium has hitherto been taken as an inescapable part of thermodynamic theory. The new result hence has a very considerable theoretical interest, and even though the effect of gravitational potential on temperature may usually be extremely small the result may sometime be of experimental or observational interest.

THE DETERMINATION OF ELECTRON DISTRIBUTIONS FROM MEASUREMENTS OF SCATTERED X-RAYS

BY ARTHUR H. COMPTON

RYERSON PHYSICAL LABORATORY, UNIVERSITY OF CHICAGO

(Received March 5, 1930)

ABSTRACT

A calculation based on classical electromagnetic theory is made of the intensity of the x-rays scattered by an atom in which the electrons are arranged with random orientation and with arbitrary radial distribution. Conversely an expression is derived for the radial distribution of the electrons in an atom, assuming that they have random orientation. This expression has the form of a Fourier integral, which can be evaluated from observed intensities of the scattered x-rays for different wave-lengths and angles.

A comparison of this calculation with Wentzel's quantum theory of x-ray scattering suggests the introduction of a certain correction factor to express more nearly the intensity of the modified rays. It is also noted that the interpretation of $\psi\bar{\psi}$ as a probability of the occurrence of an electron leads to the correct value for the intensity of total scattered x-rays.

As an example of the application of the new method of calculation, Barrett's experimental data for the scattering of x-rays by helium are analyzed to give the distribution of the electrons in the helium atom. The resulting distribution is in close agreement with the value calculated by Pauling on the basis of wave mechanics, but differs by more than the probable experimental error from the electron orbits given by Bohr's theory.

1. INTRODUCTION

IT IS well known that the intensity of the x-rays scattered at small angles may be considerably greater than is anticipated on the assumption that each electron in the scattering material acts independently of the other electrons. When the scattering of x-rays by solids and liquids is considered, at least a part of this "excess scattering" may be ascribed to the interference between the rays scattered by neighboring atoms. In the case of gases, however, such interference is negligible, since the phases of the rays scattered by neighboring molecules are random. It has nevertheless long been recognized¹ that groupings of the electrons in the atoms themselves should result in some excess scattering in the forward direction. Calculations of the intensity of the scattered x-rays for typical electron distributions have in fact been made by Debye,² Schott,³ the writer,⁴ Glocker⁵ and others. The converse problem of determining the electron distribution corresponding to an observed angular

distribution of scattered x-rays has not however been attempted. We shall in the present paper obtain a solution of this problem which applies to certain important cases, and illustrate its application by determining the electron distribution in atoms of helium.

Because of the very important information which can thus be obtained regarding atomic structures, the problem would doubtless have been long ago pressed to a solution had it not been for an obstinate theoretical difficulty. Calculations of the effect of interference on the intensity of x-ray scattering are based upon the classical electron theory and electrodynamics. In the course of these x-ray diffraction studies, however, it became evident⁶ that these classical theories are inadequate to supply a complete solution of the problem of the intensity of scattered rays. The problem was accordingly "laid on the table" until a new quantum dynamics should be developed which would be able to supply a more reliable solution. Recently Wentzel⁷ has shown how the wave mechanics may be applied to this problem, and from his discussion it appears that the classical electron theory itself should give results which are not greatly in error.

In the meantime, closely allied problems have been successfully attacked on the basis of classical electron theory. In our studies of the diffraction of x-rays by crystals, which is of course only a special case of the general problem of x-ray scattering, application of the usual wave theory has enabled us to arrive at satisfactory arrangements of the atoms in the crystals, and has recently been used to determine also electron distributions in the atoms.⁸ We have every reason to believe that the information supplied by this work regarding atomic arrangements is reliable, and even the electron distributions found by its use are too satisfactory to admit any major error in the method of analysis. Similarly the classical wave diffraction theory has been successfully applied to the x-ray study of molecular shapes and sizes of liquids,⁹ and very recently also to the study of interatomic distances in gaseous molecules.¹⁰ We are thus encouraged to undertake again a more detailed analysis of the scattering of x-rays by gases, on the basis of classical theory. The results of this analysis will then be compared with Wentzel's conclusions, to see what modifications are necessary in light of quantum mechanics.

2. INTENSITY OF THE X-RAYS SCATTERED BY A GROUP OF ELECTRONS HAVING A RANDOM ANGULAR DISTRIBUTION

Let us suppose that an atom has Z electrons whose distances from the nucleus are at any instant $r_1, r_2 \dots r_s$, and whose angular distribution is random. We imagine that this atom is traversed by an x-ray wave propagated

along the X axis, and that the forced oscillations of the electrons give rise to a scattered wave at an arbitrary distant point P at an angle ϕ . If A_e is the amplitude of the electric vector and δ the phase at P of the wave scattered by an electron coincident with the nucleus, the electric vector due to the n^{th} electron in the group is (Fig. 1),

Fig. 1.

$$E_n = A_e \cos \left\{ \delta - (2\pi/\lambda) 2r_n \cos \alpha_n \sin (\phi/2) \right\}, \quad (1)$$

where $2r_n \cos \alpha_n \sin (\phi/2)$ is the total difference in path¹¹ between the ray scattered from e_n and that scattered from O , and α_n is the angle between Oe_n and the line OQ which bisects the angle $-XOP$. Equation (1) may be written

$$E_n = A_e \cos (\delta - x_n), \quad (2)$$

where

$$x_n = (4\pi r_n / \lambda) \cos \alpha_n \sin (\phi/2). \quad (3)$$

The total electric vector due to all the electrons in the atomic group is then,

$$E = \sum_1^Z E_n = A_e \sum_1^Z \cos (\delta - x_n). \quad (4)$$

Let us choose the origin of time such that the phase of the wave scattered from O is $\delta = pt$, where $p = 2\pi\nu$ is the phase frequency of the incident wave. The electric vector at the instant t is then, from Eq. (4),

$$\begin{aligned} E &= A_e \sum_1^Z \cos (pt - x_n) \\ &= A_e \sum_1^Z (\cos pt \cos x_n + \sin pt \sin x_n). \end{aligned} \quad (5)$$

¹¹ Cf. e.g., A. H. Compton, "X-rays and Electrons," p. 385.

The intensity of the scattered ray at this instant is however proportional to E^2 , say bE^2 , or,

$$I_i = bA_e^2 \left\{ \sum_1^Z (\cos pt \cos x_n + \sin pt \sin x_n) \right\}^2. \quad (6)$$

When this expression is averaged over a complete cycle, from $t=0$ to $t=2\pi/p$, all the terms in the summation disappear except those of the form

$$\cos x_m \cos x_n + \sin x_m \sin x_n,$$

and we find for the intensity averaged over a cycle,

$$I_\alpha = \frac{1}{2} bA_e^2 \sum_1^Z \sum_1^Z (\cos x_m \cos x_n + \sin x_m \sin x_n). \quad (7)$$

For a single electron, this becomes

$$I_e = \frac{1}{2} bA_e^2. \quad (8)$$

As Thomson has shown,¹² for unpolarized x-rays

$$I_e = \frac{Ie^4}{2m^2R^2c^4} (1 + \cos^2 \phi), \quad (9)$$

where I is the intensity of the primary beam traversing the electron, e , m and c have their usual significance, and R is the distance from O to P . Equation (7) may thus be written,

$$I_\alpha = I_e \sum_1^Z \sum_1^Z (\cos x_m \cos x_n + \sin x_m \sin x_n). \quad (10)$$

Since we have assumed that the electrons have random angular distribution, we must now average this intensity over all angles α_n . The probability that any α will lie between α and $\alpha + d\alpha$ is for random orientation $\frac{1}{2} \sin \alpha d\alpha$. Writing then

$$x_n = z_n \cos \alpha_n, \quad (11)$$

where

$$z_n = (4\pi r_n / \lambda) \sin (\phi/2), \quad (12)$$

the probable contribution to the intensity due to the orientations α_n is

$$\begin{aligned} dI_\alpha = I_e \left\{ \sum_1^Z \sum_1^Z \sum_{m \neq n} \frac{1}{2} [\cos (z_m \cos \alpha_m) \cos (z_n \cos \alpha_n) \right. \\ \left. + \sin (z_m \cos \alpha_m) \sin (z_n \cos \alpha_n)] \times \sin \alpha_m \sin \alpha_n d\alpha_m d\alpha_n \right. \\ \left. + \sum_1^Z \frac{1}{2} [\cos^2 (z_n \cos \alpha_n) + \sin^2 (z_n \cos \alpha_n)] \sin \alpha_n d\alpha_n \right\}. \end{aligned}$$

¹² J. J. Thomson, *Conduction of Electricity through Gases*, 2nd Ed., p. 325; or cf. "X-rays and Electrons," p. 60.

Integrating over all values of α_m and α_n this takes the simple form,

$$I_r = I_e \left\{ Z + \sum_1^Z \sum_{m \neq n}^Z \frac{\sin z_m}{z_m} \frac{\sin z_n}{z_n} \right\}. \quad (13)$$

Equation (13) represents the scattering by electrons arranged at fixed distances $r_1, r_2 \dots$ from the nucleus, but with random orientations.

As an example of the application of this formula, consider the case of an atom with two electrons, both at a distance $r=a$ from the center, but with random orientations. We may write equation (13) in the form

$$S \equiv \frac{I_r}{ZI_e} = 1 + \frac{1}{Z} \sum \sum_{m \neq n} \frac{\sin z_m \sin z_n}{z_m z_n}, \quad (14)$$

which in the present case becomes,

$$S = 1 + \left(\frac{\sin z_a}{z_a} \right)^2. \quad (15)$$

A graph of this expression is shown in Fig. 2 by the solid line. This may be compared with scattering by two electrons separated by a fixed distance $2a$, which is given by the expression¹³

$$S = 1 + \frac{\sin 2z_a}{2z_a}, \quad (16)$$

and is represented in the figure by the broken line.

Fig. 2. Relative scattering per electron for an atom of two electrons. Solid line, both electrons at radius a and random orientation. Broken line, electrons at opposite ends of diameter $2a$.

¹³ P. Debye, reference 2, or "X-rays and Electrons," p. 72.

If the probability that any one electron shall lie between r and $r+dr$ is $u(r)dr$, and if this probability is the same for every electron, we have,

$$dI_s = I_e \left\{ Z + \sum \sum_{m \neq n} \frac{\sin kr_m \sin kr_n}{k^2 r_m r_n} u(r_m) u(r_n) dr_m dr_n \right\},$$

where

$$k \equiv z_m/r_m = (4\pi/\lambda) \sin(\phi/2). \quad (17)$$

Since $u(r_m)$ assumed the same for all electrons, the integral of this expression may be written,

$$I_s = I_e Z + I_e \sum \sum_{m \neq n} \left\{ \int_0^a u(r) \frac{\sin kr}{kr} dr \right\}^2,$$

where a is the maximum radius of the atom.

Since

$$\sum_1^Z \sum_{m \neq n}^Z 1 = Z^2 - Z,$$

$$I_s = I_e \left\{ Z + (Z^2 - Z) \left[\int_0^a u(r) \frac{\sin kr}{kr} dr \right]^2 \right\}. \quad (18)$$

For the relative scattering per electron we thus have

$$S = \frac{I_s}{ZI_e} = 1 + (Z - 1) \left\{ \int_0^a u(r) \frac{\sin kr}{kr} dr \right\}^2. \quad (19)$$

Expressions (13) or (18) may be applied to calculate the intensity of the rays scattered by an electron group, according as the electrons are at fixed distances from the center of the atom, or as they have a continuous radial distribution.

According to equation (18), I_s should never fall below ZI_e , since the term representing the interference is always positive. In this respect our calculation differs from that of Debye,² who considers electrons at fixed distances from each other, of which equation (16) is the simplest example.

3. COMPARISON WITH RESULTS OF QUANTUM MECHANICS.

Wentzel's equation (3a) for the intensity of the modified scattered rays¹⁴ may be written in the form

$$I_{unm} = I_e \left\{ \int \sum_n 4\pi r_n^2 \rho_n \frac{\sin kr}{kr} dr \right\}, \quad (20)$$

where $\sum \rho_n = \sum u_n$,² the electrical charge distribution in electronic units, the subscript indicating the n^{th} quantum number. Noting that $\sum 4\pi r^2 \rho_n$ is numerically equal to our $Zu(r)$, this may be written

$$I_{unm} = I_e \cdot Z^2 \left\{ \int u(r) \frac{\sin kr}{kr} dr \right\}^2. \quad (21)$$

¹⁴ G. Wentzel, reference 7, p. 781.

His equation (4a) for the intensity of the modified scattered rays (uncorrected for the change of wave-length) may similarly be written

$$I_{\text{mod}} = I_e \left\{ Z - \sum \left[\int 4\pi r^2 \rho_n \frac{\sin kr}{kr} dr \right]^2 \right\}. \quad (22)$$

The total intensity of the scattered rays thus becomes,

$$\begin{aligned} I_s &= I_{\text{unm}} + I_{\text{mod}} \\ &= I_e \left\{ Z - \sum \left[\int 4\pi r^2 \rho_n \frac{\sin kr}{kr} dr \right]^2 + Z^2 \left[\int u(r) \frac{\sin kr}{kr} dr \right]^2 \right\}. \end{aligned} \quad (23)$$

This expression becomes identical with equation (18) if

$$4\pi r^2 \rho_n = u(r). \quad (24)$$

We have noted above that

$$\sum_1^Z 4\pi r^2 \rho_n = Zu(r), \quad (25)$$

whence relation (24) holds if

$$\sum_1^Z 4\pi r^2 \rho_n = Z \cdot 4\pi r^2 \rho_n, \quad (26)$$

i.e. if the charge distribution for every electron is the same. This is precisely the assumption on which equation (18) is derived. Wentzel, in his numerical calculation of equation (22) takes

$$\rho_n = u_n^2 \quad (27)$$

as the charge density for the n th electron, instead of

$$\rho_n = (1/Z) \sum_1^Z u_n^2, \quad (28)$$

which is the equivalent of (26). This introduces a slight difference between the results of his calculation and that of ours. It would seem however that relation (28) is in better accord with present interpretation of quantum mechanics than is (27), and if its validity is admitted, our classical equation (18) becomes identical with Wentzel's quantum equation (23).

This comparison shows that if we interpret $\sum u_n^2 dx dy dz$ as the electric charge in the volume element, the scattering which we calculate is the *unmodified* scattering (eq. 21). If, however, we interpret it as the probability that a discrete electron will be present in the volume element, as we have done in deriving equation (18), we calculate the *total* scattering. Since the total scattering is experimentally observed, it would seem that the latter interpretation has the better physical justification.

In his derivation of equation (22), Wentzel has assumed the limiting case of very long wave-lengths, for which the scattering by a free electron is identical with that calculated on the classical theory. For shorter wave-lengths

Breit¹⁵ and Dirac¹⁶ have shown that the intensity of the modified rays from free electrons is reduced in the ratio

$$\frac{I_{\text{mod}}}{I_{\text{class}}} = \left(\frac{\lambda}{\lambda'} \right)^3 = (1 + \gamma \text{vers } \phi)^3, \quad (29)$$

where λ and λ' are the wave-lengths of the primary and the modified ray respectively, and $\gamma = h/mc\lambda$. We may accordingly expect to get a closer approximation to the intensity of the modified scattering if we multiply equation (22) by equation (29), or using the equivalent part of equation (18),

$$I_{\text{mod}} = Z I_e (1 - F^2/Z^2) (1 + \gamma \text{vers } \phi)^{-3}. \quad (30)$$

Similarly¹⁷

$$I_{\text{unm}} = I_e F^2, \quad (31)$$

where

$$F = Z \int_0^a u(r) \frac{\sin kr}{kr} dr, \quad (32)$$

which is identical with the so-called "atomic structure factor."

A convenient method of comparing the experiments with the theoretical calculations is thus to multiply the observed intensity of the modified rays by the factor $(1 + \gamma \text{vers } \phi)^3$, and add to the observed intensity of the unmodified rays. The resulting value

$$I_s' = I_{\text{mod}} (1 + \gamma \cos \phi)^3 + I_{\text{unm}} \quad (33)$$

may then be compared directly with the value of I_s derived by the classical equation (18).

4. ANALYSIS OF SCATTERING DATA TO DETERMINE RADIAL ELECTRON DISTRIBUTION

If the distribution of the electrons is spherically symmetrical, as we have assumed, we may represent the probability that an electron will lie between r and $r + dr$ by a Fourier sine series of the form,

$$u(r) = A_1 r \sin \pi r/a + A_2 r \sin 2\pi r/a + \dots + A_n r \sin n\pi r/a + \dots \quad (34)$$

Substituting this value of $u(r)$ in equation (19) we get,

$$S = 1 + (Z - 1) \left[\sum_n \int_0^a \frac{A_n}{k} \sin \left(n\pi \frac{r}{a} \right) \sin (kr) dr \right]^2. \quad (35)$$

If the scattering I_s is evaluated for $k = n\pi/a$, i.e., by equation (17) for

$$\sin (\phi/2)/\lambda = n/4a, \quad (36)$$

¹⁵ G. Breit, Phys. Rev. **27**, 242 (1926).

¹⁶ P. A. M. Dirac, Proc. Roy. Soc. **111**, 405 (1926). This relation (29) presumably does not hold for wave-lengths so short that the velocity of the recoil electron approaches c . In this case the formula of Klein and Nishina presents a closer approximation.

¹⁷ It is interesting that the ratio $I_{\text{mod}}/I_{\text{unm}}$ is expressed by equations (30) and (31) in terms of interference. It was early suggested by the writer (Phil. Mag. **46**, 910 (1923)) that this ratio might be thus expressed, as an alternative to the more obvious description developed later by Jauncey, in terms of the ratio of the energy of recoil of the scattering electron to its binding energy in the atom. Wentzel¹⁷ shows that equivalent expressions of the ratio I_u/I_m may be made in terms of either interference or energy of recoil.

where a is an assumed maximum radius, all integrals in the sum of equation (35) vanish except the n th, giving

$$S_n = 1 + (Z - 1) \left[\frac{1}{4} \frac{a^2}{k^2} A_n^2 \right]. \quad (37)$$

Thus

$$A_n = \pm \frac{2k}{a} \left\{ \frac{S_n - 1}{Z - 1} \right\}^{1/2}. \quad (38)$$

Corresponding to each value of S_n we thus determine the n th term of the Fourier series (34), and thus eventually the value of $u(r)$.

Our series (34) has in it an arbitrary radius a , and in evaluating the series the data for only certain arbitrarily chosen values of k are employed. If this arbitrary radius is made large, the values of k which are used come closer together, and our series approaches the Fourier integral,

$$u(r) = r \int_0^\infty B \sin(\pi r x) dx, \quad (39)$$

where

$$x \equiv n/a = (4/\lambda) \sin(\phi/2), \quad (40)$$

according to equation (36), and

$$B \equiv A_n a = 2\pi x \left\{ \frac{S_x - 1}{Z - 1} \right\}^{1/2}. \quad (41)$$

If instead of the probable position of a single electron, we wish to find the probable number of electrons between r and $r+dr$, we have only to multiply $u(r)$ by the number of electrons per atom, giving by equation (34)

$$U(r) = Zu(r) = Zr \sum_1^\infty A_n \sin n\pi r/a, \quad (42)$$

or by (39),

$$U(r) = Zr \int_0^\infty B \sin(\pi r x) dx. \quad (43)$$

It is interesting to compare equation (42) with the similar series expressing the radial distribution of electrons in the atoms of a crystal,¹

$$U(r) = 8\pi \frac{r}{D^2} \sum_1^\infty n F_n \sin 2\pi n \frac{r}{D}. \quad (44)$$

We note that a of equation (42) corresponds to $D/2$ of (44), since both quantities represent the assumed outer limit of the atom. The series are accordingly identical if $2\pi(r/a^2)nF_n = ZrA_n$. Using the value of A_n given by (38), and noting that $D = 2a = (n\lambda/2) \sin \frac{1}{2}\phi$, this means that

$$F_n = Z \left\{ \frac{S_x - 1}{Z - 1} \right\}^{1/2}. \quad (45)$$

This expression enables us to compare the " F " curves obtained from crystal reflection with the data given by scattering experiments.

¹⁸ A. H. Compton, "X-rays and Electrons," p. 164. An integral identical in form with (43), but representing the electron distribution in atoms of a crystal, has been given by G. E. M. Jauncey and W. D. Claus, Phys. Rev. **32**, 20 (1928).

5. TESTS OF THE METHOD OF ANALYSIS

Before applying equation (43) to the interpretation of experimental data, it will be of interest to study its application to certain cases where the solution is known.

a. Consider the intensity distribution described by equation (15). From equations (15) and (41) we have

$$B = \pm (2/a) \sin \pi x a. \quad (46)$$

Substituting this value in (43), since $Z = 2$,

$$U = 4(r/a) \int_0^\infty \sin(\pi a x) \sin(\pi r x) dx. \quad (47)$$

This integral is zero,¹⁹ except when $r = a$, in which case its value becomes infinite, indicating a concentration of the electrons at the distance $r = a$ from the nucleus, in accord with the original assumption on which (15) was based.

b. An atom of four electrons, each of whose probability of lying between r and $r + dr$ is $u(r) = 2r/a^2$ between $r = 0$ and $r = a$, and is zero beyond $r = a$.

By equation (19) we find,

$$S = 1 + 3 \left\{ \frac{2(1 - \cos \pi x a)}{\pi^2 x^2 a^2} \right\}^2. \quad (48)$$

From (41) then,

$$B = \pm \frac{4}{\pi x a^2} (1 - \cos \pi x a),$$

and equation (39) becomes,

$$u(r) = 4 \frac{r}{a} \left\{ \int_0^\infty \frac{\sin \pi r x}{\pi a x} dx - \int_0^\infty \frac{\cos \pi a x \sin \pi r x}{\pi a x} dx \right\}. \quad (49)$$

The value of the integrals is²⁰ $1/2a$ for $[r < a]$, and 0 for $[r > a]$, whence

$$\begin{aligned} u(r) &= 2r/a^2 & [r < a], \\ &= 0 & [r > a], \end{aligned} \quad (50)$$

as initially assumed.

These tests check the accuracy of the mathematical analysis. They of course say nothing, however, regarding the validity of our physical assumptions of spherical symmetry and of independence of the positions of the various electrons in the atomic groups.

6. ELECTRON DISTRIBUTION IN HELIUM

The formulas that have been developed above are directly applicable only to the scattering of x-rays by gases, in which case the interference effect due to neighboring molecules is negligible. In the case of the noble gases we are also free from interference between adjacent atoms, since the gases are mona-

¹⁹ At any point when $r \neq a$ the integral is strictly speaking indeterminate; but its average value over a finite range of x is zero.

²⁰ B. O. Peirce, "A Short Table of Integrals" (1910) nos. 484 and 485.

tomic, and according to current theories the probable electron distributions should be spherically symmetrical as we have assumed in our calculations. Fortunately recent experiments by Barrett²¹ supply sufficient information regarding the scattering by helium to yield valuable information.

In Barrett's Fig. 7 he compares the scattering by helium with that by hydrogen, which he finds identical with that calculated from the Breit-Dirac quantum formula for the range investigated. With an effective wave-length of 0.49A, he finds that helium and hydrogen scatter equally, within experimental error, at angles greater than 60°, but that at 40°, 30° and 20° the scattering by helium is greater by the ratios 1.025, 1.08 and 1.26 respectively. These values are indicated by the circles in Fig. 3, where $S \equiv I_s/ZI_e$ is plotted against x . At sufficiently small angles the phase difference between the rays from the two electrons in helium must be negligible, in which case our theory demands that the value of S must approach 2. For small values of x the phase

Fig. 3. Solid line, relative scattering by helium, based on Barrett's data (circles). Broken line, calculated scattering by Bohr type helium atom.

differences are small quantities of the first order; but the amplitudes, being proportional to the cosines of the phase differences, are affected only in the second order of small quantities.²² Thus the S curve must leave the $x=0$ axis parallel to the x axis, and must initially be of a parabolic form.²³ We can thus interpolate the S curve between $x=0$ and $x=1.4$ with some degree of assurance as indicated by the solid line.

This S curve can be transformed into a B curve by the help of equation (41), giving the result shown in Fig. 4. Here again the values given by the experimental data are shown by the circles.

²¹ C. S. Barrett, Phys. Rev. 32, 22 (1928).

²² This may be seen by finding the maximum value of E from equation (5) for small values x_n . This maximum is unaffected to the first power of x_n , but is reduced by terms containing x_n^2 .

²³ These conclusions are valid only if the atom is not of infinite extent.

For values of x greater than 3 the experiments suggest that B gradually approaches zero.²⁴ The values of the integral U are not much affected by the exact manner of this approach as long as it is slow and continuous. For con-

Fig. 4.

venience, therefore, we may assume that beyond some arbitrary value of x , say x_1 , B may be expressed by

$$B = be^{-ax} \quad [x > x_1]. \quad (51)$$

In order that at $x = x_1$ the values of B and dB/dx shall be continuous, we must have

$$a = - \left(\frac{1}{B} \frac{dB}{dx} \right)_{x_1} \quad (52)$$

and

$$b = B_1 e^{ax_1} \quad (53)$$

In order to evaluate $U(r)$ for a definite value of r we must determine the integral,

$$\Phi = \int_0^\infty B \sin(\pi r x) dx. \quad (54)$$

This may be separated into two parts,

$$\Phi_1 \equiv \int_0^{x_1} B \sin(\pi r x) dx, \quad (55)$$

and

$$\Phi_2 \equiv \int_{x_1}^\infty B \sin(\pi r x) dx. \quad (56)$$

²⁴ B must approach zero for large values of x unless the electron density at the center of the atom is infinite.

The first part Φ_1 may be evaluated graphically, by plotting $B \sin (\pi r x)$ for various values of r , as indicated by the dotted lines of Fig. 4, and integrating from O to x_1 with a planimeter. Φ_2 may be determined by substituting in equation (56) the value of B given in equation (51) and integrating, which gives

$$\Phi_2 = B_1 \frac{a \sin \pi r x_1 + \pi r \cos \pi r x_1}{a^2 + \pi^2 r^2}. \quad (57)$$

From Fig. 4 we find for helium, if $x_1=3$, $B_1=2.36$ and $a=0.46$, whence the value of Φ_2 may be determined for any desired value of r .

As typical examples, we have the following values (Table I):

TABLE I.

r	Φ_1	Φ_2	$\Phi = \Phi_1 + \Phi_2$	$U = Zr\Phi$
1.125A	5.75	1.64	7.39	1.85
0.25	8.16	-0.42	7.74	3.87
0.5	3.14	-0.35	2.79	2.79
1.0	0.86	-0.70	0.16	0.32

The resulting values of U plotted against r are shown in Fig. 5 by the solid line.

Fig. 5. Radial electron distribution in helium. Solid line, based on Barrett's x-ray scattering data. Broken line, Pauling's calculation from wave mechanics. a =radius of Bohr orbits.

It is of great interest to compare the "observed" distribution with that calculated theoretically. According to the Bohr-Sommerfeld theory, the elec-

trons in helium should both traverse approximately circular orbits with unit angular momentum, the radius of the orbits being given by

$$a = h^2 / [4\pi^2 e^2 m (Z - s)]. \quad (58)$$

where h , e , m and Z have their usual significance, and s is the "screening constant" of each electron on the other, having a value²⁵ of approximately $s = 0.39$. Using the usual values of the constants, we thus find $a = 0.33\text{\AA}$. It will be seen that this value falls very close to the radius of maximum electron density as shown in Fig. 5.

If we assume that the two electrons are on a spherical surface of fixed radius $r = 0.33\text{\AA}$, the intensity of the scattered rays should be given by equation (15). The values of s thus calculated are shown by the dotted line Fig. 3. The differences between this dotted curve and the experimental points are considerably greater than the probable experimental error. Yet it is not impossible that a combination of heterogeneous x-rays such as Barrett used and the presence of incoherent rays (Compton scattering) at the large angles might flatten out the dotted curve to resemble the experimental one.

The distribution found from this analysis of Barrett's scattering data is however in striking agreement with that calculated on Schrödinger's wave mechanics. Thus Pauling²⁵ has shown that the radial electron distribution in helium can be expressed to a close approximation by

$$U(r) = Zr^2 X^2, \quad (59)$$

where for helium in the normal state he finds,

$$X = u_{1,0} = -2 \left(\frac{Z - s}{a_0} \right)^{3/2} e^{-\xi/2} \quad (60)$$

$$a_0 = h^2 / 4\pi^2 e^2 m = 0.53\text{\AA},$$

$$Z = 2$$

$$s = \text{screening const} = 0.39$$

$$\xi = 2(Z - s)r/a_0.$$

Substituting these values in equation (59) we get the U curve shown by the dotted line of Fig. 5. The striking similarity between this distribution predicted by the quantum theory and that coming from our interpretation of the scattering experiments is the more convincing when it is noted that there are no arbitrary constants available to make the two curves correspond. This agreement is a strong argument in favor of a continuous electron distribution, as predicted by the wave-mechanics, as opposed to the Bohr quantum theory of definite orbits.

TWO NOTES ON THE PROBABILITY OF RADIATIVE TRANSITIONS

BY J. R. OPPENHEIMER

NORMAN BRIDGE LABORATORY, PASADENA

(Received March 4, 1930)

ABSTRACT

In 1 we compute the rate at which electrons and protons should, on Dirac's theory of electrons and protons, annihilate each other; this gives a mean life time for matter of the order of 10^{-10} sec.

In 2 we compute by Dirac's radiation theory the relative probability of radiative and radiationless transitions; we obtain an expression substantially equivalent to that derived by Heisenberg and Pauli.

I

AN ELECTRON satisfying Dirac's linear wave equation will very rapidly lose energy to the electromagnetic field. If the electron is free, it must lose this energy by radiating at least two quanta, in order that energy and momentum may be conserved in the process. If the electron is bound, e.g. in an atom, transitions in which only one quantum is radiated can occur, since there are then other particles present which can take up the necessary momentum. But these transitions are rare compared with the two-quantum transitions, which, as is well known, may be expected according to the theory to occur at an infinite rate. Now Dirac has suggested¹ that the reason why these transitions do not in fact occur is that the states of negative energy are filled; and this suggestion leads to a satisfactory understanding of the validity of the scattering laws derived from his wave equation. But according to Dirac not all of the states of negative energy are full; there are a few gaps in the distribution for negative electrons nearly at rest; and thus transitions to states of negative energy should not be quite excluded. Dirac further suggests that the empty states of negative energy are protons; and thus the filling of these states should correspond to the annihilation of an electron and a proton. This should occur very rarely; and if Dirac's suggestion were correct, we should expect to find a very small value for the corresponding transition probability. In this note we shall compute this transition probability on the basis of the present theory.

This computation cannot be made theoretically unique and certain until the grave difficulties introduced by the inequality of electron and proton masses are resolved; and this resolution seems to demand an essential advance² in the theory. The chief ambiguity for the present work arises from the fact that the energy radiated by the conversion of a stationary positive elec-

¹ P. A. M. Dirac, Roy. Soc. Proc. A126, 360 (1930).

² J. R. Oppenheimer, Phys. Rev. 35, 461 (1930).

tron into a stationary negative electron is $2mc^2$; whereas the energy liberated by the annihilation of a stationary electron and a stationary proton should be $(m + M_P)c^2$. We shall make the computation without explicit recognition of the difference in mass of electron and proton; this gives a transition probability which is absurdly large, and which is not appreciably reduced by the substitution of $m + M_P$ for $2m$ in the final formula.

Let us consider for definiteness an enclosure of volume V in which there is one free electron, and one gap in the negative energy distribution; and let both the electron and the gap be at rest. If electron and proton have in fact a relative velocity v , then our result will be in error by terms of the relative order $(v/c)^2$. For the wave equation of the electron we write

$$\{W/c + \alpha_0 mc + (h/2\pi i)[\alpha_1(\partial/\partial x) + \alpha_2(\partial/\partial y) + \alpha_3(\partial/\partial z)]\}\psi = 0 \quad (1)$$

We take the matrices $||\alpha_\mu(\rho\sigma)||$ in the form

$$\begin{aligned} ||\alpha_1(\rho\sigma)|| &= \begin{vmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{vmatrix}; & ||\alpha_2(\rho\sigma)|| &= \begin{vmatrix} 0 & 0 & 0 & i \\ 0 & 0 & -i & 0 \\ 0 & i & 0 & 0 \\ -i & 0 & 0 & 0 \end{vmatrix} \\ ||\alpha_3(\rho\sigma)|| &= \begin{vmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 \\ 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \end{vmatrix}; & ||\alpha_0(\rho\sigma)|| &= \begin{vmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{vmatrix} \end{aligned} \quad (2)$$

The normalized solutions corresponding to momenta p, q, r , and energy W given by

$$(W/c)^2 = m^2c^2 + p^2 + q^2 + r^2 \quad (3)$$

may then be written

$$\begin{aligned} \psi_3^\alpha &= 0; \\ \psi_4^\alpha &= \frac{(mc + W/c)e^{2\pi i/h(px+qy+rz)}}{[(mc + W/c)^2 + p^2 + q^2 + r^2]^{1/2}V^{1/2}} \\ \psi_1^\alpha &= \frac{-(p + iq)e^{2\pi i/h(px+qy+rz)}}{[(mc + W/c)^2 + p^2 + q^2 + r^2]^{1/2}V^{1/2}}; \\ \psi_2^\alpha &= \frac{re^{2\pi i/h(px+qy+rz)}}{[(mc + W/c)^2 + p^2 + q^2 + r^2]^{1/2}V^{1/2}} \end{aligned}$$

and

$$\begin{aligned} \psi_4^\beta &= 0; & \psi_3^\beta &= \psi_4^\alpha \\ \psi_1^\beta &= -\psi_2^\alpha; & \psi_2^\beta &= \tilde{\psi}_1^\alpha. \end{aligned} \quad (4)$$

The two wave functions for α and β give electrons with spin oriented parallel and antiparallel respectively to the z axis.

For the initial state of the electron we take

$$W = E_0 = h\nu_0 = mc^2; \psi_1^0 = \psi_2^0 = 0; \psi_3^0 = e^{2\pi i \gamma} (2V)^{-1/2}; \psi_4^0 = (2V)^{-1/2} \quad (5)$$

similarly for the final state we take

$$\begin{aligned} W = E^e = -h\nu_0 = -mc^2; \quad \psi_3^e = \psi_4^e = 0; \\ \psi_1^e = e^{2\pi i \delta} (2V)^{-1/2}; \quad \psi_2^e = (2V)^{-1/2}. \end{aligned} \quad (6)$$

Here γ and δ are independent indeterminate phases; if in the final results we average over these, we shall have assumed random orientations for the spins of both initial and final states; and with this understanding both (5) and (6) may be regarded as spherically symmetric.

We shall need also the wave functions for states with

$$p = q = 0; r = \pm mc; W = \pm (2)^{1/2} mc^2.$$

These are

$$\psi_2^\alpha = \psi_4^\alpha = 0; \psi_1^\alpha = \frac{-re^{\pm 2\pi i mcx/h}}{mcV^{1/2}(4 \pm 2(2)^{1/2})^{1/2}}; \psi_3^\alpha = \frac{(1 \pm (2)^{1/2})e^{\pm 2\pi i mcx/h}}{V^{1/2}(4 \pm 2(2)^{1/2})^{1/2}}$$

and

$$\psi_1^\beta = \psi_3^\beta = 0; \psi_2^\beta = -\psi_1^\alpha; \psi_4^\beta = \psi_3^\alpha. \quad (7)$$

Initially there is to be no radiation present; the electron is in the state (0). The probability amplitude at a later time t that a quantum of frequency ν , momentum \mathbf{p} , and electric vector polarized along the unit vector \mathbf{e} , shall have been emitted, and that the electron shall have jumped to a state of momentum \mathbf{P} , energy $h\bar{\nu}$, and polarization of spin $\tau = \alpha, \beta$, is then

$$\phi(\mathbf{p}, \mathbf{e}; \mathbf{P}, \bar{\nu}, \tau) = -v(0; \mathbf{p}, \mathbf{e}, \bar{\nu}, \tau) \frac{1 - e^{2\pi i(\nu + \bar{\nu} - \nu_0)t}}{\nu + \bar{\nu} - \nu_0}. \quad (8)$$

Here $v(0; \mathbf{p}, \mathbf{e}, \bar{\nu}, \tau)$ is the matrix component for the transition in question of the interaction energy between the electron and the light quantum field. This vanishes except when $\mathbf{P} = -\mathbf{p}$, and for $\mathbf{P} = -\mathbf{p}$ has the value

$$ec(2\pi/\nu hV)^{1/2} \left(\sum_{l=1}^3 \epsilon_l \alpha_l e^{-2\pi i/h(\mathbf{p} \cdot \mathbf{r})} \right) 0; \bar{\nu}, P, \tau; \text{ with } \bar{\nu}^2 = \nu_0^2 + \nu^2 \quad (9)$$

where

$$\left(\sum_{l=1}^3 \epsilon_l \alpha_l e^{-2\pi i/h(\mathbf{p} \cdot \mathbf{r})} \right) 0; \bar{\nu}, P, \tau$$

is the matrix component corresponding to the electronic transition

$$(0) \rightarrow (\bar{\nu}, P, \tau)$$

of the component of the vector

$$\mathbf{a} e^{-2\pi i/h(\mathbf{p} \cdot \mathbf{r})}$$

parallel to \mathbf{e} .

The probability amplitude that the electron should have jumped to state (e), and that a second quantum of frequency ν' , momentum \mathbf{p}' , and polarization along $\boldsymbol{\varepsilon}'$ should have been emitted, vanishes except when $\mathbf{p}' = -\mathbf{p} = \mathbf{P}$, and for $\mathbf{p}' = \mathbf{P}$ has the value

$$\phi(\mathbf{p}, \boldsymbol{\varepsilon}, \mathbf{p}', \boldsymbol{\varepsilon}'; e) = \frac{2\pi e^2 c^2}{h\nu V} \sum \left\{ \frac{1 - e^{2\pi i(\nu - \bar{\nu} - \nu_0)t}}{\nu - \bar{\nu} - \nu_0} - \frac{1 - e^{4\pi i(\nu - \nu_0)t}}{2(\nu - \nu_0)} \right\}$$

with

$$\begin{aligned} \sum = & \sum_{\bar{\nu}} \sum_t \left\{ \left(\sum_{l=1}^3 \epsilon_l \alpha_l e^{-2\pi i/h(\mathbf{p}, \mathbf{r})} \right)_{0; \bar{\nu}, P, \tau} \left(\sum_{l=1}^3 \epsilon'_l \alpha_l e^{2\pi i/h(\mathbf{p}, \mathbf{r})} \right)_{\nu, P, \tau; e} \right. \\ & \left. + \left(\sum_{l=1}^3 \epsilon'_l \alpha_l e^{2\pi i/h(\mathbf{p}, \mathbf{r})} \right)_{0; 0, P, \tau} \left(\sum_{l=1}^3 \epsilon_l \alpha_l e^{-2\pi i/h(\mathbf{p}, \mathbf{r})} \right)_{0, P, \tau; e} \right\} (\nu + \bar{\nu} - \nu^{-1}) \end{aligned} \quad (10)$$

This grows large only for $\nu \sim \nu_0$, $\bar{\nu} \sim \pm (2)^{1/2} \nu_0$; and here the first term in the bracket may be neglected.

To evaluate \sum for $\nu = \nu_0$, $\bar{\nu} = \pm (2)^{1/2} \nu_0$, we may without loss of generality take \mathbf{p} along z , since both initial and final wave functions are effectively spherically symmetric. We may further take, again without loss of generality, $\boldsymbol{\varepsilon}$ along x . There are then two cases to consider, with $\boldsymbol{\varepsilon}'$ along x and along y respectively. For these cases we have in turn

$$\begin{aligned} \sum = & \sum_{\bar{\nu} = \pm (2)^{1/2} \nu_0} \sum_{\tau = \alpha, \beta} \bar{\nu}^{-1} \left\{ \left[\int dV \sum_{\rho, \sigma} \bar{\psi}_{\sigma}^{\bar{\nu}, P, \tau} e^{-2\pi i/c \cdot \nu_0 z} \alpha(\sigma \rho) \psi_{\rho}^0 \right] \right. \\ & \left. \left\{ \int dV \sum_{\rho, \sigma} \psi_{\sigma}^e e^{2\pi i/c \nu_0 z} \left\{ \begin{matrix} \alpha_1(\sigma, \rho) \\ \alpha_2(\sigma, \rho) \end{matrix} \right\} \psi_{\rho}^{\bar{\nu}, P, t} \right\} \right. \\ & \left. + \left\{ \int dV \sum_{\rho, \sigma} \bar{\psi}_{\sigma}^{\nu, P, \tau} e^{2\pi i/c \cdot \nu_0 z} \left\{ \begin{matrix} \alpha_1(\sigma, \rho) \\ \alpha_2(\sigma, \rho) \end{matrix} \right\} \psi_{\rho}^0 \right\} \left\{ \int dV \sum_{\rho, \sigma} \bar{\psi}_{\sigma}^e e^{-2\pi i/c \cdot \nu_0 z} \alpha_1(\sigma, \rho) \psi_{\rho}^{\bar{\nu}, P, \tau} \right\} \right] \right\}. \end{aligned} \quad (11)$$

If we use (2) and (7) this gives us

$$\begin{aligned} \sum &= 0 \text{ for } \boldsymbol{\varepsilon}' \parallel x \\ \sum &= (-i/2\nu_0)(1 + e^{2\pi i(\gamma - \delta)}) \text{ for } \boldsymbol{\varepsilon}' \parallel y. \end{aligned} \quad (12)$$

From this we conclude that the probability of an emission is proportional to the square of the sine of the angle between the electric vectors of the two quanta.

Now there are $2\nu_0^2(V/c^3)$ components of the radiation field per unit solid angle per unit frequency about ν_0 ; the direction of propagation of one quantum can vary over a hemisphere; but when this is fixed polarization, frequency and direction of propagation of the other quantum are determinate. Thus we get the total chance of an emission at time t by integrating the absolute value of the square of ϕ (averaged over γ and δ) over a hemisphere of solid angle and all frequencies, and multiplying by $2\nu_0^2(V/c^3)$; thus

$$\begin{aligned}
\sum_{p, \epsilon} \int d\gamma \int d\delta |\phi(p, \epsilon, -p, \epsilon'; c)|^2 \\
= \frac{4\pi\nu_0^2 V}{c^3} \frac{e^4 c^4 \cdot 4\pi^2}{h^2 \nu_0^2 V^2} \frac{1}{2\nu_0^2} \int_0^\infty \frac{d\nu |1 - e^{4\pi i(\nu - \nu_0)t}|^2}{4(\nu - \nu_0)^2} \\
= t \cdot \frac{16\pi^4 e^4 c}{h^2 \nu_0^2 V} \int_{-\infty}^\infty \frac{1 - \cos x}{x^2} dx \\
= t \cdot \frac{16\pi^5 e^4}{m^2 c^3 V}.
\end{aligned} \tag{13}$$

The mean life time of an electron in a proton density of n_P protons per unit volume is thus

$$T = \frac{m^2 c^3}{16\pi^5 e^4 n_P} \sim \frac{5 \times 10^{10}}{n_P} \text{ sec.} \tag{14}$$

It should be observed that the retention of the terms for $\bar{\nu} = -2^{1/2}\nu_0$ in the expression (11) for \sum , may be justified by an argument similar to that used by Dirac to validate the scattering formulae. For although the electron cannot jump to this state of negative energy, because it is already filled, there is a double transition which gives just the same terms in \sum , and in which first a negative electron in the state $(-2^{1/2}\nu_0, P, \tau)$ jumps to a state near the state (0), and then the original positive electron jumps down from the state (0) to the state $(-2^{1/2}\nu_0, P, \tau)$; in either transition either of the two quanta may be emitted.

If we try to correct (13) to take account of the fact that the energy radiated should be $(m + M_P)c^2$ and not $2mc^2$, we get in place of (14)

$$T' = \frac{(m + M_P)^2 c^3}{64\pi^5 e^4 n_P} \sim \frac{5 \times 10^{16}}{n_P} \text{ sec.} \tag{15}$$

Both (14) and (15) give an absurdly short mean life time for matter. With $n_P = 10^{25}$ we get

$$T \sim 5 \times 10^{-15}; \quad T' \sim 5 \times 10^{-9}.$$

Of course the protons and electrons of matter are not in general free, nor uniformly distributed, nor at rest. But we should hardly expect their agglomeration into nuclei, or even atoms, to reduce appreciably the mean transition probability, since this would mean essentially an increase in the effective n_P to be used. In any case (14) or (15) should apply roughly to electrons and protons in a discharge tube.

II

In their paper on the relativistic treatment of the interaction of radiation and matter, Heisenberg and Pauli point out that according to their theory the radiationless transitions of the quantum mechanics may always be expected

to be accompanied by transitions which correspond to a change in the material system and the emission of at least one quantum of light.³ So, for example, in the Auger jumps, in the ionization of an atom in an electric field, in the capture of electrons by alpha-particles, and in the radioactive decay of nuclei, the energy of the liberated particles should show a certain diffuseness; and energy is only conserved by the emission of an appropriate continuous distribution of light. Heisenberg and Pauli derive an expression for the probability of such transitions involving radiation; they show that this probability is small, compared with that of the radiationless transitions, of the order

$$e^2/hc (v/c)^2.$$

They apply this result to the problem of radioactive disintegration, where the escape of the alpha and beta particles may be roughly schematized as a diffusion through a high wall of potential energy; and they obtain so an explanation of the sharp definition of the energies of alpha-particles, and the great diffuseness of the beta spectrum. The non-appearance of the gamma radiation, which, on this theory, should accompany beta-ray disintegration, remains unexplained.

In this note we shall compute the relative probability of such radiative transitions on the basis of the Dirac radiation theory. For this probability we obtain an expression which, in the approximation to which the calculations of H. P. were carried, should agree with the results of that calculation. In our formula certain terms appear which were deliberately neglected in H. P.; and further this formula is applicable to a slightly more general group of problems than that of H. P., which cannot strictly be applied to any of the problems mentioned above except that of the Auger jumps; but except for these minor modifications our result reduces to that of H. P.; and it gives the same predictions when applied to the theory of radioactive disintegration. The present work is rather simpler than that on the basis of the more general theory.

For the occurrence of radiationless transitions it is essential that the material system (and we shall call this the "atom") be in a quasistationary state of an energy equal to the energy of some aperiodic motion of the system. Let the wave equation for the atom,—which may be written in the configuration space, and without explicit reference to the radiation field, to the order $(v/c)^2$ —be

$$(H - h\nu)\psi_v = 0. \quad (16)$$

Let the initial state have the energy

$$E_0 = h\nu_0 \quad (17)$$

and be given by a wave packet which satisfies the equation

$$(H - V - h\nu_0)\psi_0 = 0. \quad (18)$$

³ W. Heisenberg and W. Pauli, *Zeits. f. Physik* **56**, 1 (1929); cited as H. P.

The wave packets for the quasistationary aperiodic states of the atom we call θ_ν ; they satisfy

$$(H - V' - h\nu)\theta_\nu = 0; E = h\nu \quad (19)$$

and shall be normalized to $d\nu$. Then the probability of a radiationless transition to the continuum is given, to the first order in the small quantity λ_0/ν_0 , by

$$\lambda_0 = 4\pi^2/\hbar^2 |V_{\nu_0}|^2; V_{\nu_0} = \int d\tau \delta_{\nu_0} V \psi_0. \quad (20)$$

(The integral over $d\tau$ is to be taken over the configuration space of the atom.)

Now let there be no radiation present initially. Since the atom has energy levels lower than E_0 , it can make radiative transitions to these states; Dirac's radiation theory gives us, for the probability per unit time per unit frequency ν_s of the radiation, for this transition

$$\lambda_s d\nu_s = 16\pi^2 \nu_s d\nu_s / 3\hbar c^3 | \dot{P}_{\nu_0-\nu_s, 0} |^2$$

with

$$\dot{P}_{\nu_0-\nu_s, 0} = \int d\tau \bar{\theta}_{\nu_0-\nu_s} \dot{P} \psi_0 \quad (21)$$

where \dot{P} is the time rate of change of the electric moment of the atom. (With Dirac's linear Hamiltonian for the electron it will be

$$\sum_R e_k \mathbf{a}^k$$

where e_k is the charge on the k 'th particle, and the \mathbf{a}^k s are the Dirac matrices, and the summation is to be taken over all particles.)

Now when V is not very small, (21) gives us only a very poor approximation for the probability of the corresponding transitions. Somewhat inaccurately we may say that the system can reach the same final state by a double jump, in which, e.g., the atom goes over into some arbitrary state in the continuum, and then—but there is no interval between the jumps,—jumps to the final state and emits a quantum. In this process of course only the total energy of the system is conserved, and that only when one considers the double jump as a single process. This is the effect treated by H. P.; and to obtain it we have only to carry the perturbation theory a step farther than was necessary for the derivation of (20) and (21).

The Dirac wave equation for the probability amplitude ϕ for the whole system, taken as a function of the state, which for brevity we describe by the single index ν , of the atom, and the number $N_{\nu s}$ of quanta of frequency ν_s , polarization p , and given direction of propagation, is

$$\begin{aligned}
- h/2\pi i \cdot \partial/\partial t \phi(\nu, N_{sp}) &= \sum_{\nu' N'_{sp}} H(\nu, N_{sp}; \nu' N'_{sp}) \phi(\nu', N'_{sp}) \\
&= \int d\nu' V'_{\nu\nu'} \phi(\nu', N_{sp}) + V_{\nu 0} \phi(0, N_{sp}) \\
&+ \int d\nu' \sum_{s' p'} N_{s' p'}^{1/2} \nu_{s' p'}^{1/2} (\mathbf{e}_{s' p'} \cdot \dot{\mathbf{P}}_{\nu\nu'}) \phi(\nu', N_{sp} - \delta_{ss'} \delta_{pp'}) \\
&+ \int d\nu' \sum_{s' p'} (N_{s' p'} + 1)^{1/2} \nu_{s' p'}^{1/2} (\mathbf{e}_{s' p'} \cdot \dot{\mathbf{P}}_{\nu\nu'}) \phi(\nu', N_{sp} + \delta_{ss'} \delta_{pp'})
\end{aligned} \quad (22)$$

with

$$\kappa_{sp} = h/2\pi c^3 \sigma_{sp}.$$

Here σ_{sp} is the number of components of the radiation field of given polarization per unit frequency about ν_s per unit solid angle for the direction of propagation; and \mathbf{e}_p is a unit vector parallel to the electric vector of the component sp . The summation \sum_{sp} , and the product \prod_{sp} infra, are to be taken over all the components of the field.

If we take for our initial conditions for ϕ

$$\begin{aligned}
\phi(\nu, N_{sp}) &= 0 \\
\phi(0, N_{sp}) &= \prod_{sp} \delta(N_{sp}, 0) e^{-2\pi i \nu_0 t}
\end{aligned} \quad (23)$$

and put these values in (7), we find in first approximation

$$\begin{aligned}
\phi_1(\nu, N_{sp}) &= \prod_{sp} \delta(N_{sp}, 0) V_{\nu_0} \frac{e^{-2\pi i \nu t} - e^{-2\pi i \nu_0 t}}{h(\nu - \nu_0)} \\
&+ \sum_{s' p'} \delta(N_{s' p'}, 1) \prod_{s'' p''} \delta(N_{s'' p''}, 0) \nu_{s' p'}^{1/2} \nu_{s'' p''}^{1/2} (\mathbf{e}_{s' p'} \cdot \dot{\mathbf{P}}_{\nu\nu_0}) \frac{e^{-2\pi i (\nu + \nu_{s'}) t} - e^{-2\pi i \nu_0 t}}{h(\nu + \nu_{s'} - \nu_0)}
\end{aligned} \quad (24)$$

In Π' the factor for $s'' = s'$, $p'' = p'$ is to be omitted.

If one puts this expression (24) for ϕ_1 in (22), integrates the equation to obtain the second approximation $\phi_2(\nu, N_{sp})$, and takes the sum over all components of the field

$$\sum_p \int d\nu_s \int d\omega_s |\phi_2(\nu, 1_{sp})|^2,$$

this gives the probability that the system has, at time t emitted a quantum of frequency near $\nu_s = \nu_0 - \bar{\nu}$, and made a transition to a state in the continuum of energy near $h\bar{\nu}$. The coefficient of t in this expression gives the transition probability for transitions to a state in the range $\bar{\nu}$ to $\bar{\nu} + \Delta\bar{\nu}$:

$$\lambda_s(\bar{\nu}) \Delta\bar{\nu} = \frac{16\pi^2 \nu_s \Delta\bar{\nu}}{3c^3 h^3} \left| h \dot{\mathbf{P}}_{0\nu} - \int \frac{d\nu' V_{0\nu'} \dot{\mathbf{P}}_{\nu'\bar{\nu}}}{\nu_0 - \nu'} - \int \frac{d\nu' \dot{\mathbf{P}}_{0\nu'} V'_{\nu'\bar{\nu}}}{\bar{\nu} - \nu'} \right|^2. \quad (25)$$

The first term in the bracket is the direct emission given by (21) and neglected by H. P.; the remaining terms differ from those of H. P. (132) only by having

V' in place of V . When ψ_0 and θ_v are characteristic functions of the same equation, these terms reduce to those given in H. P.

It should be observed that both (25) and H. P. (132) are derived as approximations; in particular, the momentum of the light quantum, and terms of higher order in v/c , are neglected in both computations. The retention of this momentum leads to the same modification in (25) and H. P. (132); and so does the retention of terms of the fourth order in v/c . But in higher orders only the method of H. P. can be used, since then no equation of the form (16) holds for the atom, and it is necessary to work directly from the more general equations of quantum electrodynamics, and take more complete account of the retardation of the forces between the particles of the atom.

To obtain the order of magnitude of the total radiative transition probability for radioactive disintegrations, we may observe that V and V' may be expected to be of the same order of magnitude as $h\nu_0$, and we integrate (25) for all frequencies ν_s up to ν_0 ; this gives

$$\lambda_s = \int_0^{\nu_0} \lambda_s(\bar{\nu}) d\bar{\nu} \sim v^2 \nu_0^2 e^2 / c^3 h \left| \int d\tau \bar{\theta}_v \psi_0 \right|^2. \quad (26)$$

The ratio of this to (20) gives the relative probability that radiation will be emitted in the disintegration:

$$\lambda_s / \lambda_0 \sim e^2 / hc \cdot (v/c)^2 \quad (27)$$

in agreement with H. P. (133). From (25) it is clear that only a much more detailed knowledge of θ_v and ψ_0 and of the form of the Hamiltonian H in (16) than is at present available can give us any precise value for λ_s / λ_0 .

The application of (27) enables us to estimate the relative probability of radiative and radiationless capture of electrons from atoms by an alpha particle, and gives for the ratio of the probabilities 10^{-6} , in agreement with the more detailed calculations of the effect.

BOUNDARY CONDITIONS AND THE MEANING OF WAVE GROUPS IN WAVE MECHANICS

BY H. A. WILSON

RICE INSTITUTE, HOUSTON, TEXAS

(Received January 29, 1930)

ABSTRACT

Reasons are given for believing that the boundary conditions at a discontinuity in the potential (V) in wave mechanics may be $\phi_1 = \phi_2 \mu^{1/2}$ and $\phi_1 d\phi_1/dx = \phi_2 d\phi_2/dx$. Here ϕ is the wave function and μ the ratio of the group velocities. With these boundary conditions the waves are either completely transmitted or completely reflected according as the energy E is greater or less than V . The particles therefore need not be supposed to enter the region in which $V > E$ where their velocities would be imaginary and their kinetic energies negative. It is suggested that the group of waves associated with a particle should be identified with the particle and that the energy and momentum of the particle are the energy and momentum of the group of waves. When the group is stopped or absorbed it contracts to small dimensions and so becomes a particle.

IN THE applications of wave mechanics to the theory of thermionics and of the disintegration of atomic nuclei the boundary conditions at a discontinuity in the potential have been considered and it is customary to suppose that the wave function ϕ and its first derivative must be continuous at the discontinuity.

Consider the case of a particle with energy E moving along x in the positive direction and suppose that its potential energy is zero for $x < 0$ and equal to V' for $x > 0$ so that there is a discontinuity in the potential at $x = 0$. The usual wave equations in this case are

$$\begin{aligned} \frac{d^2\phi}{dx^2} + k^2 E \phi &= 0, & x < 0 \\ \frac{d^2\phi}{dx^2} + k^2 (E - V') \phi &= 0, & x > 0. \end{aligned}$$

As a solution we may take, as usual, when $E > V'$,

$$\begin{aligned} \phi_1 &= a e^{-ikE^{1/2}x} + b e^{ikE^{1/2}x}, & x < 0 \\ \phi_2 &= c e^{-ik(E-V')^{1/2}x}, & x > 0. \end{aligned}$$

To determine b and c in terms of a it is usual to suppose that $\phi_1 = \phi_2$ and $d\phi_1/dx = d\phi_2/dx$ at $x = 0$. We then get $b = a(1 - \mu)/(1 + \mu)$ and $c = 2a/(1 + \mu)$ where $\mu = [(E - V')/E]^{1/2}$ which is equal to v_2/v_1 where v_1 is the group velocity for $x < 0$ and v_2 that for $x > 0$.

The condition $\phi_1 = \phi_2$ at $x = 0$ gives $a + b = c$. This equation is not obviously correct. Consider two points A and B one at $x = -d$ and the other at $x = +d$. Since there is a discontinuity in the potential at $x = 0$, so that the group velo-

city v_1 for $x < 0$ changes to v_2 for $x > 0$, it is not clear that the chance that the particle is in an element dx at A should become equal to the chance that it is in a dx at B as d is diminished indefinitely. This is so because A and B are on opposite sides of the discontinuity even when $d = 0$.

To determine the correct boundary conditions at $x = 0$ we may begin by considering a case in which the potential varies gradually from 0 to V' near $x = 0$ and then make the distance in which the change from 0 to V' takes place small.

Let a train of waves moving along x in the positive direction be represented by $\phi = A e^{-ikB}$ where A and B are functions of x which we shall suppose to be real quantities. ϕ must satisfy the wave equation

$$\frac{d^2\phi}{dx^2} + k^2(E - V)\phi = 0$$

where E is the total energy and V the potential energy of the particle. Substituting the above value of ϕ in this equation we get

$$\frac{1}{A} \frac{d^2A}{dx^2} - k^2 \left(\frac{dB}{dx} \right)^2 - ik \left(\frac{d^2B}{dx^2} + \frac{2}{A} \frac{dA}{dx} \frac{dB}{dx} \right) + k^2(E - V) = 0$$

Hence we must have $d^2B/dx^2 + (2/A) (dB/dx) (dA/dx) = 0$ which gives $C = A^2 dB/dx$ where C is a constant. It will be noted that this result is exact not merely an approximation. Also

$$\frac{1}{A} \frac{d^2A}{dx^2} - k^2 \frac{c^2}{A^4} + k^2(E - V) = 0. \quad (1)$$

Now let $A = A_1 + (A_2 - A_1)/(\epsilon^{-\alpha x} + 1)$ where α is a positive constant. This makes $A = A_2$ where αx is large and positive and $A = A_1$ where αx is large and negative. Thus A changes from A_1 to A_2 in the region near $x = 0$ and if we suppose α to become infinite then we shall have $A = A_1$ for $x < 0$ and $A = A_2$ for $x > 0$.

Substituting this value of A in (1) and putting $c = A_1^2 E^{1/2}$ we get

$$V = \frac{\alpha^2(A_2 - A_1)(\epsilon^{-\alpha x} - 1)\epsilon^{-\alpha x}}{k^2(A_2 + A_1\epsilon^{-\alpha x})(1 + \epsilon^{-\alpha x})^2} + E \left\{ 1 - \left(\frac{A_1(1 + \epsilon^{-\alpha x})}{A_2 + A_1\epsilon^{-\alpha x}} \right)^4 \right\}.$$

According to this when αx is large and negative then $V = 0$ and when αx is large and positive then $V = E \{ 1 - (A_1/A_2)^4 \} = V'$.

Thus if α is supposed large this solution of the wave equation gives the variation of A with x when the potential changes rapidly near $x = 0$ from the constant value zero when x is negative to the constant value V' when x is positive.

The value of B can be found if desired since $C = A^2 dB/dx$ but since $\phi \bar{\phi} = A^2$ it is not required.

Put $\alpha^2 = \beta k^2 E$ where β is a constant and also let $y = \epsilon^{-\alpha x}$. The expression for V above then becomes in the case when $A_2 = 2A_1$.

$$V = E \left\{ \frac{\beta y(y-1)}{(2+y)(1+y)^2} + 1 - \left(\frac{1+y}{2+y} \right)^4 \right\}$$

¹ An approximate result equivalent to this is well known.

The expression $y(y-1)/(2+y)(1+y)^2$ has a maximum value equal to about 0.08 when $y=3.3$. $\{(1+y)/(2+y)\}^4$ is then about 0.4 so that β may be made equal to 4 without danger of V becoming greater than E . Fig. 1 shows the variation of A with $2kE^{1/2}x$ when $A_2=2A_1$ and $\beta=4$. Fig. 2 shows the corresponding variation of V/E with $2kE^{1/2}x$ and Fig. 3 shows the variation of V/E with $2(2)^{1/2}kE^{1/2}x$ with $\beta=8$. In Fig. 3 V/E becomes greater than unity.

It appears that, in this case, with $\beta=4$, practically all the changes in A and V takes place in a range of $2kE^{1/2}x$ equal to about 5. Thus if d denotes the thickness of the layer in which the potential changes then we have $d=5/2kE^{1/2}$. For electrons $k=4\times 10^{13}$ and $E=1.6\times 10^{-12}P$ where P is the potential difference in volts equivalent to E . Hence $d=5\times 10^{-8}/P^{1/2}$. The wave-length λ of the waves associated with an electron is given by $\lambda=12.25/P^{1/2}$ so that $d=0.4\lambda$. Thus if $P=10$ volts then $d=2\times 10^{-8}$ cm and if $P=1$ volt then $d=5\times 10^{-8}$ cm. In the case considered V' is equal to $15E/16$. It appears that the potential does not become greater than E in a layer similar to those on the surface of metals for which V' is about 10 volts and d about 5×10^{-8} cm.

Fig. 1.

Fig. 2.

Fig. 3.

When V' is equal to $15E/16$ then the ratio of the group velocities $\mu = v_2/v_1 = \frac{1}{4}$ so that $b = a(1-\mu)/(1+\mu)$ is equal to $3a/5$. Hence $b^2a^2 = 9/25$ so that $9/25$ of the electrons should be reflected back if the boundary conditions $\phi_1 = \phi_2$ and $d\phi_1/dx = d\phi_2/dx$ are correct. But as we have just seen when V changes from 0 to $15/16$ of E in a distance of about half a wave-length there is no reflection. This suggests that the boundary conditions should be modified so as to make the reflection zero when $E > V'$.

The equation $V' = E\{1 - (A_1/A_2)^4\}$ gives $A_2/A_1 = (v_1/v_2)^{1/2}$ or $A_2 = A_1\mu^{1/2}$.

For $x < 0$ let $\phi_1 = a\epsilon^{-ikE^{1/2}x}$ so that $A_1 = a$ and $B = E^{1/2}x$. It then follows that for $x > 0$ $\phi_2 = (a/\mu^{1/2})\epsilon^{-ik(E-V')^{1/2}x}$.

It appears therefore that in the equations

$$\phi_1 = a\epsilon^{-ikE^{1/2}x} + b\epsilon^{+ikE^{1/2}x}$$

$$\phi_2 = c\epsilon^{-ik(E-V')^{1/2}x}$$

we must have $b=0$ and $c=a/\mu^{1/2}$, if there is no reflexion when V' is less than E .

According to this the boundary condition $\phi_1 = \phi_2$ at $x=0$ must be replaced by $\phi_1 = \phi_2 \mu^{1/2}$. The condition $d\phi_1/dx = d\phi_2/dx$ cannot then be correct. Since the number of particles falling on the surface at $x=0$ must be equal to the number leaving it we must have $a^2 v_1 = b^2 v_1 + c^2 v_2$ or $a^2 - b^2 = c^2 \mu$. The condition $\phi_1 = \phi_2 \mu^{1/2}$ gives $a + b = c \mu^{1/2}$ so that $a - b = c \mu^{1/2}$. This requires that $\mu^{1/2} d\phi_1/dx$ should be equal to $d\phi_2/dx$ or that $\phi_1 d\phi_1/dx = \phi_2 d\phi_2/dx$. This suggests that the correct boundary conditions at the discontinuity may be $\phi_1 = \phi_2 \mu^{1/2}$ and $\phi_1 d\phi_1/dx = \phi_2 d\phi_2/dx$. These conditions give $a + b = c \mu^{1/2}$ and $(a+b)(a-b) = c^2 \mu$. These equations have two solutions which are $b = 0$ and $c = a/\mu^{1/2}$ and $c = 0$ and $b = -a$. The first solution as we have seen is the one to use when $E > V'$ so that then $\phi_1 = a e^{-ikE^{1/2}x}$, $\phi_2 = (a/\mu^{1/2}) e^{-ik(E-V')^{1/2}x}$ so that all the particles go through the plane $x=0$ exactly as in classical theory. The other solution is clearly the one to use when $V' > E$ so that then $\phi_1 = a e^{-ikE^{1/2}x} - a e^{ikE^{1/2}x}$, $\phi_2 = 0$ so that all the particles are reflected back at $x=0$ exactly as in classical theory.

Thus if the boundary conditions at a discontinuity are $\phi_1 = \phi_2 \mu^{1/2}$ and $\phi_1 d\phi_1/dx = \phi_2 d\phi_2/dx$ then when $V' > E$ the waves are reflected completely at the discontinuity so that the particles need not be supposed ever to enter the region in which $V' > E$ where their kinetic energy is negative. This seems to the writer to be a very strong argument in favor of these boundary conditions.² It is very difficult to imagine any sort of physical meaning which can be attached to the idea of a particle with an imaginary velocity and a negative kinetic energy.

The writer now proposes to bring forward some considerations with regard to the nature of wave groups in wave mechanics. The view proposed is perhaps unorthodox and may not meet with approval but it seems to the writer to be worth considering.

It was originally suggested by Schroedinger that the wave function ϕ could be interpreted by supposing that the density of the electricity is proportional to $\phi \bar{\phi}$. This view has been replaced, at least in many cases, by the idea that the chance that an electron is in an element of volume dv is proportional to $\phi \bar{\phi} dv$. According to the original idea the electron in standing waves was at rest but was spread out over the whole volume occupied by the waves. A moving electron was spread out over a moving group of waves. According to the later view the electron is presumably somewhere in the standing waves or group but its location and motion, if any, are unknown. According to the first view the electron when it appears somewhere as a minute particle must have contracted from its state of diffusion over the waves. This necessary contraction seems to me to be of fundamental importance, as will be explained below.

Although according to the present view the motion of an electron in standing waves cannot be determined it seems to the writer to be nevertheless allowable to suppose that it must move from one point to another,

² Nordheim (Proc. Roy. Soc. A December 3, 1928) concludes that practically all the electrons having $E > V'$ escape from a metal because of the effect of the image forces in rounding off the discontinuity.

when it does move, along some definite path. That is, it will not do to suppose that it disappears at one point and appears at another without occupying the intermediate positions.

Another possible view, very similar to Schroedinger's original suggestion, is that the group of waves and the electron are identical and that when the group is stopped or absorbed and appears at a point the group of waves contracts to small dimensions and so becomes a particle.

If we suppose that a particle is associated with or is a group of waves of length l then it is easy to show that l diminishes when the velocity v of the group diminishes. This idea is not new but it does not seem to have attracted much attention.

According to Heisenberg's uncertainty principle we have $\delta E \delta t = h$, roughly at least, where δE is the uncertainty in the energy of the particle and δt that in its time of passing a given point. If v is the group velocity then we have $\delta t = l/v$ and since $E = h\nu$ where ν is the frequency of the waves we get $l = v/\delta\nu^2$ where $\delta\nu$ is the uncertainty in the frequency ν . There seems to be no reason to suppose that δE or $\delta\nu$ should vary as the group moves along so that we may conclude that the group length l should be approximately proportional to the group velocity v . Thus if the group enters a field of force in which it is gradually slowed down we should expect l to become smaller and to become very small on a surface where the group velocity is zero. It does not become zero at this point because owing to the uncertainty in E there is some uncertainty in the position of the surface in question.

Darwin's solution⁴ of the motion of a group in a uniform force field does not indicate such a variation of l which must mean that his solution involves a variation of $\delta\nu$ with v so that $v/\delta\nu$ remains constant or rather only varies to the extent demanded by the uncertainty in v . It seems to the writer that $\delta\nu$ should be supposed constant and so l should vary with v . Thus when a group is brought to rest it becomes very small or we may say that it becomes a particle. If preferred we may say that the group contracts onto the particle in it which is so located in a nearly definite position when the group stops. According to this we should expect the group and particle to come to rest approximately on a surface at which $E - V = 0$ and so either to remain on such a surface or else to move back into the region where $E > V$. We should not expect the particle to penetrate into the region where $V > E$ where its kinetic energy would be negative. It seems to the writer that this is as it should be. When a mathematical theory indicates that particles in a certain region would have imaginary velocities and negative kinetic energies then the proper conclusion to draw is that the particles do not go into that region. Of course when there is uncertainty in E then the position of the surface $E - V = 0$ is subject to a corresponding uncertainty. This conclusion is supported by the results obtained above on the motion of electrons through a discontinuity or near discontinuity in the

³ This result is given by H. T. Flint, Proc. Roy. Soc. A, December 2, 1929.

⁴ Darwin, Proc. Roy. Soc. A, December 1, 1927.

potential. The electrons and the waves also are probably reflected unless $E > V'$.

Bridgman's suggestion that the negative sign on the kinetic energy of particles inside the region where $V > E$ is merely the "bar sinister" on particles which have got in improperly is similar to Rutherford's suggestion that particles somehow leak through a potential hump although they have not got enough energy to get over it. In my opinion it is better to suppose that they do not get into regions where $V > E$ in any case.

It seems worth while to point out that the conclusion that particles can enter regions in which $V > E$ may be due to the assumption that the energy E can have a definite value with zero uncertainty. It seems probable that there should always be some uncertainty in E so that any one particular solution of the wave equation $\Delta\phi + k^2(E - V)\phi = 0$ for an exact value of E does not really represent a possible state of things. Such solutions correspond to a group of waves of infinite length, since $l = \hbar v / \delta E$, and if the group is really of finite length then they are merely approximations. When the region occupied by the waves is of atomic dimensions the group may be long enough to overlap itself many times and so the solution for a group of infinite length is a good approximation. But there should be some uncertainty in E so that the particle may have enough energy to go through the surface $E - V = 0$ of the approximate solution⁵ without its kinetic energy becoming negative.

Consider the case of an electron moving normally between two parallel plane surfaces at which it is reflected back. As in the theory of the discontinuity with $V' > E$, if we suppose the group length to be infinite, we may take $\phi\bar{\phi} = 4a^2 \sin^2 kE^{1/2}x$. Thus we have nodal planes half a wave-length apart on which $\phi\bar{\phi} = 0$. The distance between the parallel reflectors must be a multiple of the half wave-length. The chance that the electron is between any pair of adjacent planes is then $\lambda/2 d$ where d is the distance between the reflectors. We do not know where the electron is but it is supposed to be moving backwards and forwards between the reflectors with uniform velocity v . It is therefore supposed to pass through the nodal planes one after another. But on these planes $\phi\bar{\phi} = 0$ so that the chance that the electron is at any nodal plane is zero. It cannot therefore be supposed to be moving with uniform velocity and so passing through the nodal planes.⁶ We may if we like suppose a large number of electrons present all having the same energy and so all having nodal planes in the same positions.

Wiener's experiments on standing light waves may be considered in this connection. The particles are then photons instead of electrons. He showed by means of a thin photographic film that there were nodal planes half a wave-length apart at which the film was unaffected. If the photons were moving towards and away from the mirror they would pass through the

⁵ The exact solution, of course, would be the sum of a number of the solutions for particular values of E each multiplied by a suitable factor.

⁶ The argument here is directed against the *assumption* that the electron is moving with uniform velocity v .

film whatever its distance from the mirror and so the film would be equally affected at any distance. The fact that the film is affected between the nodal planes shows that the photons get there but the fact that it is not affected on the nodal planes shows that the photons do not pass through the nodal planes.

In the opinion of the writer, if the idea that a group of waves contains a particle is retained, then these considerations about standing waves make it necessary to suppose that in standing waves the particle is at rest. This amounts to a partial return to Schroedinger's original idea. In the case of a large number of particles being reflected normally we must suppose that they are arranged in layers between the nodal planes. The way in which such an arrangement could be brought about can be easily imagined.

Consider a group of waves of length l containing one particle⁷ and suppose that the particle is at a distance d from the front of the group. If the group is reflected normally the reflected waves will meet the particle when it is at a distance $d/2$ from the mirror. The particle will then stop since it is in standing waves and it will remain stopped for a time $(l-d)/v$ and will then move away with the reflected waves. According to this the waves must convey the momentum $2mv$ which the particle loses to the mirror. It is therefore necessary to suppose that the waves of wave mechanics are not merely waves of probability but that they are real physical waves which can convey energy and momentum. In fact it would seem to be best to regard the energy and momentum of a particle as the energy and momentum of its group of waves. When the group is stopped the energy and momentum appear on the particle or the group becomes a particle.

It will be observed that according to this when a particle is reflected back at a discontinuity in the potential in which $V' > E$ the particle does not get to the discontinuity at all unless it happens to be exactly at the front of its group of waves.⁸ Hence even if we suppose that the waves do penetrate through the discontinuity with amplitude falling off exponentially on the other side the particle need not be supposed ever to go through. For example we might suppose that the particle is always located at the crest of a wave and so is never exactly at the front of the group.

To represent a moving particle it is necessary to have a moving group of waves. Standing waves do not represent moving particles. Any solution of the equation $\Delta\phi + k^2(E - V)\phi = 0$ which represents standing waves may be said to be a group of waves at rest. For example when an electron is captured by a proton the group of the electron may be said to form the waves of the resulting hydrogen atom. The electron group contracts to atomic dimensions in this case. The electron group is of finite length and so must have uncertainty in its energy which should persist in the energy of the atom formed.

⁷ Particle here may mean either electron or photon. The groups associated with photons are of finite length which indicates uncertainty in the frequency and energy just as for electrons.

⁸ The particle is supposed to be somewhere in its group. To assume that it is at a distance d from the front of the group does not involve the assumption that d can be determined experimentally.

The standing waves may be said to be the particle but if it is desired to suppose that there is a particle somewhere in the standing waves then since it should be at rest it seems natural to suppose that it is on the surface $E - V = 0$ or else in a region where V is constant. If the particle remains at rest on the surface $E - V = 0$ or anywhere in a field of force it cannot be supposed to be acted on by the field of force. It is therefore necessary to suppose that fields of force do not act directly on the particles but merely alter the wave velocity. This of course is implied by the accepted method in wave mechanics which is to calculate the effect of the force field on the waves and not on the particles.

According to what has been said above the waves should not be supposed to go into the regions where $V > E$ but should be reflected at the surface $E - V = 0$ or else it should be supposed that $\phi\bar{\phi}dv$ is only proportional to the probability that a particle is in dv when $E \geq V$ at dv . The integral $\int \phi\bar{\phi}dv$ should in this case be made equal to unity when taken only over the region in which $E \geq V$. A third alternative which seems to the writer very plausible is to suppose that the energy E has enough uncertainty in its value to account for the chance that the particle may be in the region where $V > E$. That is we suppose $E = E_0 \pm \delta E$ and if a particle is found where $V > E_0$ then δE is equal to $V - E_0$ at least.

The second or third alternatives seem at the moment to be the more acceptable but it may be worth while to mention that the energy levels of the hydrogen atom may be very simply obtained by supposing that spherical waves are reflected at the surface $E - V = 0$ and so form standing waves.

Since in the hydrogen atom the wave velocity is equal to $E/(2m(E + e^2/r))^{1/2}$ the time T required for spherical waves to move from the nucleus to a sphere of radius $-e^2/E$ and back is given by

$$T = 2 \int_0^{-e^2/E} \frac{[2m(E + e^2/r)]^{1/2}}{E} dr = -\frac{\pi e^2}{E} \left(\frac{2m}{-E} \right)^{1/2}.$$

We may suppose that $T = n/\nu$ where ν is the frequency of the standing waves and n is an integer and that $E = -h\nu$ so that $E = -2\pi^2 m e^4 / n^2 h^2$ as usual.

One of the difficulties in optical theory is to see how the energy and momentum of the waves can become concentrated at points when the light is absorbed. The view that the waves have no energy or momentum is not satisfactory because for example it is difficult to see how waves with no energy could be reflected by a mirror. Reflexion requires the electrons all over the surface of the mirror to oscillate with the frequency of the light. The hypothesis of virtual oscillators in the mirror is also very unsatisfactory. A similar difficulty is present in the wave theory of electrons. The waves are diffracted as though they had uniformly distributed energy but appear as electrons when absorbed. According to what has been said above this difficulty may be to some extent removed by supposing that the wave groups contract to small dimensions when stopped. This process of contraction is made possible by the increase in the wave velocity as the group velocity

diminishes. The wave velocity becomes infinite when the group velocity becomes zero so that the group can contract very rapidly as it stops. It seems reasonable to suppose that the same thing happens with light as with electrons. When light is moving in empty space the wave and group velocities are equal but in the intense fields inside atoms we may suppose that the group velocity is diminished and the wave velocity increased. It is nevertheless very difficult to imagine a group occupying many cubic feet to be absorbed by an electron. If it is supposed that when the photon in a group is slowed down the wave velocity all over the group becomes very large and infinite when the photon stops then it is possible to imagine a very large group to contract very rapidly onto the photon. Even if we admit such sudden group contractions to be possible great difficulties remain. For example we have to explain why some groups are reflected and others not and how a group can be reflected without giving up any energy to the mirror.

As we have seen above a group of waves associated with a particle of energy E is either completely transmitted or completely reflected at a discontinuity in the potential according as $E > V'$ or $E < V'$. This suggests that the group associated with a photon must be either completely transmitted or completely reflected by a mirror. If the energy and momentum of photons and electrons are in the wave groups associated with them then it is necessary to suppose that these groups never divide into two and so must be either completely reflected or completely absorbed. In the case of photons exceptions to this may be supposed possible since a single photon may be imagined to give rise to two or more photons having the same total energy as the original one. The classical theory of reflexion must then be supposed to give the probability that a wave group and its photon are reflected together and not merely the chance that the photon is reflected.

The view suggested is therefore that a particle such as a photon or electron is practically identical with the group of waves associated with it. The energy and momentum are spread out over the group and not concentrated at a point. When the group is stopped or absorbed it contracts to small dimensions and so becomes a particle. The group cannot be divided by reflexion or by passing through a small aperture in an opaque screen but must be either all stopped or all get through. The group of waves must be regarded as a material entity and wave theory must be regarded as an approximation in so far as it now seems to require wave groups to be divided by reflexion and other similar processes which do not involve any change of frequency.

The writer does not claim to have removed the difficulties in optical and mechanical wave theory but he hopes that the above discussion may help to make the serious nature of these difficulties clearer.

THE HEAT OF DISSOCIATION OF CARBON MONOXIDE

BY JOSEPH KAPLAN

UNIVERSITY OF CALIFORNIA AT LOS ANGELES

(Received January 15, 1930)

ABSTRACT

The author's method for calculating the heat of dissociation of nitrogen, has now been applied to carbon monoxide. For both N_2 and CO the method agrees with the best values obtained by other methods. Using the present value of 10.3 volts for the heat of dissociation of CO, the dissociation products of the molecule are discussed for several electronic levels. In this way it is shown that the recent value of 1.3 volts for the energy of the metastable 1D_2 state in oxygen, obtained by McLennan and Crawford, agrees best with the present work.

IN A short paper that appeared last March,¹ the writer has calculated the heat of dissociation of nitrogen and found it to be equal to 9.0 volts. In a paper on the determination of heats of dissociation by means of band spectra, Professor R. T. Birge² has called attention to the difficulty of determining definitely the most probable value of D for N_2 . At the same time however he has given what is in his opinion the best value of the heat of dissociation of N_2 and that value is 9.1 volts. Since the method used by the writer yielded a value which is in such good agreement with the one given by Birge, it will be of some interest to try the same method for some other molecule. One of the cases that is of immediate interest is that of carbon monoxide.

It is now generally recognized that the bands of the third positive group of carbon arise in transitions from the b to the a level, and that only the $v'=0$ progression has been observed.³ The same reason for the non-appearance of higher progressions can be given here as was given for the fourth positive group of nitrogen. If the value of ω_0x for the b level of CO is very large, then the heat of dissociation in that level will be very small and dissociation will occur when the total energy of the molecule in the b level is only slightly greater than its electronic energy. It may be that ω_0x is of such a magnitude that not even a single discrete vibrational state exists, in which the total energy of the molecule is less than the heat of dissociation.

If one uses the above reasoning as a basis, it is then possible to determine the heat of dissociation, since the products of dissociation from the b level have been theoretically predicted to be a normal carbon atom and a normal oxygen atom.⁴ It immediately follows that the heat of dissociation of CO is either equal to or only slightly greater than the electronic energy in the b level. This energy is equal to 10.35 volts, so that the heat of dissociation of CO must

¹ Kaplan, Proc. Nat. Acad. Sci. **15**, 226 (1929).

⁴ R. C. Johnson, Trans. Farad. Soc. **15**, 649 (1929).

be almost equal to 10.35 volts. It is interesting here to remark that the value given by Birge in his Faraday Transactions paper is equal to 10.3 volts. The agreement between the present method and the method used by Birge is extremely satisfactory. The fact, that the fourth positive group of N_2 and the third positive bands of CO are the two outstanding examples of bands for which there is only one v' progression, certainly indicates that the present explanation is worth consideration.

The new value of D will now be applied to a brief discussion of some recent ideas regarding carbon monoxide. Johnson has given a very extensive discussion of the carbon monoxide molecule in his Faraday Society paper, and in particular he has discussed tentatively the dissociation products from the various electronic states of the molecule.

If the present value of 10.3 volts is to be accepted then it follows that at least one of the dissociation products from the electronic states that lie above 10.3 volts, must be in an excited state. Using the formerly accepted value of 11.2 volts for D , Johnson has already made the above statement for the c level. In view of the present lower value for D , the same statement must now apply to the b' level, the dissociation products of which were predicted to be a normal carbon and a normal oxygen atom.

One of the most interesting levels, from the point of view of the ideas presented in this paper, is the F level. The value of ν_e for this level is 99,730 cm^{-1} and ω_0 and ω_0x are 1914 cm^{-1} and 198 cm^{-1} , respectively. The F level is thus an example of a molecular level having a very high value for ω_0x , as compared with the values of ω_0x for nearly all of the known molecular levels. Because of the large ω_0x , a linear extrapolation of the vibrational levels, associated with the F level, yields a small and probably a fairly accurate heat of dissociation. The heat of dissociation is equal to 0.57 volts and the total energy in the F level is 12.88 volts. The difference between this and the heat of dissociation yields 2.5 volts as the energy of the two products of dissociation. Since the products of dissociation from this level are predicted to be a 1D_2 carbon atom and a 1D_2 oxygen atom, the sum of the energies of 1D_2 in carbon and in oxygen must be equal to 2.5 volts and this is probably a fairly good estimate of the sum.

One other state that possesses a fairly high value of ω_0x is the B level and a linear extrapolation yields a value of 2.8 volts as the heat of dissociation for this level and a value of 3.2 volts for the energy of the dissociation products. This extrapolation is longer than the one for the F level and is undoubtedly less trustworthy, probably being too high. Once again the products of dissociation are predicted to be a 1D carbon and a 1D oxygen atom, so that if the assumption is made that the error in the extrapolation is about 25 percent then the lower value is not far from being correct. A 25 percent error in a linear extrapolation of the above magnitude is not unusual in the determination of heats of dissociation from band spectra.

Two values for the difference $^3P-^1D_2$ in oxygen have been suggested. One of these is about 1.95 volts, suggested independently by L. A. Sommer⁵

⁵ L. A. Sommer, *Zeits. f. Physik* 51, 451 (1928).

and the author,⁶ and the other is 1.3 volts, obtained by McLennan and Crawford.⁷ It is difficult, in view of the theoretical predictions regarding the F level, to accept the higher of the two values, because then the difference $^3P - ^1D_2$ in carbon would have to be only about 0.6 volts. A comparison of carbon with the spectroscopically similar atoms N^+ and O^{++} ⁸ makes such a low value highly improbable. On the other hand the 1.3 volt value of McLennan and Crawford is a very reasonable one, since that would make the 1D level of carbon possess a value of about 1.2 volts and this is much more reasonable than the lower one of 0.6 volts.

The main purpose of this paper has been to point out the fact that the assumption, that the b level is extremely anharmonic, yields a very good value for D . Consequently a more detailed discussion of evidence regarding the energy in the 1D_2 state of the oxygen atom would be out of place here and will be left for another communication.

THE BAND SPECTRUM OF SILVER CHLORIDE

BY BROOKS A. BRICE

NEW YORK UNIVERSITY, UNIVERSITY HEIGHTS

(Received March 10, 1930)

ABSTRACT

Analysis of vibrational structure. —The electronic band system of AgCl extending from $\lambda 3124$ to $\lambda 3400$ has been obtained in emission and absorption, the latter under high dispersion. A complete vibrational quantum analysis has been carried out, giving the following formula for the heads of the bands of the molecule $\text{Ag}^{107}\text{Cl}^{35}$:

$$\nu = 31574.4 + 275.0\nu' - 6.20\nu'^2 - 0.133\nu'^3 - 342.4\nu'' + 1.163\nu''^2.$$

The data give $\omega_e'' = 343.6 \text{ cm}^{-1}$, $\omega_e' = 281.0$, and $\nu_e = 31606.9 \text{ cm}^{-1}$. Vibrational quantum numbers have been assigned to Franck and Kuhn's data for AgBr and AgI.

Isotope effects. —The vibrational isotope effect was observed for both the Cl and the Ag atoms. The complete spectrum consists of four overlapping systems due to the four possible isotopic molecules. The order of magnitude of the isotope shift for the Cl isotope effect was 1 to 30 cm^{-1} ; for the Ag isotope effect, 1 to 4 cm^{-1} . The agreement of observed shifts with those calculated from the equations recently derived by Birge (not yet published) is close.

Energies and products of dissociation. The heats of dissociation of the AgCl molecule are $D_0'' = 3.11$ volts in the normal state, $D_0' = 0.31$ volt in the excited state. The energy of excitation of the atoms resulting by dissociation from the excited state is 1.10 ± 0.12 volt. This value can be explained if it is assumed that $^2D'$ states exist in Ag as in Cu and Au. It is concluded that the silver halides dissociate from the excited state into a silver atom in a $^2D'$ state and a halogen atom in the metastable $^2P_{1/2}$ state.

INTRODUCTION

THE spectrum of silver chloride vapor consists of a system of single-headed bands in the ultra-violet, all the bands being shaded toward the red. These bands were first obtained by Franck and Kuhn¹ in absorption and fluorescence. Their work was concerned chiefly with a study of the type of molecular binding of the silver halides AgI, AgBr, and AgCl. Their results indicate that these molecules are of the "atom-molecule" type, in contrast to the alkali halide "ion-molecule" type. AgCl gave only a discontinuous band spectrum, whereas AgBr and AgI each showed a single continuous spectrum in addition to bands. The heats of dissociation of AgI and AgBr were calculated from the long wave-length limit of the continuous spectrum assuming that the product of dissociation from the excited state were a normal silver atom and an excited halogen atom. The heats of dissociation were also found independently by extrapolation of the fluorescence series. But for AgCl no direct calculation was possible by either method. The authors were not able to assign vibrational quantum numbers for any of these band systems. No mention was made of an isotope effect.

¹ Franck and Kuhn, *Zeits. f. Physik*, **43**, 164 (1927); **44**, 607 (1927).

In the present research, a complete vibrational quantum analysis of the AgCl band spectrum has been made. Accurate determinations of the heats of dissociation of the molecule in both the normal and the excited states lead to new conclusions as to the products of dissociation of the silver halides. In addition, the vibrational isotope effect of both atoms simultaneously has been obtained.² This is the first time the silver isotope effect has been obtained in spectra.

EMISSION SPECTRUM

The silver chloride band spectrum was obtained in emission³ by viewing the region immediately above a long silver electrode covered with fused AgCl, in a high voltage discharge in hydrogen at about 1 mm pressure. Photographs were made with a quartz Hilger E2 spectrograph. The small number of bands appearing in emission permitted a ready assignment of vibrational quantum numbers. The heads of the following bands were obtained in emission: (0, 0), (1, 0), (0, 1), (1, 1), (2, 1), (1, 2), (3, 2), (2, 3), (3, 4). Of the bands recorded by Franck and Kuhn, those which do not fit into this assignment can be shown to belong to the fainter isotope molecule AgCl³⁷. In order to extend the observations of the isotope effect and to obtain accurate values for

SILVER CHLORIDE ABSORPTION

Fig. 1.

the heats of dissociation, it was considered worth while to photograph AgCl vapor in absorption under high dispersion.

ABSORPTION SPECTRUM

The absorption spectrum was obtained by passing white light from a tungsten quartz lamp through AgCl vapor. The salt was heated to about 900°C in an open quartz tube 2 ft long surrounded by an electric furnace. Photographs were taken using a 21 ft concave grating, giving a dispersion of 2.5 Å/mm in the first order and 1.3 Å/mm in the second order. The grating* is mounted according to Paschen in a temperature-controlled room. The photographs are reproduced in the accompanying plate. Photograph *A* shows the first order spectrum, *B* the second order; the enlargements *C* and *D* illustrate in more detail the isotope effect, showing the four heads composing each band. The comparison spectrum is that of an iron arc, the standard wave-lengths being taken from Kayser's Handbuch Vol. VII.

Table I gives the wave-lengths in air of the observed heads. The corresponding wave-numbers are corrected to vacuum by using Kayser's table. The values recorded are the mean of two independent measurements on a first order plate and one on a second order plate. The heads given by Franck and Kuhn are also recorded for comparison. It is evident that their measurements are from 3 to 10 cm⁻¹ too high.

VIBRATIONAL ANALYSIS

Throughout this paper the notation used will be as far as possible consistent with that proposed recently by Mulliken for the general theory of band spectra, and that proposed by Birge⁴ for the isotope theory. The *true* vibrational quantum number is integral, $v=0, 1, 2, \dots$; the *effective* quantum number is half-integral, $u=v+\frac{1}{2}$. Subscripts *e* refer to the vibrationless but impossible state for which $u=0$; subscripts 0 refer to the lowest possible vibrational state, for which $u=1/2$.

The possible energy levels of a non-rotating molecule are given by

$$G_u = \omega_e(u - x_e u^2 + y_e u^3 + \dots) \quad (1)$$

where ω_e is the mechanical vibration frequency for vanishingly small amplitude. The wave-numbers of the origins of the bands in the spectrum are

$$\nu = \nu_e + \omega_e'(u' - x_e' u'^2 + y_e' u'^3 + \dots) - \omega_e''(u'' - x_e'' u''^2 + y_e'' u''^3 + \dots) \quad (2)$$

where ν_e corresponds to the electronic energy change, and is defined as the origin of the band system. The classical vibration frequency is obtained from Eq. (1) by differentiation: $\omega_u = dG_u/du$. But experiment yields values of $\omega_{u+1/2}$, which is the spacing of the energy levels. From Eq. (1)

$$\omega_{u+1/2} = G_{u+1} - G_u = \omega_e u [1 - 2x_e(u + \frac{1}{2}) + 3y_e(u + \frac{1}{2})^2 + \dots] \quad (3)$$

* The Anderson grating used at present in this mounting is the property of Townsend Harris Hall, College of the City of New York.

⁴ R. T. Birge, unpublished work.

If the data are sufficient, a plot of the observed spacings $\omega_{u+1/2}$ against $u + \frac{1}{2}$ can be used to determine the constants of Eq. (2). The value of ω_u for any value of u can then be obtained from the resulting curve by interpolation or extrapolation. Eq. (2) will then represent the origins (or heads, in practice) of the observed bands.

It is found experimentally that for non-polar molecules the $\omega_u:u$ curve is linear for low values of u , and that extrapolation of the linear part to $u = u_0$ when $\omega_u = 0$ leads to a fairly reliable determination of the heat of dissociation.⁵ This gives $u_0 = \omega_e / 2x_e\omega_e$. Geometrically the heat of dissociation is given by the area under the $\omega_u:u$ curve:

$$D_e = \int_0^{u_0} \omega_u du = \frac{1}{2} \frac{\omega_e^2}{2x_e\omega_e} \quad D_0 = \int_{1/2}^{u_0} \omega_u du = \frac{1}{2} \frac{\omega_0^2}{2x_e\omega_e} \quad (5), (6)$$

Eq. (5) gives the heat of dissociation referred to the equilibrium state. Eq. (6) is the *true* heat of dissociation, referred to the lowest possible vibrational state. There will be a value D_0'' for dissociation by vibration from the normal state, and a value D_0' for the excited state.

Fig. 2 shows the observed heads of the most abundant molecule $\text{Ag}^{107}\text{Cl}^{35}$ arranged in the customary array which determines the true assignment of vibrational quantum numbers, and which yields the experimental values of $\omega_{u+1/2}''$ and $\omega_{u+1/2}'$. The intensity distribution here is characteristic of molecules having a small change in moment of inertia on electronic transition.

Fig. 3. u_u : u curves: A'' normal, A' excited state of $\text{Ag}^{107}\text{Cl}^{35}$; B'' normal, B' excited state of $\text{Ag}^{107}\text{Cl}^{37}$; C'' normal state of $\text{Ag}^{109}\text{Cl}^{35}$; E'' normal state of $\text{Ag}^{109}\text{Cl}^{37}$.

The equation representing the heads of the bands for the molecule $\text{Ag}^{107}\text{Cl}^{35}$, from Eq. (2) and the above data is:

$$\nu = 31574.4 + 275.0\nu' - 6.20\nu'^2 - 0.133\nu'^3 - 342.4\nu'' + 1.163\nu''^2 \quad (7)$$

The value of u'' for which the spacings of the levels becomes zero is $u_0'' = 148$. By Eq. (5), $D_e'' = 25390 \text{ cm}^{-1} = 3.13$ volts; by Eq. (6), $D_0'' = 3.11$ volts. The latter is the true heat of dissociation of the molecule $\text{Ag}^{107}\text{Cl}^{35}$. Its accuracy is estimated as ± 0.10 volt. This agrees closely with the value 3.1 volts taken from thermochemical data.*

For the excited state, extrapolation of the $\omega_u:u$ curve is somewhat uncertain. It is safe to assume however that a maximum value will be set by extrapolating a straight line drawn through the first three points. This gives $D_0' = 0.33$ volt. A lower limit may be set by calculating the area under the actual curve, using the empirical equation. This gives 0.28 volt. Hence we may take $D_0' = 0.31 \pm 0.02$ volt.

THEORY OF THE ISOTOPE EFFECT

The theory of the vibrational isotope effect, first formulated by Mulliken,^{5a} has recently been applied in a form more convenient for calculation of isotope shifts in bands of high vibrational quantum numbers by Gibson,⁶ Patkowski and Curtis,⁷ and R. T. Birge.⁴ Professor Birge has given a thorough discussion of the applicability of this method, and has kindly made his results available to the writer in advance of their publication. In the following, his notation will be followed, and some of his equations given. Superscripts i will refer to the "isotope" or less abundant molecule, while letters without superscript will denote the "main" or more abundant molecule.

The vibrational energy of a non-rotating molecule as given by Mulliken^{5a} is $G_u = f(u\mu^{-1/2})$ where $\mu = M_1M_2/M_1 + M_2$, the effective or reduced mass of the molecule, M_1 and M_2 being the relative masses of the two atoms composing the molecule. If an isotope of one of the atoms is present, the reduced mass of the isotope molecule is μ^i , and if we let $\rho = (\mu/\mu^i)^{1/2}$ the vibrational energy of this molecule is $G_u^i = f(u\rho\mu^{-1/2})$. Hence for a given value of u , regardless of the functional form of G_u given by Eq. (1), we obtain G_u^i by replacing u by $u\rho$. Writing Eq. (1) for the isotope molecule:

$$G_u^i = \omega_e[u\rho - x_e\rho^2u^2 + y_e\rho^3u^3 + \dots] \quad (8)$$

Subtracting Eq. (1) from Eq. (8) we obtain the general form of the isotope shift, as given by Birge:

$$G_u^i - G_u = \omega_e[(\rho - 1)u - (\rho^2 - 1)x_eu^2 + (\rho^3 - 1)y_eu^3 + \dots] \quad (9)$$

When an electron transition occurs, this becomes, in terms of the wave numbers of the origins of the bands,

* Taken from ref. 1.

^{5a} R. S. Mulliken, Phys. Rev. **25**, 119 (1925).

⁶ G. E. Gibson, Zeits. f. Physik **50**, 692 (1928).

⁷ Patkowski and Curtis, Trans. Far. Soc. **25**, 725 (1929).

$$\begin{aligned} \nu_0^i - \nu_0 = \Delta\nu_0 = & (\rho - 1)(\omega_e' u' - \omega_e'' u'') \\ & - (\rho^2 - 1)(\omega_e x_e' u'^2 - \omega_e'' x_e'' u''^2) \\ & + (\rho^3 - 1)(\omega_e y_e' u'^3 - \omega_e'' y_e'' u''^3) + \dots \end{aligned} \quad (10)$$

Eq. (10) can be used for calculating the direction and magnitude of the isotope shift when the data are sufficient to give an analytic function representing the bands. This is more general than Loomis's Eq. (7)⁸ and is in terms of half integral quantum numbers.

As shown by Birge, an approximate equation can be written for Eq. (9):

$$G_u^i - G_u = (\rho - 1)\omega_u u. \quad (11)$$

This gives, on transition,

$$\Delta\nu_0 = (\rho - 1)(\omega_u' u' - \omega_u'' u''). \quad (12)$$

The advantage of Eq. (12) is that it can be used independently of any functional form of G_u . It is necessary only to know the values of ω_u for the band whose isotope shift is to be calculated. The value of ω_u may be read directly from the $\omega_u:u$ curve, or interpolated linearly between $\omega_{u+1/2}$ and $\omega_{u-1/2}$, which are obtained directly from the spectrum.

This theory shows that the isotope effect is zero at the true origin of the band system. It also shows that the isotope shift does not increase uniformly as u increases. For, by differentiating Eq. (9) and equating the result to 0, a maximum value of the shift for a certain value $u = u_c$ is obtained. In case the $\omega_u:u$ curve is linear, u_c is approximately $1/2u_0$. The theory shows further that the apparent heats of dissociation D_e and D_e^i are equal. Geometrically, the $\omega_u:u$ curves for the main molecule and the isotope molecule cross each other at $u = u_c$, and the area under each is the same since $u_0/u_0^i = \rho$ and $\omega_e^i/\omega_e = \rho$. But the true heats of dissociation D_0 and D_0^i are not the same. The theory has been verified by Patkowski and Curtis⁷ by application to the bands of ICl, and by Birge⁴ to ICl and Cl₂, both of which involve isotope effects in the region of relatively high quantum numbers.

ISOTOPE EFFECT IN AgCl

The $\omega_u:u$ curves for the four isotopic molecules Ag¹⁰⁷Cl³⁵, Ag¹⁰⁹Cl³⁵, Ag¹⁰⁷Cl³⁷, and Ag¹⁰⁹Cl³⁷ are shown in Fig. 3. The curves for the excited states of the two Ag isotope molecules are not shown, since they almost coincide with the other two curves. The curves A'' and B'' for the normal states of the first set of Cl isotope molecules are very nearly parallel and show no intersection. But this is to be expected, since the extrapolated value of u_0'' was 148, and therefore u_c is about 74. However, the extrapolated values of ω_e for these molecules are in the ratio $336/343.6 = 0.978$, in close agreement with the calculated value of $\rho = 0.9794$. Also, for the strong pair of silver isotope bands, curves C'' and A'' , the ratio $\omega_e^i/\omega_e = 342.4/343.6 = 0.997$ in close agreement with $\rho = 0.9977$. However, due to the slight uncertainty in determining the

proper slopes, it cannot be verified from the data that D_e is the same for all the molecules and D_0 different.

Curves A' and B' for the excited states of the first set of Cl isotope bands apparently show approach of intersection. The value of u_0' could not be accurately determined, but probably lies between 15 and 23. Hence the cross-over value u_c' is probably just outside the range of observation.

Table III contains the observed and calculated isotope shifts. Values of $\Delta\lambda$ were calculated from the mean of the observed displacements from the original measurements of the plates, and not the difference between the mean wave-lengths of Table I. The observed $\Delta\nu$ were calculated from these $\Delta\lambda$. The values of $\rho - 1$ are also recorded in this table for the four sets of isotope bands. The main molecule in each case is written in italics. For the first set of Cl isotope bands, the calculated values of $\Delta\nu_0$ were obtained in three ways for comparison: column I using the approximate Eq. (12), column II the analytic Eq. (10), and column III the old equation $\Delta\nu = (\rho - 1)\nu_u$ where ν_u is the difference between the wave-numbers of the head of the main molecule and ν_e , the origin of the band system. All three methods agree about equally well for most of the shifts. But Eqs. (10) and (12) are superior when high values of u' are involved. The old equation gives very poor agreement for bands having a high u' and low u'' . This is to be expected, since III should agree asymptotically with I and II for low quantum numbers, and the greatest departure of III should occur when u is relatively high, as it is here in the excited state. The observed values of u in the normal state are relatively low.

The shifts for the other sets of isotope bands were calculated by Eq. (12). The observed shifts for the Ag isotopes are somewhat erratic due to the smallness of separation of the heads and their lack of sharpness, as well as their faintness in some cases. The results here confirm the existence of two isotopes of silver, of relative mass 107 and 109.

PRODUCTS OF DISSOCIATION

It has been shown by Franck,⁹ Dymond,¹⁰ and others that when absorption of light by an "atom-molecule" results in dissociation by vibration from the excited state, at least one of the resulting atoms is excited. From a study of the $\omega_u:u$ curves in the normal state, Birge and Sponer¹¹ showed it quite probable that most molecules in dissociating by vibration from the normal state yield two normal atoms. The difference between the total energy (measured from the normal state) required to dissociate the molecule in the two cases should correspond to the amount of excitation of the resulting atoms. Hence, if a continuous spectrum exists which corresponds to the convergence limit of the $u'' = 0$ progression of the vibration bands, then by subtracting the lowest excitation energy in one of the resulting atoms from the long wave-length limit of this continuum, a value for the normal heat of dissociation D_0'' is obtained. For example, this was done by Dymond for I_2 .

⁹ J. Franck, Trans. Far. Soc. 22, 536 (1925).

¹⁰ Dymond, Zeits. f. Physik 34, 553 (1925).

¹¹ Birge and Sponer, see ref. 5.

Conversely, if it is possible from the data for a given molecule to determine the heats of dissociation in both the normal and excited states, it is sometimes possible to find the states of the atoms resulting by dissociation.

In their work on the silver halides, Franck and Kuhn¹ report a continuous spectrum for AgI overlapping the discontinuous bands, and showing a maximum at $\lambda 3170$. The long wave-length edge is variable with temperature and pressure. Assuming a normal silver atom and an excited (metastable) iodine atom formed by dissociation, and adding to this atomic energy the thermochemical value of D_0'' , they obtained an energy value agreeing approximately with the observed long wave-length limit at $\lambda 3740$. It appears to the writer that the use of the long wave-length limit of this continuum is in this case not at all reliable. Furthermore, the writer's conclusions as to the products of dissociation differ from Franck and Kuhn's. The use of the maximum at $\lambda 3170$, which is on the high frequency side of the bands, would give close agreement. The same criticism would apply to AgBr. No continuous spectrum appeared with AgCl.

Fig. 4. Energy relations in AgCl.

Fig. 4 summarizes the results obtained in the present paper for AgCl. $D_0'' = 3.11 \pm 0.10$ volts, $D_0' = 0.31 \pm 0.02$ volt, and the energy corresponding to the (0, 0) band is 3.90 volts. This leaves 1.10 ± 0.12 volts as the electronic excitation of the atoms resulting by dissociation. In accounting for this energy, several possibilities must be examined. If the products are: (1) Ag^+ and Cl^- , the resultant energy would be the ionization potential of Ag minus the electron affinity of Cl, or $7.53 - 4.1 = 3.42$ volts. (2) Normal Ag and excited Cl; the separation $^2P_{1/2} - ^2P_{3/2}$ in the normal state of Cl is 0.11 volt. This is the process which would be assumed consistent with Franck and Kuhn's conclusions. Other levels in the Cl atom may be excluded because of their high energy. (3) Excited Ag and normal Cl; this case was barred by Franck because of the large separation between the 2P and 2S levels of silver. (4) Both atoms excited.

The present results definitely exclude cases (1) and (2) even allowing a wide limit of error. However, (3) and (4) may be considered. Now in both Cu and Au there exist 2D states between the 2P and 2S states, due to terms based

on the d^9 s configuration of the ion.¹² The lines of the Ag spectrum have not been completely classified, but since Ag stands between Cu and Au in the periodic table, it is a plausible assumption that these low-lying states exist also in Ag.¹³ If the silver halides dissociate into a normal halogen atom and a silver atom in this metastable $^2D(d^9s^2)$ state, then the electronic energy obtained as indicated in Fig. 4 should be *constant* for all three silver halides.

The writer has succeeded in assigning vibrational quantum numbers to Franck and Kuhn's data¹ for AgI and AgBr. This assignment is shown in

AgI

$v \backslash v''$	0	1	2	3	4	5	6	7	8	9	10	11	12	13
0	×	×	×	×	×	×	×	×		×	×	×	×	×
1	×	×	×			×	×	×						
2	×													
3	×													
4	×													

AgBr

$v \backslash v''$	0	1	2	3	4	5	6	7	8	9	10	11	12	13
0	×	×	×	×	×	×	×	×	×	×	×	×		
1			×		×	×	×	×	×					
2			×	×	×	×	×	×	×	×				
3														

Fig. 5. Assignment of vibrational quantum numbers to AgI and AgBr.

Fig. 5, which includes both absorption and fluorescence bands. Approximate equations representing the bands are as follows:

$$\begin{aligned}\text{AgI: } \nu &= 31153 + 127.5v' - 5.7v'^2 - 205.7v'' + 0.57v''^2, \\ \text{AgBr: } \nu &= 31421 + 179.4v' - 9.5v'^2 - 249.4v'' + 0.83v''^2.\end{aligned}$$

This gives for AgI, $\omega_0'' = 205.7 \text{ cm}^{-1}$ and $\omega_0''x'' = 0.57$, and for AgBr $\omega_0'' = 249.4$, $\omega_0''x'' = 0.83$. These agree with the values deduced by Birge from Franck and Kuhn's data, 205.8, 0.56, 247.2, and 0.81 respectively.¹⁴ On account of the uncertainty of the measurements, the $\omega_u: u$ curves are uncertain, and the heats of dissociation obtained by this data are not very accurate. But it is certain that the heats of dissociation in the excited states are very small and therefore a large error in determining them by extrapolation will not affect the results appreciably.

¹² Grotian, *Graphische Darstellung von Atomen . . . I*, p. 73, II, p. 44, 51, A. G. Shonstone, *Phys. Rev.* **28**, 449 (1926) Cu.

¹³ But the d^{10} s configuration of Ag is expected to be more stable for Ag than for Cu or Au. See Hund's "Spectrallinien" p. 169-170; also R. Ruedy, *Jour. de Phys. et le Radium* **10**, 129 (1929); also *Trans. Far. Soc.* **25** (Dec. 1929) p. 752 (Bengtsson and Hulthén). For evidence of instability see J. Kaplan *Zeits. f. Phys.* **52**, 883 (1929).

¹⁴ *Int. Crit. Tables*, Vol. V, p. 411 (Birge's table).

As in Fig. 4 we may now calculate approximately the resulting electron excitation E of the dissociation products by the sum $\nu_0 + D_0' - D_0'' = E$, where ν_0 represents the energy corresponding to the (0, 0) band. For AgBr and AgI we will use the thermochemical values¹⁴ for D_0'' and the extrapolated values from the above analysis for D_0' .

$$\text{AgCl: } 3.90 + 0.31 - 3.11 = 1.10$$

$$\text{AgBr: } 3.88 + 0.11 - 2.6 = 1.39$$

$$\text{AgI: } 3.85 + 0.09 - 2.0 = 1.94$$

The resulting values of E are thus not constant. But if we now subtract from these values of E the ${}^2P_{1/2} - {}^2P_{3/2}$ separation in the normal states of the halogens, which are respectively 0.11, 0.46, 0.94 volt¹⁵ we obtain for E in the three cases 0.99, 0.93, 1.00 volt respectively, which is now very nearly constant. This indicates that the silver halides dissociate from the excited state into a silver atom in a ${}^2D(d^9s^2)$ state and a halogen atom in the ${}^2P_{3/2}$ state.

As in Cu and Au, combinations may occur in the silver atom between the 2P and these ${}^2D'$ terms. Assuming the ${}^2D'$ level to be 0.99 ± 0.1 volt, or $8000 \pm 800 \text{ cm}^{-1}$, above the normal 2S level, we would expect a line in the Ag spectrum at $4400 \pm 150 \text{ \AA}$ for the transition ${}^2P_{3/2} - {}^2D_{3/2}'$. There are several fairly strong unclassified lines in this region. Referring to Kayser's Handbuch Vol. VII, the two lines $\lambda 4888.3 (2u)$ and $\lambda 4677.9 (4u)$ have a wave-number separation 920 cm^{-1} , which agrees with the 2P doublet separation. They are the only lines found giving this difference. Hence it is possible that they correspond to transitions ${}^2P_{3/2} - {}^2D_{1/2}'$ and ${}^2P_{1/2} - {}^2D_{1/2}'$ in Ag. The next line of the same type as these two is $\lambda 4396.3 (2u)$. If this is the ${}^2P_{3/2} - {}^2D_{3/2}'$ line, this leaves 7731 cm^{-1} or 0.955 volt for the ${}^2D' - {}^2S$ separation. This is in close agreement with the above value $E = 0.99$ volt deduced from the band spectrum of AgCl. Extrapolations such as were made in obtaining this value should be done cautiously. But even allowing a wide limit of error, the conclusions seem to be unaffected.

The above agreement may indeed be accidental, and awaits further testing by the final analysis of the Ag spectrum,* and by more accurate work on the band spectra of AgI and AgBr. The latter will be carried out by the author in the near future.

In conclusion, the writer expresses much appreciation for the valuable suggestions and constant interest of Dr. F. A. Jenkins, under whom this work was begun. I also am greatly indebted to Professor R. T. Birge for use of his manuscript on the vibrational isotope effect. Suggestions and interest of Dr. F. W. Loomis, and Dr. G. Breit were also helpful.

¹⁵ L. A. Turner, Phys. Rev. 27, 397 (1926).

* Dr. A. G. Shenstone has kindly informed me that his recent work on the Ag spectrum predicts these ${}^2D(d^9s^2)$ terms to be near 30000 cm^{-1} , close to the 2P terms, with a doublet separation of about 5000 cm^{-1} . He believes that the lines mentioned above are due to the terms ${}^4P^{\circ}D^{\circ}F^{\circ}(d^9sp)$ combining with ${}^4D(d^9s, s)$, though he has not as yet been able to identify them. If this is correct, the value of E obtained by the writer remains unexplained.

THE RELATION BETWEEN THE INTENSITY AND POSITION
OF THE OVERTONES OF SOME ORGANIC LIQUIDS

BY P. E. SHEARIN

UNIVERSITY OF NORTH CAROLINA

(Received February 20, 1930)

ABSTRACT

A theoretical study of the intensity relations of the overtones of some organic liquids has been made with a view of determining whether there exists a relation between the intensity and position of overtones. A brief summary of some of the work that has been done by other observers is included. By the graphical method the intensities of the first and second overtones of some liquids were measured. These results, together with the ratio of the intensities of the first and second overtones and also a list of the products of this ratio times the correction factor, x , are given in a table. Values are also listed for three diatomic gases, the intensities having been obtained by other observers and the ratio of these intensities times the correction factor being calculated in this work. For both the liquids and the gases the product of the ratio of the intensities of the first and second overtones and the correction factor, x , is of the same order of magnitude and, in consideration of the errors involved, appears to be constant.

A STUDY of the intensity relations of the overtones of some polyatomic molecules in the liquid state has been made with the purpose of determining whether there exists any relation between the relative intensities of the overtones and the correction factor as applied to the position of the bands. The position of an overtone is given by the relation, $\nu_n = n\nu_0(1 - nx)$, where ν is the frequency of the overtone, n the number of the overtone, ν_0 the theoretical frequency of the fundamental band and x the correction factor. Some calculations have already been made on the intensity relations for the fine structure of gases by several observers. Dennison¹ has, through the aid of the correspondence principle, computed the intensities of certain infra-red bands in order to gain information concerning the structure of the molecule. He computed the intensities of harmonic bands of some diatomic molecules—HCl, HBr and HF. Since some of the constants used in the calculations depend upon a knowledge of the fine structure of the bands, the method could not be used generally. In order to check the results, the relative intensities of overtones were obtained from experimental curves by taking for each band the maximum value of the absorption coefficient, α , rather than the actual value of the integral, $\int_0^\infty \alpha d\nu$.

The intensities of bands of symmetrical triatomic molecules and of axially symmetrical molecules with four atoms were studied by making certain assumptions concerning the relative positions of the atoms in the molecule, and it was found that the experimental and theoretical values were of the same order of magnitude.

¹ Dennison, Phil. Mag. 1, 195 (1926).

Tolman² made some calculations of intensities of lines by graphical integration under the experimental curve for the absorption coefficient, and also by making the approximation of putting the integral, $\int_0^\infty \alpha_\nu d\nu$, proportional to the product of the maximum value of α_m and the spectral width, $\Delta\nu$, at which the value of α has sunk to one half its maximum value. This relation may be denoted by the following equation:

$$\int_0^\infty \alpha_\nu d\nu = K\alpha_m\Delta\nu.$$

Dennison,³ in a more recent paper, has investigated the intensities and shapes of absorption lines of HCl. Formulae for comparing the relative intensities of a set of lines were developed. The area under the curve was measured in relative absorption times waves per cm.

The studies which have been briefly outlined above were all made upon the fine structure of the bands of gases. In the case of liquids this fine structure overlaps to such an extent that the individual lines cannot be observed at all, but only their envelope, which may be considered as the addition of all the separate lines in the band. In order to obtain the intensity of such a band the integral $\int_0^\infty \alpha_\nu d\nu$, was evaluated by the graphical method. The area under the curve was divided into a number of very narrow strips. The area of each strip was measured, and the sum of the areas of the rectangles taken as the area under the curve. The original curves were plotted in percent transmission as a function of spectrometer settings rather than in the coefficient of absorption as a function of waves per cm; however, the percent transmission was changed to coefficient of absorption by plotting a curve for each cell thickness showing relative transmission as a function of the coefficient of absorption. The relation between the relative transmission, I/I_0 , the coefficient of absorption, α , and cell thickness, d , is given by the following equation: $\alpha = [\log(I/I_0)]/d$. In another curve the spectrometer settings were plotted against waves per cm. The dimensions of the small rectangles were found in terms of percent transmission and spectrometer settings. Each value was then changed to absorption coefficient or to waves per cm as the case might be. The curves which were used were greatly enlarged by projecting them on a piece of coordinate paper by means of a projection lantern.

Although a large number of measurements of infra-red bands have been made, most of them have been taken with prism spectroscopes of low resolving power and large slit width. The true shape of the band is lacking due to the width of the slit, and the true position of the band cannot be determined accurately due to the low resolving power of the instrument. The emphasis has been placed upon the position of the bands rather than upon their true shape. These and other inaccuracies make many curves which have been observed, useless for intensity calculations. However, in the work of Spence^{4,5},

² Tolman, *Phys. Rev.* **23**, 693 (1924).

⁴ Easley, Fenner and Spence, *Astrophys. J.* **67**, 185 (1928).

⁵ Spence and Easley, *Phys. Rev.* **34**, 730 (1929).

and his associates the absorption bands of several organic liquids have been measured with great accuracy. Their measurements were made with a grating spectrometer of slit width 0.25 mm. The settings were made with an accuracy corresponding to 0.5Å. A grating with 10,000 lines to the inch was used up to 2μ . From this point on it was necessary to use a grating with 2,500 lines per inch. The entire range was gone over with cells of 1.4 cm, 0.7 cm, and 0.15 cm thickness. The absorption of the cell walls was compensated for by having two quartz plates of the same thickness of the cell walls to place in the beam of light when the cell was removed.

The relative intensity of the first and second harmonic bands of six different liquids as obtained by Spence and his associates was computed. Only six^{4,5} were used since the remainder of the curves were very irregular. It was thought that some of these irregularities might have been due to overlapping of other bands.

If overtones exist for an harmonic oscillator, the ratio of frequencies of the successive harmonics to the fundamental should be 2:3:4, etc. Due to the anharmonic oscillation, strong overtones or harmonics occur in some substances, and their frequencies are found to be in the ratio $2\nu_0(1-2x):3\nu_0(1-3x):4\nu_0(1-4x)$, etc., where x is a correction factor. The correction factor, x , and the relative intensity of the harmonics are both functions of the anharmonicity of the oscillation, so it seems probable that there should be some definite relation between the two. That this is the case is shown by the present work. The results of the calculations are listed in Table I. There are

TABLE I. *The intensity of the first and second harmonics of certain liquids and gases and the ratio of these intensities times the correction factor, x . (ρ_2^2 = intensity of first harmonic. ρ_3^2 = intensity of second harmonic.)*

also listed in this table values for CO, HBr and HCl. The relative intensities of the overtones for these three substances were taken from the work of other observers^{6,7}. The value for the relative intensity of the first and second overtones of CO is due to C. Schaefer and M. Thomas,⁶ the value of x being given

⁶ C. Schaefer and M. Thomas, *Zeits. f. Physik* 12, 330 (1923).

⁷ B. Burmeister, *Verh. d. D. Phys. Ges.* 40, 589 (1913).

by Burmeister.⁷ For HCl and HBr the values of x were computed from the work of Schaefer and Thomas. Using this and the value for the relative intensity of the fundamental and first overtone as given by Brinsmade and Kemble,⁸ the relative intensity of the first and second overtones was computed by means of the equation for x as given by Dennison.¹

Some very interesting relations can be noted in these results. In general as the value of x increases the ratio of the intensities of the first and second overtones decreases, or, in other words, as x increases the intensity of the harmonic band increases. The last column shows the product of the ratio and the value of x . It can be seen that this product is approximately a constant for the bands under consideration. The largest variation is in the value of $\text{CHCl}_2\text{CHCl}_2$. This discrepancy was not accounted for. The variation of the other values is well within the range of experimental error. The values for the three diatomic molecules, CO, HBr and HCl, as obtained by other observers are in excellent agreement with the results as obtained for the liquids.

In order to check the accuracy of the method used, the intensity of the first overtones of three different liquids was measured from the band obtained from a different cell thickness. The two values checked very closely except in the case of CHBr_3 . There evidently was some error in the drawing of the curve for cell thickness of 0.7 cm. By reference to these curves⁴ it can be seen that this band does not follow the form of the band for 1.4 cm cell thickness. For CHCl_3 the values checked very closely, and for $\text{CHBr}_2\text{CHBr}_2$ the check was almost perfect. The original bands did not extend to the 100 percent line, and some error was necessarily involved in the extrapolation of the bands to this line, but since the value of α is very small in this part of the band the error is not very great. In order to determine what possible error might be involved, one pair of curves was extrapolated in two ways, one extrapolation making the area much larger and the other making it much smaller than probable. It was found that the difference between the two areas amounted to about 10 percent.

While no general conclusion can be drawn from these results until a larger amount of data is available, yet it appears that, for the substances under consideration at least, the ratio of intensities of the first and second harmonic bands times the correction factor is approximately a constant.

The writer is indebted to Dr. E. K. Plyler who suggested the above problem.

THE MAGNETIC SUSCEPTIBILITY OF RUBIDIUM

BY C. T. LANE*

MACDONALD PHYSICS LABORATORY, MCGILL UNIVERSITY

(Received February 27, 1930)

ABSTRACT

In view of the theoretical interest involved in Pauli's theory of paramagnetism, the author has reinvestigated the magnetic susceptibility of rubidium. The metal used is subjected to double distillation in vacuum to ensure purity. The technique employed for this is fully described. The susceptibility is determined at nine different field strengths ranging from approximately 9 to 25 kilogauss. No variation in the susceptibility of more than 2 percent is observed over this range. The estimated error in the mean value of the susceptibility is between 2 and 3 percent. The uniformity of the susceptibility, accordingly, shows absence of serious ferromagnetic impurity. The mean value of the mass susceptibility is found to be $+0.217 \times 10^{-6}$ at 20°C , the Pauli theoretical value being $+0.32 \times 10^{-6}$. A table is included showing the results found by all other investigators on this subject. The bearing of the results on the Pauli theory is discussed briefly.

I. INTRODUCTION

THE quantum statistics of an electron gas, first proposed by Fermi, has, in the hands of Sommerfeld, Pauli and many others, yielded much interesting information concerning the electrical and optical properties of metals. More particularly Pauli has applied these statistics to the calculation of the susceptibility of the alkali metals.¹ The agreement between theory and experiment in the case of the metals Na, K and Cs is, considering the nature of the Pauli calculation, quite remarkable.² In the case of rubidium however, upon which, up to the present work, three independent measurements have been made³ very wide differences exist both between one another and the theoretical result. From the point of view of divergence from the theory rubidium appears to be distinctly "anomalous," and this is the more remarkable when it is seen that the allied element caesium is in good agreement with the theoretical value.

The author has accordingly made a new determination of the susceptibility of this element applying the methods used in his previous work on this subject. The results of this investigation are communicated in the following pages.

II. PREPARATION OF THE METAL

The rubidium metal was supplied by Messrs. Eimer and Amend, New York, and stated to be "chemically pure." Nevertheless it was felt that fur-

³ M. Owen, *Ann. d. Physik* **37**, 657 (1912); W. Sucksmith, *Phil. Mag.* **2**, 21 (1926); McLennan, Ruedy and Cohen, *Proc. Roy. Soc. A* **116**, 468 (1927).

ther purification would be desirable especially since it is highly important to avoid even minute traces of ferromagnetic substances. Accordingly the metal was subjected to double distillation in vacuum.

Figure 1 shows, schematically, the apparatus by which this was accomplished. The necessary high vacuum was produced by a Langmuir mercury pump, backed with a Cenco "Hy-vac" pump. The former had attached to it the usual liquid air trap (L) consisting of a bulb of nut charcoal.

The distilling apparatus proper consisted of bulbs B_1 and B_2 fitted with a charging tube F and a ground glass stopper W . The specimen tube, into which the distilled metal is received is shown at S . The latter consists of a thin-walled glass tube, of uniform bore (about 0.4 mm) and some 18 cm long.

Fig. 1. Diagram of apparatus.

The diameter of the tube was uniform to within 1/5 percent. The whole apparatus was constructed of Pyrex glass.

The metal was received from the makers in 1 gr lots packed in a heavy oil. The tubes containing the metal were broken under petroleum ether, and the metal washed in two separate baths of the same material, and then quickly introduced into the charging tube F . While the charging was in progress a stream of nitrogen was kept flowing through the distilling apparatus. When the requisite amount of metal had been placed in F the nitrogen was cut off, the stopper W replaced and the whole apparatus pumped down. The metal was then melted into bulb B_1 and the tube F sealed off. An electric furnace was now placed over bulb B_1 and the metal gently distilled into bulb B_2 . Bulb B_1 was then sealed off from B_2 and the operation repeated until about half the metal in B_2 was distilled into the specimen tube S . The latter was

kept in an oil bath at a temperature of about 70°C. This was allowed to cool down to room temperature, and then was sealed off from the main apparatus. The distillation process took about two hours to perform.

III. METHOD OF MEASUREMENT

The Gouy method⁴ for measuring the susceptibility was used wherein the specimen in the form of a long cylinder is suspended between the poles of an electromagnet, the axis of the former being perpendicular to the lines of force. The downward pull on the cylinder is given by the relation

$$P = \frac{1}{2} \chi A d (H_1^2 - H_0^2)$$

where P is the force in dynes; χ the mass susceptibility; A the cross sectional area cylinder in cm²; d the density of specimen in gr per cc; H_1 the field in gauss in the magnet gap; and H_0 the field in gauss at the other extremity of the cylinder. The pull P was measured with a balance accurate to 1/50 mg. The magnetic field was produced by a large Weiss electromagnet provided with water cooling arrangements. An aluminum housing was built around the magnet in order to shield the specimen from draughts. The former was provided with a celluloid front through which the specimen could be observed at all times. A thermometer could also be observed through this window. The water control allowed a very constant temperature to be maintained in the housing. The measurements were carried out at about 20°C.

Due to the fact that the glass tube containing the metal is diamagnetic a blank test had to be performed upon it, at the various field strengths used. After the measurement had been made on the metal, the tube was cleaned out and re-exhausted of air and the blank test made at the same temperature as the original measurement.⁵

The magnetic field was measured by means of a null method, developed by the author, which has been fully described previously.⁶ A survey of the field in the vicinity of the magnet showed H_0^2 to be negligible compared to H_1^2 .

IV. RESULTS

The results of the measurement are given in Table I below, in each case the specific or mass susceptibility is quoted. In the first column is given the value of the exciting current in the magnet, in the second the force P corrected for the effect of the glass container and in the third and fourth the magnetic field intensity and mass susceptibility respectively. The density of rubidium (1.53) is the value quoted in "International Critical Tables."

The susceptibility is seen to be constant over the field range used (approximately 19 kilogauss) to within about 2 percent which is within the experimental error.

⁴ Stoner, "Magnetism and atomic structure," p. 40.

⁵ This latter point is important since the susceptibility of glass varies greatly with temperature. Some rough tests on the glass used here (Pyrex) indicated that it had a temperature coefficient of approx. $\frac{1}{3}\%$ per degree C. The temperatures at which the two measurements were made agreed to within 1°C. See in this connection Gerlach and Little, *Zeits. f. Physik* 52, 464 (1928).

⁶ C. T. Lane, reference 2.

6.2	7.90	19060	0.21 ₆
7.0	9.47	20950	0.21 ₅
9.0	12.50	23830	0.21 ₉
12.0	14.24	25300	0.22 ₁

Mean value $+0.21_7 \times 10^{-6}$
 Area cross section specimen = 0.1288 cm²
 Density = 1.53 gms per cc.

Owen⁷ has shown that if iron be present in the specimen we should have the following relation between susceptibility and field strength, viz.

$$x = x_0 + \sigma/H$$

where x is the measured susceptibility; x_0 the "iron free" value of susceptibility; σ the saturation intensity of magnetization (per unit mass) of the uncombined iron impurity; and H the magnetic field intensity. The susceptibility should therefore decrease with increasing field according to an hyperbolic law if any noticeable ferromagnetic impurity be present. The susceptibility should be independent of field strength if no noticeable impurity exists, as is the case in the present experiment.

In Table II the various experimental results on rubidium are collected, together with the theoretically predicted value. The estimated accuracy of the present measurement is between 2 and 3 percent.

TABLE II. *Various results on mass-susceptibility of rubidium.*
(All values to be multiplied by 10^{-6})

Observer	Owen 18°C	Sucksmith 0°C	McLennan, Ruedy, Cohen	Author 20°C	Pauli (calculated)
Mass susceptibility	+0.07	+0.07	+0.17	+0.21 ₇	+0.32

V. DISCUSSION

It is seen that the result found by McLennan, Ruedy and Cohen is in close agreement with the present work. The divergence between these results and those of Owen and Sucksmith may perhaps be accounted for by the fact that in the latter experiments no especial precautions were taken to ensure purity in the specimens used.

The most remarkable feature is the wide difference between the experimental and calculated values, especially in view of the fact that the agreement between theory and experiment in the case of Na, Rb and Cs is remarkably

⁷ M. Owen, reference 3.

close; nowhere differing by more than 10 percent of the calculated value. In this respect, then, rubidium seems to be anomalous.

We may recall that the Pauli formula for the susceptibility is

$$x = 12(\pi/3)^{2/3} \mu_0^2 n^{1/3} m_0 h^{-2} d^{-1} = 2.21 \times 10^{-14} n^{1/3} / d$$

where x is the mass susceptibility; n the number of free electrons per cc; d the density of the substance; μ_0 the value of the Bohr magneton; and m_0 and h have their usual significance. The only factor in this formula which might conceivably be incorrect is n , the number of free electrons per unit volume. Pauli makes the reasonable assumption that this is equal to the number of atoms per unit volume. Now in order to bring the theoretical value into agreement with the observed it would be necessary to suppose that n is actually about one-third its present accepted value, or rather, for some reason, only about one-third the number of free electrons per cc contribute to the paramagnetism. Of course we should not expect very close agreement with the Pauli formula since the latter neglects certain factors which should contribute to the susceptibility, viz.: (I) the diamagnetic effect of the atom cores; (II) a possible diamagnetic "induction" effect of the free electrons. We are at present unable to make any definite statement about the magnitude of these effects since no satisfactory theory for them has appeared.⁸ All we can say is that the Pauli formula should produce higher values than those observed.

In any event the Pauli theory can only be considered as provisional since in its present form it is quite unable to account for at least two important observed facts, namely, the observations of McLennan, Ruedy and Cohen on the variation of susceptibility with orientation in single crystals of zinc and cadmium⁹ and also on the observations of the author on the sudden change in susceptibility in passing over from the solid to the liquid state in the case of caesium.¹⁰

On the other hand, it must be remembered that it is the only theory in existence which even remotely gives the correct values for the susceptibility of the alkali metals, and further it accounts for that remarkable experimental fact that the susceptibility of the alkali metals (for a given state) is independent of the temperature.

In conclusion it gives me great pleasure to thank Dr. A. S. Eve, F. R. S. for his continued interest in this work. I am indebted also to Mr. H. G. I. Watson, Lecturer in Physics, for his aid in some of the numerical work.

⁸ Cf. L. Rosenfeld, *Naturwissenschaften* **17**, 49 (1929). In this paper Rosenfeld has estimated the diamagnetic effect of the cores as a function of the "lattice potential" (V_0) of the metal. The quantity V_0 is estimated from G. P. Thomson and Rupp's data on electron beam diffraction experiments. Since only the order of the quantity V_0 is known the correction appears rather uncertain. In any event no data whatever exist for the alkali metals.

⁹ McLennan, Ruedy and Cohen, *Proc. Roy. Soc. A* **121**, 9 (1928). In this paper the authors have apparently neglected to make a correction for the susceptibility of air which would have the effect of somewhat lowering their values. The values quoted for an isotropic crystal aggregate of Zn and Cd should be decreased by approximately 2.5 and 2.6 percent respectively. This brings their result into much better agreement with previous measurements.

SECONDARY ELECTRONS FROM CONTAMINATED SURFACES

BY PAUL L. COPELAND
STATE UNIVERSITY OF IOWA
(Received February 21, 1930)

ABSTRACT

Surface fields.—Small quantities of grease, or condensed vapors, or foreign metal upon a metallic surface have in the past been the cause of many spurious electrical effects. Stuhlmann and Compton cite a spurious contact potential difference of some 60 volts. Using electron reflection and secondary emission as a tool, some of the properties of such surfaces have been investigated. The results indicate that surface fields are set up retarding the reflected electrons.

Insulating layers.—New evidence is found for a sudden breakdown of the insulation of oils in thin films which has been investigated by Brüninghaus and by Watson and Menon. The bearing of the present results on suggested interpretations of the effect is briefly discussed.

THE fields in the neighborhood of incandescent filaments have been investigated^{1,2} through a study of characteristics of the saturation curve. In the present investigation an attempt is made to study the fields in the neighborhood of cold metallic surfaces. The currents used are obtained by reflection and secondary emission of electrons at the surface to be studied.

APPARATUS

The apparatus used is shown in Fig. 1. A filament, F , (of 7 mil tungsten wire) is placed at the center of a molybdenum cylinder, C , the diameter

Fig. 1. Apparatus.

of which is about 1 cm. Electrons emitted by the filament are accelerated toward the cylinder by an applied potential. Some pass out through the slit (of width 0.25 mm) and strike the target, T , which is placed directly before it. The target consists of a second tungsten wire.

The potential of the cylinders, C and M , may be below that of the target, giving a field tending to prevent the escape of reflected electrons, or above it tending to accelerate them in their escape. With the cylinders at low potential, the escape may be almost entirely avoided; with C positive, the number

¹ Irving Langmuir, G. E. Rev. 23, 503 (1920).

² Becker and Mueller, Phys. Rev. 31, 431 (1928).

of electrons leaving may be greater than the primary ones which hit and the current to the target be actually positive.

The tungsten wire used for a target was in the earlier experiments a 10 mil and in the later experiments a 20 mil filament. This form of target was selected to facilitate the application of rather intense, homogeneous fields at its surface. With such a target, however, there is the danger that the full primary current will not strike it and, more serious, that the fraction which does strike it will vary as the field is changed. Fig. 2 shows the results of experiments performed to investigate this question. The current to the target was observed for different settings of the target near the slit as it was moved transverse to the slit. The numbered divisions correspond to motions of the target of approximately $1/7$ cm or 0.056 in. transverse to the slit.

Fig. 2. Electron beam.

The curves in Fig. 2 show the results for a 20 mil target. The impacting speed was such as to produce large secondary emission in each case—in curve 1 this emission was allowed to leave; in curve 2 the field prevented secondary emission. In curve 1 the cylinders were maintained at a potential of 240 volts positive and the target 142 volts positive with respect to the source, F . Between the target and its surroundings was a potential difference of 98 volts, the field being in such a direction as to aid electrons in leaving the target. There is no current to the target until it comes into the direct electron beam from the slit. It rapidly approaches a maximum value and maintains this value while the target is moved about $1/7$ mm transverse to the slit.

In the second curve, the target is 142 volts positive, but the cylinders have been lowered to 60 volts positive with respect to the source. The general shape of the curve is much the same as before except that the current is reversed in sense. The flat plateau on both of these curves indicates that the

target is larger than the electron beam and hence receives the full current for a number of settings. This result would be expected from the dimensions involved. When using a 20 mil filament, the target is enough larger than the beam so that the primary current can be considered constant as the field about the target is changed. Probably also a 10 mil target receives nearly all of the current through the slit.

INFLUENCE OF THE SURFACE ELECTRIC FIELD ON SECONDARY EMISSION

To investigate the fields present at the surface of the target, the current carried by the target was observed as a function of the applied field, all the other conditions being held as nearly constant as possible. A given potential,³ which for any single curve was held constant, was applied between the filament and the target. The effect of variation of secondary emission with bombarding velocity was thus eliminated. In the curves which follow, the abscissas give the potential of the cylinders, *C* and *M*, relative to the target. The ordinates give the net current to the target. Electron currents to the target are plotted as negative.

In the investigation of surface fields, a tungsten wire, without any special treatment whatever, was fastened in place as a target. The current to the target was then measured for different fields determined by the potential of the cylinders relative to the target, and the resulting curve was plotted. The target was then cleaned by heating it to incandescence,⁴ and after this the observations of target current against cylinder potential were repeated. The difference in the shape of the two curves thus obtained indicates the influence of the impurities eliminated by the heating.

The curve indicated as number 1 in Fig. 3 was obtained soon after the target had been cleaned through heating it by an electric current. At the left of the curve, the negative current is not increasing; very few of the electrons are reflected with sufficient velocity to overcome these high retarding fields. As the potential of the cylinders is raised, an increasing number of electrons leave the target; this decreases the net current. The increase of the return current is particularly rapid when the retarding field is removed, for this enables the slow speed electrons to leave. Finally, the net current is reversed in sign; more electrons leave the target than strike it. In addition, then, to the electrons of the original beam which have been reflected, there must be others in the return current liberated by ionization at the surface. The positive current comes to a maximum value at once. This saturation of the secondary current with low positive potentials is exactly what we should expect; all the secondary electrons are able to leave the target if no field retards their escape.

The case is different, however, for targets which have surface contamination. The second curve indicated in Fig. 3 is one obtained just before the

³ It was found that electrons of 100 volts energy produced secondary currents of suitable value, and in the curves which follow, the source was maintained 100 volts negative with respect to the target unless some other value is given.

⁴ Such high temperatures were later found to be unnecessary for the removal of the impurities causing the pronounced effects observed.

heating of the target. The most significant feature is the poor saturation of the positive current. This must be due to retarding fields in the neighborhood of the target surface; otherwise we would expect all electrons emitted to be able to leave the target. This poor saturation appears to be the analogue of that observed for composite surfaces in thermionic emission. This has been explained as an effect of the fields in the neighborhood of the filament surface. Somewhat similar fields must exist here.

Fig. 3. Influence of electric field on secondary emission.

An attempt was made to observe by the present method fields due to thorium on a tungsten filament. That a surface field exists about an incandescent filament partly covered with thorium is known from saturation characteristics in thermionic emission. The results in the case of reflected electrons, however were not decisive. The effect of thorium on the saturation curve does not appear to be as pronounced as that due to the more easily volatilized impurities responsible for the above results.

INSULATING PROPERTY OF THIN OIL FILMS

The erratic behavior of metal surfaces contaminated by slight quantities of oil or wax have been at various times observed. Stuhlmann and Compton⁵ in attempting to account for abnormally high velocities of photoelectrons showed that slight quantities of wax vapor could result in surface charges, sometimes as high as 60 volts, which acted in some respects as a contact difference of potential. A real contact potential difference of this amount is hardly plausible, and it would seem likely that the results are to be attributed to an insulating layer which was charged as high as sixty volts before the insulation broke down.

In the present experiment in the case of extreme contamination by oil particles, an interesting kind of "one way conduction" was observed which can be explained as due to an insulating layer. In the apparatus used for this experiment, the target was fastened onto wires entering the vacuum system

⁵ Stuhlmann and Compton, *Phys. Rev.* **2**, 199 (1913).

through a stop-cock. Oil was placed around the top of the stop-cock; the stop-cock was then raised slightly from its socket, and the oil was injected into the system as a spray. The curve of Fig. 4, obtained after such treatment, follows the axis for a considerable range of potentials. The number of electrons striking the target in this range just equals the number leaving it. This rather striking result was confirmed by repeating the treatment several times.

To explain this we must suppose that the oil forms an insulating layer on the surface of the target which breaks down at some critical potential, apparently about 50 volts. The difficulty is that with retarding fields, even for small values of these fields, a negative current is indicated. To explain the entire curve on the basis of a continuous insulating layer would demand the assumption of some sort of one way conduction in the layer.

Fig. 4. Insulation due to oil film.

The curve can, however, be explained on two assumptions: first that the surface is only partially covered with minute droplets of oil, and second that these insulate only below some critical potential of about 50 volts; the insulation then breaks down. This leads to the insulation observed for small accelerating fields, which corresponds to the region *B* of the curve. The oil surface is raised by the more than one hundred percent reflection up to the potential of the cylinders,⁶ and after this the secondary equals the primary current. The total current is zero. At higher potentials, such as in the region *A*, the insulation breaks down; electrons are supplied through the layer, and more than one hundred percent secondary current results. As soon as the potential of the cylinders has been reduced below that of the target, the primary and secondary currents find a way to the clean metal somewhat as

⁶ See Fig. 3. The zero of current for the contaminated surface closely approaches the zero of the applied field. The zero of current does not usually fall more than five volts from the zero of applied potential. It should be noted that the argument used here does not depend upon the zero of current being exactly at the zero of the applied field.

shown in the lower sketch at the right of Fig. 4. This accounts for the negative currents indicated in the region C.

The apparent breakdown potential of this thin film is interesting. It has been known, of course, for some time that vaseline and other oils, which are ordinarily good insulators, may be used in thin films on electrical contacts to lower the resistance. The assumptions made above concerning this thin film and its breakdown potential appear to be in substantial agreement with the results of a number of rather detailed investigations^{7,8} in which thin films (about 10μ thick) were included between two conducting planes to which a potential difference was applied. This was a simple and direct method of investigation; the results obtained could be interpreted quantitatively at once. The results obtained in the present experiment are of a more complicated nature; exact quantitative interpretations are perhaps impossible. The present verification of the effect, however, has some advantages. The results

Fig. 5. Insulation at lower bombarding potentials.

of the present experiment eliminate the objection (possible in the case of the previous investigations although perhaps unfair in view of the care with which they were performed) that the breakdown obtained might be due to small projections of metal completing the circuit between the plates. In this experiment, small projecting areas are assumed to exist to explain the shape of the curves obtained. The breakdown, however, is evident; the positive current observed depends upon ionization over very considerable areas of the target surface to which the charge must be supplied through the oil. By the same argument, the experiment would seem to indicate something as to the nature of the phenomenon, because an explanation of the above results seems to demand the assumption of conductivity in the film over considerable areas. Some theories⁹ have treated the conductivity as quite local.

⁷ L. Brünighaus, *Comptes Rendus*, **188**, 1386-88 (1929).

⁸ H. E. Watson and A. S. Menon, *Roy. Soc. Proc.* **123**, 185-202 (1929).

⁹ A. Gyemant, *Phys. Zeits.* **30**, 33-58 (1929).

It is probable, however, that the general electronic bombardment of the oil surface causes the disturbance to become quite general over the film. If, for instance, the theory of Güntherschulze¹⁰ is correct and the breakdown is due to the movement of the ions in the film producing strong local heating with evaporation and the formation of gas bubbles in which the discharge takes place, it may be that the heating or the ionization produced by the impact of an electron would make such a breakdown more probable. The impact of electrons of the primary beam does in fact influence the breakdown. If the energy of the electrons striking the surface is greater than 100 volts, the breakdown occurs at a lower potential than indicated in Fig. 4. If the incident electrons are slow, the breakdown occurs at a higher potential. Fig. 5 shows the results for a bombarding velocity corresponding to 70 volts difference between the target and source. The curve follows the axis for a greater range of cylinder potentials than the curve of Fig. 4. The effect is even more pronounced at lower bombarding potentials.

In the present experiment, discharge does not occur between two metallic electrodes. The conduction appears to be from the metal to the surface of the film from which the charge may be dislodged only by electronic impact. The present results suggest that the conduction is continuous and general for the bombarded parts of the film.

CONCLUSIONS

The experiments reported here lead to the conclusions:

1. Strong fields are set up in the neighborhood of a contaminated surface retarding the escape of reflected electrons.
2. In extreme cases of oil contamination the impurities form an insulating film which breaks down at some critical value of the applied field.
3. The breakdown potential of a given film varies with the energy of the incident electrons.
4. The conductivity observed in these films appears to be rather general and continuous.

The writer wishes to thank the members of the staff of the Department of Physics of the State University of Iowa for their interest and assistance. Thanks are especially due to Professor J. A. Eldridge who suggested and directed the investigation.

THOMSON EFFECT IN ZINC CRYSTALS

BY L. A. WARE

PHYSICS LABORATORY, UNIVERSITY OF IOWA

(Received March 4, 1930)

ABSTRACT

The *Thomson coefficient*, σ , is directly determined for a group of zinc crystal rods with orientations distributed fairly uniformly over the entire possible range. At 49.5°C and at 125°C the values of σ seem to obey the Voigt-Thomson symmetry relation, although not as good a check is obtained at the higher temperature on account of increased experimental error. The principal values obtained are:

$$\begin{array}{l} \text{At } 49.5^\circ\text{C, } \sigma_{\perp} = 0.98 \times 10^{-6} \text{ cal.} \cdot \text{coul.}^{-1} \cdot \text{deg.}^{-1} \\ \quad \sigma_{\parallel} = 0.38 \times 10^{-6} \text{ " " " } \\ \text{At } 125^\circ\text{C, } \sigma_{\perp} = 2.09 \times 10^{-6} \text{ " " " } \\ \quad \sigma_{\parallel} = 1.08 \times 10^{-6} \text{ " " " } \end{array}$$

The values at 49.5°C are found to compare favorably with values for polycrystalline zinc calculated from Sommerfeld's theory of conduction, (0.32×10^{-6} cal. · coul.⁻¹ · deg.⁻¹), and found by Borelius experimentally, (0.88×10^{-6} cal. · coul.⁻¹ · deg.⁻¹). The increase of σ with increased temperature is greater than has been previously reported for polycrystalline zinc but is in approximate agreement with some earlier determinations by the writer. In addition, *specific resistivity* and *temperature coefficient of resistivity* are determined.

INTRODUCTION

ABOUT two years ago the writer determined directly values of the Thomson coefficient for a few zinc single crystals¹ of orientations² near 0° and 90°. The main emphasis in this earlier work was placed on the variation of σ , the Thomson coefficient, with temperature, although it was possible to make some comparison with values of $(\sigma_{\perp} - \sigma_{\parallel})$ computed from the previously published thermal e.m.f. determinations of Linder,³ Bridgman,⁴ and Grüneisen and Goens.⁵ Following the work just mentioned, some determinations of σ were made at a single temperature, (about 50°C), on a group of crystals covering a wider range of orientations, particularly with a view to checking the Voigt-Thomson symmetry relation for the Thomson coefficient. These crystals were a by-product of the investigations of Tyndall⁶ and of Hoyem and Tyndall⁷ and were therefore grown under somewhat different conditions and

throughout a rather long period of time. It is certain also that the zinc came from several lots (although of the same kind of zinc). In view of other work done recently in this laboratory, it is not now surprising that such a miscellaneous series of crystals failed to give very consistent results. In particular σ was not determined as a definite function of the orientation. A third series covering a good range of orientations was therefore prepared by Mr. Hoyem. The crystals were made consecutively, were grown at the same rate, were of very nearly the same diameter, and the zinc came from only one original container. The material was Kahlbanm's best zinc. The work reported herein consists mainly of a direct determination of the Thomson coefficient at two temperatures (49.5°C and 125°C) for each crystal of this last series. From these data it is possible to check the usual thermodynamic theory of thermoelectricity and to test the Voigt-Thomson symmetry relation directly for σ .

In addition the specific resistance at 20°C and the temperature coefficient of resistivity were measured, mainly as tests for purity of the zinc, freedom of the crystals from strain, etc.

APPARATUS AND EXPERIMENTAL PROCEDURE

The Thomson coefficient was measured in the fashion described by Nettleton⁸ with some slight modifications which are described below. In this method the two ends of the specimen, which is a short wire or rod, are kept at constant, but different temperatures. At the same time a current, I_1 , is passed in such a direction through the specimen that the Thomson effect causes a generation of heat. If this current is reversed the temperature at the center of the specimen will decrease slightly, as the Thomson heat is now being subtracted. If, however, on reversal, a suitable increase in the current, to I_2 , is made an extra generation of Joulean heat compensates for the previous loss and the temperature remains unchanged. The apparatus is designed to measure directly the difference between I_2 and $I_1 (=i_0)$ and to detect, with a bolometer coil and a Wheatstone bridge, any change in temperature at the center of the crystal, so that the state of zero-change may be found. Let R represent the resistance of the crystals, U , the difference in temperature between the two ends, and J , the constant 4.18 joules per calorie. Then, as Nettleton has shown, the Thomson coefficient, σ , will be given by the equation, $\sigma = i_0 R / JU$ cal. · coul.⁻¹ · deg.⁻¹ provided certain conditions are satisfied. It is believed that all these are satisfied in the present work except that the crystals were made longer than Nettleton considered because of their very low resistance. The heat insulation was improved greatly, however, over previous methods and it seems certain that the equation is satisfactory for the lengths and diameters used.

To determine the specific resistance, ρ , and the temperature coefficient of resistivity, α , curves were plotted for resistance against temperature between room temperature and 110°C. For a linear relationship between resistance and temperature, α is given by;—

⁸ H. R. Nettleton, Proc. Phys. Soc. Lond. **34**, 77 (1921); **29**, 59 (1916).

$$\frac{1 - p}{t_2 p - t_1}$$

in which $p = R_1/R_2$; R_1 and R_2 being resistances measured at temperatures t_1 and t_2 respectively. The specific resistance at any temperature is given by:

$$\rho = RM/\delta L^2$$

where R is the resistance at the desired temperature, M is the mass of the crystal, δ is the density, and L is the length. The resistance measurements were made by the usual potentiometer method, the crystal being immersed in a constant temperature oil-bath heated by an electric heating coil. The bath could be adjusted easily for any temperature between room temperature and 125°C . In this case, room temperature to 110°C was used as the range.

Fig. 1 shows the arrangement of apparatus used to measure the Thomson coefficient. The details of the terminals H and C will be considered with Fig. 3. In Fig. 1, H represents the hot end of the crystal and C , the cold. V is

Fig. 1. Apparatus wiring diagram.

a source of 12 volts for which storage batteries were used so that the current would be as uniform as possible. B_1 and B_2 represent the two bolometer coils wound around the middle third of the crystal for the purpose of detecting a change in temperature when the current through the crystal is reversed. Apparently only one coil was used by Nettleton, but the use of two coils in opposite arms of the Wheatstone bridge was adopted on account of the increased sensitivity. The bridge is shown in Fig. 2. Actually the windings of B_1 and B_2 are interspaced as shown in Fig. 1 although shown separated in Fig. 2 to render the electrical connections clearer. In Fig. 1 the resistance 1 is about 10 ohms, 2 is a 500 ohm resistance box adjustable to 0.1 ohm, 3 is a rheostat of 2000 ohms, and 4, which controls the main current, is 47 ohms. The switch S is especially constructed to be very rapid and of very low resistance. E is a source of 110 volts A.C. supplying the heater coils at both ends of the crystal.

Fig. 3 presents the method of producing the constant temperatures at the ends of the crystals. Brass blocks were turned down to make the pieces A and

B, each about one inch in diameter and 1.5 inches long. *A* was threaded into the end of the basin *C* so that the crystal could be directly connected to it. An opening *D* was made in *A* to facilitate the circulation of water. On *A*, a heating coil was wound of No. 24 Karma wire and leads taken out. The heating coil was used to melt the solder for the purpose of either putting the crystal in place or removing it. A screen partition, *E*, was placed as shown to prevent the ice getting into the stirrer. This arrangement maintained the cold end of the crystal very constantly at about one degree above 0°C . At *H*, a double

Fig. 2. Wheatstone bridge connection.

cylinder was used with heat insulating powder in the space *F*. The block, *B*, was similar in all respects to *A*, it being threaded into the end of the cylinder, and having a heating coil for the double purpose of mounting the crystal and heating the enclosure to a constant temperature when readings were being made. During an experiment the space, *G*, was filled with water and maintained by the heater at very nearly the boiling point. The thermometer, *T*, was used to read the temperature. By keeping the current about 0.9 ampere, *B* could be maintained at a remarkably uniform temperature for about three hours. Thus was obtained a very satisfactory method of maintaining a tem-

Fig. 3. Details of hot and cold terminals.

perature difference of about 97°C for a considerable length of time and it proved to be a much better method than that used later in obtaining the results for an average temperature of 125°C .

The details of the bridge circuit are shown in Fig. 2. Here, R_1 is a fixed resistance of about 6 ohms which, with as much of the wiring as possible, was inclosed in a heat insulated box. R_2 is a resistance made up of shunts across a coil, similar to R_1 , and in series with a slide wire resistance of 0.1 ohm capable of adjustment to about 0.01 ohm. The function of the two coils, B_1 and B_2 , has

been described already. The compensating coils, C_1 and C_2 , are used to decrease the drift of the galvanometer due to the change of resistance of the leads to B_1 and B_2 . B_1 , B_2 , and R_2 as well as R_1 are all about 6 ohms resistance. The bolometer coils and compensators were constructed of No. 40 copper wire silk insulated. The Wheatstone bridge thus arranged proved to be much more sensitive than the arrangement used in the previous work, which contained only one bolometer coil and no compensating coils.

For the purpose of determining σ at the average temperature of 125°C it was necessary to make a few minor changes in the arrangement shown in Figs. 1 and 3. In Fig. 1 the source, V , was reversed as well as all the meters contained in the circuit. A little inspection will demonstrate that this allows the measurement of positive σ^* if H and C are also interchanged. In this case the method of heating H was unchanged, it being, as before, maintained near the boiling point of water. However, the ice water in C was removed and polarine oil was substituted. The heating coil on A was brought into use and the temperature of the oil maintained at about 150°C . Here it was rather difficult to maintain the temperature sufficiently constant, a condition which slowed the procedure somewhat. The temperature at the hot end of the crystal was measured by a sensitive thermometer placed in the opening, D . The readings of the thermometers at both ends of the crystal were checked by means of thermocouples connected to the face of A and B near the ends of the crystal. It was found that the temperature gradient determined from the readings of the thermometers differed from the actual gradient by about 2 percent. In computing the results, a suitable correction was, of course, made.

Measurements on the crystals were taken as follows. First a crystal is carefully cut to about 9 cm length, weighed, and to each end is soldered, by a very small amount of solder, a small copper wire, at about the middle of the wire, so that its two ends can serve as current and potential leads, respectively, for the resistance measurements. The crystal is then suspended in the oil bath, the heater in the oil bath is adjusted for the desired temperature, and the assembly is allowed to stand until the temperature, as indicated on a calibrated thermometer, is steady. A current of 0.3 ampere is then sent through the crystal and the P.D. read on the potentiometer. The current is reversed and readings made again. The average of four readings, (two in each direction), gives sufficient data to determine the resistance at this particular temperature. This is repeated for six or seven different temperatures and a curve plotted from which ρ and α can be determined.

After these data have been obtained the crystal is taken from the oil bath, the leads unsoldered, and two bolometer coils wound on at the center as indicated above. The heaters A and B of Fig. 3 are then started and when sufficiently hot the crystal is soldered closely against the face of A and B as there indicated. It is necessary in this procedure to be very careful not to strain the crystal. When the crystal has been fastened in place and the bolometer and compensating coils have been connected to the bridge, kieselguhr is

* σ is positive if heat is generated for current flow down the temperature gradient.

packed into the space between *A* and *B* and around the crystal to a radius of about 5 cm. Over this is packed a considerable amount of cotton and the apparatus is ready for the establishment of a temperature gradient. The space, *G*, is filled with water, and with the thermometer in place the current is established through the heater, *B*. It is given a high value at first and as the temperature approaches 98° or 99°C it is reduced to 0.9 ampere, where it is left. In the meantime, with the current shut off in *A*, the container is filled with water, the screen put in place, and the space above the screen filled with cracked ice. The stirrer is then started and the whole assembly is allowed to attain a steady state. As it begins to approach such a state the currents through the Wheatstone bridge and through the crystal are established. A determination of the balancing current, i_0 , is made as follows: Referring to Fig. 1, it is seen that with the switch, *S*, to the left the main current divides, part going through the crystal and part through the milliammeter, M.A. When *S* is thrown to the right all the line current goes through the crystal. Thus the current through the crystal has been increased on reversal and if the rheostats 1 and 3 are correctly adjusted, the milliammeter, for any particular setting of resistance 2 and the main current, will read the same for either position of the switch, *S*. In this case the reading of the milliammeter is the i_0 required in the working equation. Thus it is necessary first to adjust resistances, 1 and 3, (Fig. 1), so that the milliammeter reads the same for both positions of *S*, then, if the system is otherwise balanced, some value of i is tried and the bridge, (Fig. 2), is adjusted for left position of *S*. Switch *S* is then thrown to the right and if the bridge indicates a decrease of temperature at the center of the crystal, i is increased, and the procedure repeated until it is just determinable that the current, i , is too low. A similar process is gone through with i being successively reduced from a value initially too high. The balancing current, i_0 , is the mean of these two limiting values of i . The difference between these two values is generally less than 10 percent of i_0 .

The procedure for the determination of σ at the higher temperature, 125°C, is similar to that at 49.5°C. However, in this case it should be pointed out that it was not so easy to maintain a constant temperature at the hot end. This introduced a certain amount of unsteadiness, and a corresponding decrease in the reliability of the results.

RESULTS

The experimental results are exhibited graphically in Figs. 4 and 5. The specific resistance will be considered first. It is plotted in Fig. 4 against the square of the cosine of the orientation. This plot should yield a straight line since the validity of the Voigt-Thomson law for specific resistance of zinc crystals has been established, particularly by Bridgman.* The solid straight line shown is that for data recently obtained by Bridgman.⁹ It is actually drawn by him through the lowest of his points, in spite of the fact that the

* The Voigt-Thomson symmetry relation states that the thermo-electric effects in crystals plotted against the square of the cosine of the angle of orientation should yield a straight line.

⁹ P. W. Bridgman, Proc. Am. Acad. Arts and Sc. 63, 351 (1929).

scattering of his observations is about half as great as that shown in Fig. 4. This procedure is justified by his discovery that any very slight strain raises the resistance of a zinc crystal. Five of the writer's crystals were therefore rechecked with the purpose of determining what effect resulted from intentional slight strains. The points so obtained are indicated by triangles. In two cases the resistivity changed and it increased. Of the three crystals which

Fig. 4. Specific resistivity in ohms per cm^3 plotted against $\cos^2\theta$.

did not change in resistivity, two already had high values and the other probably was not very much strained as it was a 90° crystal and therefore stiff. The greatest increase was about 3 percent. It will be noted also that the value for crystal No. 20, ($\rho = 5.8 \times 10^{-6}$, $\cos^2\theta = 0.22$) has increased due to annealing. However, this crystal has shown very inconsistent results in other respects. Following the idea of Bridgman that the lowest values are more probably correct, the dashed straight line has been drawn through four low

Fig. 5. The Thomson coefficient in $\text{cal.} \cdot \text{coul.}^{-1} \cdot \text{deg.}^{-1}$ as a function of $\cos^2\theta$.

points neglecting the point for crystal No. 20. The values of ρ obtained from this line for $\cos^2\theta = 0$ and $\cos^2\theta = 1$ are: $\rho_{\perp} = 5.78 \times 10^{-6}$, $\rho_{\parallel} = 6.05 \times 10^{-6}$. These given for $(\rho_{\parallel} - \rho_{\perp})$, 0.27 whereas Bridgman obtains 0.23. Bridgman's ratio $\rho_{\parallel}/\rho_{\perp}$ is 1.04 while the values above yield 1.05. Grüneisen and Goens obtain 1.08. The agreement with Bridgman in the matter of specific resistance and the effect of strains is quite satisfactory.

The variation of resistance with temperature, between 20°C and 110°C is for all but four of the crystals accurately linear. These four show only a very slight deviation. The temperature coefficient, α , was therefore computed in the manner explained above. The values of α lie between 0.00413 and 0.00437 and show no very certain variation with orientation. The average value is 0.00425, a value about 2 percent higher than that obtained by Bridgman.

The values of the Thomson coefficient for both 49.5°C and 125°C are presented in Fig. 5. If the best straight line is drawn through the points for 49.5°C it will be found that the deviation from the line is, in all except two cases, within the experimental error. These two cases are those of crystals No. 20 and No. 21, ($\theta = 62^\circ$). No. 20 has already been mentioned in the case of resistivity as being anomalous and here it is seen that even at 125°C the value of σ is lower than for 49.5°C. Also, No. 20 was annealed, as mentioned before, and the same value for σ was again obtained at 49.5°C. There was no visible evidence of No. 20 or No. 21 being different from the other crystals and the explanation of their deviation is not readily apparent.

Although a straight line has been drawn through the points for 125°C, the writer does not claim that the data afford a test of the Voigt-Thomson symmetry relation at this temperature. The deviations from the line as drawn are no greater, however, than the experimental error at this temperature. Moreover the value of $(\sigma_\perp - \sigma_\parallel)$, obtained from this line and stated just below agrees as well with indirectly determined values as is the case at 49.5°C.

The values of σ_\perp and σ_\parallel at 49.5°C are 0.98×10^{-6} cal. · coul.⁻¹ · deg.⁻¹ and 0.38×10^{-6} cal. · coul.⁻¹ · deg.⁻¹ respectively. Thus a value of $(\sigma_\perp - \sigma_\parallel)$, 0.60×10^{-6} cal. · coul.⁻¹ · deg.⁻¹ results. From the relation, $(\sigma_\perp - \sigma_\parallel) = T \frac{d^2 E}{dT^2}$, Bridgman⁹ obtains 0.661×10^{-6} , Grüneisen and Goens,⁵ 0.622×10^{-6} , and Linder,³ 0.521×10^{-6} cal. · coul.⁻¹ · deg.⁻¹. At 125°C the writer obtains the value 1.01×10^{-6} cal. · coul.⁻¹ · deg.⁻¹ as compared with Bridgman's⁹ 0.813×10^{-6} , Grüneisen and Goens' 1.12×10^{-6} , and Linder's 0.795×10^{-6} cal. · coul.⁻¹ · deg.⁻¹. Borelius and Gunneson¹⁰ have made measurements on several polycrystalline metals and obtain for zinc at 49.5°C, 0.885×10^{-6} cal. · coul.⁻¹ · deg.⁻¹. Taking $\sigma_{54.5}$ as representative of σ in polycrystalline zinc, the writer obtains 0.78×10^{-6} cal. · coul.⁻¹ · deg.⁻¹. The difference in purity of the material used by the various investigators may well account for the rather wide range of values obtained.

In general it can be said that the observation of Bridgman concerning resistivity is substantiated. The average value of α obtained is slightly higher than that given by Bridgman and there appears to be a somewhat greater difference between α_\perp and α_\parallel than that which Bridgman finds. The values of $(\sigma_\perp - \sigma_\parallel)$ for 49.5°C agree with those calculated by the thermodynamic formula from the previously observed thermal e.m.f. vs. temperature curve. The Voigt-Thomson relation is supported within the limits of error by the data on $\sigma_{49.5}$. The data on σ_{125} are presented for what they may be worth.

Sommerfeld,¹¹ by an extension of his theory of electrical conduction, has

¹⁰ G. Borelius and F. Gunneson, *Ann. d. Physik* **65**, 520 (1921).

¹¹ A. Sommerfeld, *Zeits. f. Physik* **47**, 143 (1928).

developed an equation for the Thomson coefficient which to the first approximation is:

$$\sigma = \frac{2\pi^2}{3} \frac{m k^2 T}{e h^2} \left[\frac{8\pi}{3n} \right]^{2/3}$$

which is seen to be dependent on T , the absolute temperature, and n , the number of atoms per cc, only as variables. This, calculated for zinc, gives, at 49.5°C , $0.32 \times 10^{-6} \text{ cal.} \cdot \text{coul.}^{-1} \cdot \text{deg.}^{-1}$, a value agreeing, in order of magnitude with existing data.

No theory has been developed for the Thomson effect in single crystals, although Houston¹² has extended his work in this direction.

The writer wishes to express his thanks to Dr. E. P. T. Tyndall, under whose direction this work was undertaken, for his help and encouragement at all times. He wishes also to thank Mr. Hoyem for so kindly consenting to grow the crystals used in this work. Thanks are also extended to members of the department for their advice and suggestions.

E.M.F., RESISTANCE, AND CAPACITANCE PHENOMENA IN
PHOTOVOLTAIC CELLS CONTAINING GRIGNARD
REAGENTS

BY H. E. HAMMOND

UNIVERSITY OF MISSOURI

(Received February 10, 1930)

ABSTRACT

E.m.f., resistance, and polarization capacitance have been measured in light-sensitive cells containing ether solutions of Grignard reagents in an effort to determine whether the known voltage variations with illumination are due to ionization changes or to electrode-film variations. Voltage alterations with illumination or x-ray irradiation are described. Resistance variations with illumination are found in ethylmagnesium bromide cells but not in phenylmagnesium bromide cells until a "forming" process has been carried out. Solvation changes seem to offer a more reasonable explanation than ionization changes. Capacitance changes seem unrelated to resistance or voltage changes. Unsymmetrical resistances are noted in several cases. Capacitances as high as 7 mf per cm² of electrode area have been found. Film thicknesses are estimated to be of approximately molecular dimensions, greater for benzene-ring compounds than for short-chain compounds. Voltage variations are thought to be due to phenomena taking place on or very near electrode surfaces.

THE Becquerel effect is the name applied to an alteration of the electromotive force of a voltaic cell upon exposure of the cell to light. Originally found by Becquerel¹ to take place in a cell having platinum or silver plates coated with a silver halide and immersed in dilute sulphuric acid, the effect was later discovered by Rigollot² to exist with solutions of fluorescent dyes. Now the effect is known to be very common. Through the work of Nichols and Merritt,³ Hodge,⁴ and others, the effect has been shown to be located at or very near the electrode surface in the case of the dye solutions. Goldmann⁵ offered a theory based on the photoelectric effect. Baur⁶ proposed a photochemical theory for the effect, which has been upheld by Garrison,⁷ Tucker,⁸ and Russell⁹ among others. A reasonably comprehensive survey of the work carried on with solutions in water and in absolute alcohol is presented by Lifschitz and Hooghoudt.¹⁰

A number of papers have been published on the luminescence of Grignard compounds, organo-magnesium halides, under suitable conditions.^{11,12} Kondyrew¹² showed that cells containing ether solutions of ethylmagnesium bromide produced an e.m.f. He also measured the temperature-resistance coefficient. Such cells show the Becquerel effect.^{11,12} Considerable work, much of it as yet unpublished, has been done by others on the variation of the e.m.f. of Grignard cells with changes in illumination, in wave-length of light used, in temperature, etc.

The primary purpose of this investigation was to uncover new evidence as to whether the photovoltaic effect in Grignard cells took place on or near the electrodes or in the body of the electrolyte. A photoelectric effect should produce a change in the conductivity of the solution and an alteration in an electrode film might cause a detectable change in the cell capacitance. The method employed contemplated tests of many such cells, first as to the nature and magnitude of e.m.f. alterations, second as to the existence and magnitude of any resistance and capacitance changes under exposure to light or to x-rays. The results obtained suggested a further investigation of certain of the effects of electrolysis on these cells, a feature not originally planned. Certain interesting results were obtained.

Most of the cells were made up in one-inch test tubes with the electrodes mounted on glass tubes passing through rubber stoppers. The supporting wires were either of the same materials as the electrodes or else the electrodes were long enough to keep the wires out of the solutions. A few H-cells with one electrode in each arm were used. Some cells hermetically sealed in glass were made, since it was desired to test whether the properties were retained for a long time, if the evaporation of the ether was prevented. The Grignard reagents were made in an atmosphere of nitrogen, but in the solution there may be formed an etherate of the magnesium halide. It has not been possible to determine how far these etherates influenced the actions noted. The compounds used were phenylmagnesium bromide, ethylmagnesium bromide, the corresponding iodides, and bromo-ethylmagnesium bromide. These compounds were used because previous work by others had shown that they gave the largest photovoltaic responses. Various concentrations and electrode combinations were used.

The cells were mounted in a constant-temperature water bath packed in sawdust in a large light-proof box provided with a window and sliding shutter. Each cell was in a separate stall. A shielded cable ran from the cell-box to a selector panel by which any cell could be connected to the measuring apparatus. A 1000-watt lamp was used as the light source and the light was concentrated upon the cell under test by means of a large glass lens. An x-ray tube was also available.

The other resistances and capacitances are parts of the modified Wagner ground. The parenthetical correction factor in Eq. (1) is usually near enough to unity to be safely neglected, but in some of the cells tested here it was found to be as low as 0.75. Eq. (2) made possible the computation of the cell capacitance from data obtained during the measurement of the cell resistance. It can be seen that the balance conditions are functions of the frequency of the bridge current. Since the oscillators both gave out several harmonics, it was never possible to obtain complete silence in the phones, but merely to balance out the fundamental.

A number of tests were made which indicated that the resistance measured by the bridge was the electrolytic resistance and was very slightly affected, if at all, by films on the electrodes. For example, tests showed that variations of the distance between electrodes produced proportional changes in the resistance.

When an approximate value of the cell-resistance was known, bridge readings could be taken every minute. Potentiometer readings were taken at one-minute or half-minute intervals. Usually cells were illuminated for five minutes and then allowed to remain dark for an equal period.

The tests made can be classified under four general headings, which will be discussed in turn.

(a) *The effects of illumination and mechanical agitation on e.m.f.* Every cell was tested in this way. Ordinarily the entire cell was illuminated. With H-cells, tests were also made by illuminating separate electrodes or the cross-bar. In a few cases, a slit was placed in front of a straight cell so that a narrow ribbon of light passed parallel to the electrode surface or merely through the solution. Tests were made with varying degrees of mechanical agitation. As most of this part of the work was a repetition of what had been done by others, only the general conclusions will be given.

The e.m.f. was greatly affected by agitation of the cell and by polarization. The photovoltaic effects occurred without noticeable temperature changes. Oscillations of e.m.f., due to some unknown cause, took place even in the dark. Any change in the electrode surface caused an e.m.f. change, for example, exposing the electrode to air for a moment, cleaning the surface, etc. E.m.f. changed with age of the cell, partly because of concentration changes and partly no doubt because of slow electrolysis by minute leakage currents. Cells sealed in glass retained properties for many months but the e.m.f. varied and also the magnitude of the photovoltaic response. Light affected the potential of a given electrode almost invariably in the same way. Illumination of the electrolyte alone produced very small effects, possibly due to scattered light reaching the electrodes. In a few cases readings closely spaced showed that the light-e.m.f. effect involved two or three successive alterations. These were shown, by illuminating first one electrode and then the other by means of the narrow slit, to take place part near one electrode and part near the other, but very little, if any, in the body of the liquid. These tests, in general, favored the belief that the voltage phenomena are mainly localized near the electrodes. As a whole, these

conclusions are in agreement with those given in papers by the writer's colleague, R. T. Dufford, already quoted^{11,12} or soon to be published.

(b) *Measurements of e.m.f. as affected by irradiation with x-rays.* The general results obtained upon exposing certain cells to a beam of x-rays have already been reported in a brief note.¹⁵ Although they gave some promise as a means of measuring x-ray intensities, there were uncertainties about their behavior which need clearing up. This x-ray response differed from that produced by visible light in magnitude and frequently in sign, indicating that it was a different sort of action. Fig. 2 is a typical graph.

(c) *Measurements of e.m.f., resistance, and capacitance of cells as affected by visible light or by x-rays.* The accuracy of resistance measurements was about 0.1 percent, while that of the capacitance measurements was about

Fig. 2. E.m.f. as affected by light and x-ray illumination.

1 percent. Values of the cell-capacitances found by this bridge agreed with those indicated by a Leeds and Northrup Farad Bridge. All the cells studied carefully were of the test-tube type with electrodes about 5 mm apart. Platinum electrodes were of 1 cm² area, most of the others were of 5 cm² area. Resistance of a cell ranged between 500 and 20,000 ohms, capacitance from 0.4 to 35 mf.

Seven cells contained phenylmagnesium bromide with various electrode combinations. None of these cells showed any change in resistance upon exposure to light when the cells were new, but one, with platinum and copper electrodes, developed such sensitivity after about six months. The light-induced change was a drop of about 1 percent in resistance, recovery taking

¹⁵ R. T. Dufford and H. E. Hammond, Phys. Rev. 33, 124 (1929).

place in an equal period. Temperature rise produced an increased resistance which persisted as long as the cell was observed, indicating that the light effect was a different phenomenon.

Two cells filled with ethylmagnesium iodide gave no definite light-resistance response.

Four cells contained ethylmagnesium bromide. These were all symmetrical cells with electrodes of aluminum, platinum, copper, and sodium respectively. These cells showed lower resistances than those containing phenylmagnesium bromide. The resistances decreased and the capacitances increased with age in general. A single cell with platinum and aluminum electrodes and containing bromo-ethylmagnesium bromide showed a high

Fig. 3. Effect of light on e.m.f., resistance and capacitance. Upward-pointing arrows indicate when light was turned on; downward-pointing arrows when light was turned off. The same notation is followed in succeeding figures.

initial resistance, which became smaller with age, while the capacitance increased. All these cells showed an increase of about 1 or 2 percent in resistance during five minutes illumination, followed by recovery in an equal period of darkness. The changes in resistance could be detected within a few seconds after turning on or off the light. Resistance changes due to temperature rise could not be detected so soon and the changed value usually persisted after the temperature had come back to the original level. Furthermore, these light-induced changes were not in the same sense as those due to temperature rise in all cases. Figs. 3, 4, and 5 show typical sets of results. It was not possible to trace any general interrelation between the changes in e.m.f., resistance, and capacitance when the cells were illuminated. Fig. 4 shows the only example found of any apparent regular relation between

the capacitance values and the presence or absence of light on the cell. This relation existed for only a part of the test, as can be seen.

No tests of specific resistance were made for the Grignard solutions, but the values must be high in view of the high resistances compared with the cell dimensions. Secular variations in resistance ran as high as 50 or 60 percent, while the light-induced changes never exceeded 2 percent. The former changes were not reversible, the latter were. The photoelectric hypothesis is not tenable as some of the light-induced changes were increases in resistance. Neither does it seem reasonable to attribute a voltage variation of from 10 to 50 percent to a process which caused a resistance change of only 1 or 2 percent. The secular changes in resistance were undoubtedly due to chemical changes in the cell composition, evidences of which sometimes be-

Figs. 4 and 5. Effect of light on e.m.f., resistance, and capacitance.

came evident to the eye as time went on. The writer believes that the light-induced resistance changes were due to temporary and reversible variations in solvation of the ions rather than in percentage of ionization. These data, therefore, served to strengthen the idea that the voltage phenomena are due to changes near the plate surfaces, but the lack of any consistent relation between the capacitance changes and the presence or absence of light did not give any definite evidence to locate the seat of action on the surface itself.

Operation of the x-ray apparatus caused so much noise in the phones that the bridge could not be balanced while the cell was being irradiated. If the resistance or capacitance was affected by x-rays, the effect did not persist long enough to be measured after the apparatus was shut off.

As the high-frequency bridge current sometimes altered the e.m.f. of the cells, the potentiometer tests were always made first and the bridge measurements as soon as possible thereafter.

(d) The development of light-resistance sensitivity in one phenylmagnesium bromide cell after several months suggested that electrolysis of these cells might yield some interesting results. The high values of the capacitance per unit area in several of the cells also increased the belief that interesting data of that sort might be found by an application of the electrolytic or "forming" process. Although this feature was not a part of the program originally outlined, it was hoped that something bearing on the general question might be developed.

Electrolysis of ether solutions shows some features not common to aqueous solution. Ollar¹⁶ showed that in certain cases hydrogen was evolved at both electrodes, but he offered no explanation. Only a few papers¹⁷ have yet been published upon the electrolysis of Grignard reagents but work along that line is now being done. It is not possible to say just what happened in the cells treated in this paper, except that in some cases magnesium in the "tree" form was deposited on the cathode. Most of the deposit fell off the plate as soon as the current ceased, but the plate area may have been increased enough to account for at least a part of the increase in capacitance always noted. Luminescence has been observed during electrolysis, sometimes on the anode, sometimes on the cathode, sometimes on both plates.

In the electrolysis, a current of a few milliamperes at 15 volts was passed for 15 minutes through the phenylmagnesium bromide cells in the same direction as the current they generated. With the lower-resistance ethylmagnesium bromide cells 5 volts was applied for 5 minutes. With the first-mentioned type, the process resulted uniformly in decreased resistance, increased capacitance, and a light-resistance sensitivity where none had existed before. In the presence of light a decrease in resistance took place, while in a period of darkness equal to that of the illumination the original resistance was recovered. The ethylmagnesium bromide cells all developed capacitances 2 to 6 times the former values, but the resistance varied differently in different cells. No special change in light-resistance sensitivity was observed, except a small diminution in the magnitude.

Figs. 6 and 7 show results of tests with one cell of each type. Again no general relation was found between e.m.f., resistance, and capacitance changes under illumination. No resistance or capacitance effects were noted under x-ray irradiation.

In several cases, cells measured with an ordinary d.c. Wheatstone bridge showed asymmetrical resistances somewhat like those shown by aluminum rectifiers, but the asymmetry was not so pronounced. In one case, the resistances to currents in opposite directions were 8000 and 16000 ohms respectively, while in another the figures were 2600 and 19000 ohms, the higher resistance being uniformly offered to a current opposite to the "forming"

¹⁶ A. Ollar, Thesis, University of Missouri (1926).

¹⁷ L. W. Gaddum and H. E. French, *Jour. Am. Chem. Soc.* **49**, 1295 (1927).

current. The aluminum rectifier stops a current flowing in the same direction as the forming current. The cells which showed this characteristic had aluminum plates and contained phenylmagnesium bromide. Such differences of resistance are not great enough to be of practical use.

One other interesting point remains to be discussed, but lack of exact knowledge of the chemistry of these cells forces rather vague conclusions. Films on aluminum in electrolytic condensers have been found to have thicknesses ranging from 10^{-2} to 5×10^{-6} cm and the dielectric constant was estimated as 14.5.¹⁸ Assuming a value of 1 for the dielectric constant in the present cases, film thicknesses have been computed for two cells which showed very large capacitances. An ethylmagnesium bromide cell gave over 7 mf per cm^2 after "forming". For $k = 1$, the film thickness was 1.2×10^{-8}

Figs. 6 and 7. Effect of light on e.m.f., resistance and capacitance.

cm. A phenylmagnesium bromide cell with copper plates showed about the same capacitance per unit area and the thickness figures were 8×10^{-8} cm. These figures are of the order of interplane distances in crystals, so it is possible that the films are single layers of molecules or a few such layers. It may be noted that the thickness attributed to the film in phenylmagnesium bromide, a benzene-ring compound, is greater than that found for ethylmagnesium bromide, a short-chain compound, as might be expected. The very large capacitance per unit area, 7 mf per cm^2 , is worthy of note. If these thickness figures are near the truth, it seems strange that regular light-capacitance effects were not found, especially in view of the fact that other evidence seems to indicate that the photovoltaic effect is dependent upon condition of the electrode surface.

¹⁸ H. O. Siegmund, Trans. Am. Elect. Chem. Soc. 53, 203 (1928).

The following conclusions may be drawn.

(a) The conclusions of others as to variations in the e.m.f. of Grignard cells with age, with mechanical agitation, and with illumination are corroborated. The evidence seems to locate the seat of the phenomena at or near the surfaces of the electrodes.

(b) Several types of cells gave large voltage responses when exposed to x-rays and also showed large changes in current through a high-resistance circuit during such irradiation. The phenomenon is apparently a different one from the photovoltaic effect in the same cells.

(c) The resistance and polarization capacitance of a number of cells have been measured by means of a high-frequency bridge. Cells containing phenylmagnesium bromide showed no light-resistance response when freshly made, some containing ethylmagnesium bromide and one containing bromoethylmagnesium bromide did. This has been shown not to be a temperature effect. Some cells showed an increase of 1 or 2 percent in resistance when illuminated and some a decrease of about the same percentage, but a given cell was consistent. These results made a general photoelectric theory untenable and also indicated that the rather large voltage variations were not of the same origin as the resistance changes. The small reversible changes in conductivity were laid to alterations in solvation of the ions rather than to changes in ionization percentage. Such capacitance changes as were found seemed unrelated to other phenomena.

(d) A "forming" or electrolytic process was carried out with several cells containing phenylmagnesium bromide and ethylmagnesium bromide. The former then showed a light-resistance sensitivity. After the process, larger capacitances were observed in all cases, but no regular light-capacitance response.

Asymmetrical resistances, smaller than those in aluminum rectifiers, were found in a few cells.

Capacitances as high as 7 mf per cm² were found. Assuming a value of unity for the dielectric constant of the films, the probable thickness of the films was estimated to be of the order of the diameter of a molecule or a small multiple of that diameter. The thickness was greater for a benzene-ring compound than for the short-chain compounds used.

No effects on resistance or capacitance due to x-ray irradiation were detected.

In general, the evidence supports the belief that the voltage variations with illumination must be attributed to phenomena near enough to the electrodes to be affected by changes on their surfaces. The capacitance effects were inconclusive as to whether light-induced effects occurred in the films.

The writer expresses his sincere gratitude to Mr. R. T. Dufford, at whose suggestion the investigation was attempted and whose assistance and advice have been invaluable in carrying out the work; also to Professor O. M. Stewart for suggestions as to the bridge circuit and for the provision of the necessary apparatus and materials.

THERMAL CONVECTION

By R. W. BABCOCK

DE PAUW UNIVERSITY, GREENCASTLE, INDIANA

(Received March 8, 1930)

ABSTRACT

The differential equations which apply to slow steady convective motion of a viscous fluid are the standard equations of hydrodynamical theory, combined with equations expressing the law of thermal interchanges in a moving fluid. Approximate solutions are found following the method outlined by Oberbeck (*Ann. d. Physik*, 1879, p. 271). A comparative study of the exact solution of a special system of non-linear ordinary equations and the Oberbeck approximate solution shows that the magnitude of the constants in the system controls the rate of convergence of the approximation, and often produces divergence. Solutions with graphs of temperature and velocity fields have been computed for special cases of cylindrical and plane boundaries with sinusoidal impressed boundary temperatures. If this temperature has a vertical gradient only, the Oberbeck method produces a null solution, corresponding to equilibrium in stratified layers. Arithmetical solutions for common liquids at ordinary temperatures show that the Oberbeck solutions diverge unless the gradient is much too small to be easily applied in laboratory practice.

ANALYTIC solution of the problems of convection in fluids presents extreme difficulty. No methods have been devised for the exact solution of the differential equations, which are non-linear, and must be solved subject to complicated boundary conditions.

Free convection in a fluid consists of the motions produced by gravity throughout its volume due to changes in its density caused by variations in temperature. This paper presents approximate solutions of certain special cases of steady free convection, produced by temperature differences maintained at the fixed boundaries of the fluid.

If expressions are formed to represent: (1) the flow of momentum; (2) the flow of mass; (3) the flow of energy throughout any volume chosen in the fluid, and terms of second order are neglected, the resulting equations are

$$(dV/dt) - \alpha gT + (1/\rho)\nabla p - \nu\nabla^2 V = 0, \quad (1)$$

$$\text{div } V - \alpha dT/dt = 0, \quad (2)$$

$$(dT/dt) - h^2\nabla^2 T = 0. \quad (3)$$

The symbol g denotes a vector of magnitude $|g| = 32.2 \text{ ft/sec.}^2$ whose direction is upward.

The simplest cases are the flow of a liquid between two infinite parallel plane plates (Fig. 1), and between two infinitely long vertical concentric circular cylindrical pipes (Fig. 2). In both of these cases, the velocity equation reduces to $\nabla^4 u = 0$, and the temperature equation to

$$\alpha gT + \nu\nabla^2 u = 0. \quad (4)$$

When temperatures $\pm t$ are maintained on the plane plates, whose equations are $y = \pm a$, the solutions are

$$u = -\frac{\alpha g t}{6 a \nu} (y^3 - a^2 y), \quad (5)$$

$$T = ty/a. \quad (6)$$

For the cylinders whose radii are 1 and e , upon whose boundaries are maintained temperatures respectively of 0 and 0.5, the solutions are (using the physical constants of water)

$$u = 4.126 [r^2 - 1 - \log r (1.849 - 0.615 r^2)], \quad (7)$$

$$T = 0.5 \log r. \quad (8)$$

In both these cases, it is seen that the temperature is exactly what would be produced by conduction alone in a rigid body filling the space now occupied by the flowing liquid and having the same physical constants.

Fig. 1. T , solid curve; u , dotted curve.

Fig. 2. T , solid curve; u , dotted curve.

Fig. 3. Temperature field and isothermal lines.

For the solution of other cases, this paper follows the rule for approximation of such equations which was developed by Oberbeck.¹ This method reduces the analysis to equations of the type $\nabla^2 f(x, y, z) = F(x, y, z)$ subject to proper boundary conditions. Oberbeck, in his paper, starts the approximate analytic solution of the convection of a liquid between two concentric spherical shells, which are maintained at different constant temperatures, computing the first velocity terms and the second temperature term. He does not consider conditions of convergence of the solution.

To check Oberbeck's method of solution, a pair of similar simultaneous ordinary differential equations,

$$\frac{d^2 \Psi}{dx^2} - a \frac{dT}{dx} = 0, \quad (9)$$

$$\frac{d^2 T}{dx^2} - b \frac{dT}{dx} \cdot \frac{d\Psi}{dx} = 0, \quad (10)$$

¹ Oberbeck, Ann. d. Physik, 1879, S 271.

may be solved and the results computed numerically for various values assigned to a and b . The exact solution, subject to boundary values, $T(0) = -\alpha$, $T(l) = \alpha$, $\Psi(0) = \Psi(l) = 0$, is

$$\Psi = \frac{2}{b} \log \left[\cos \frac{Bl}{2} \sec B \left(x - \frac{l}{2} \right) \right], \quad (11)$$

$$T = \frac{2B}{ab} \tan B \left(x - \frac{l}{2} \right), \quad (12)$$

where B is the first positive root of the transcendental equation $B \tan (Bl/2) - (\alpha ab/2) = 0$. For $\alpha abl^{-1} = 0.25$, the Oberbeck type of series approximations converge rapidly toward the Maclaurin expansions of the exact solution; for $\alpha abl^{-1} = 1$, the convergence is slow; and for $\alpha abl^{-1} = 5$, divergence of the series is obtained. Any approximation, therefore, to equations of type of Eqs. (1), (2), (3), must depend for their convergence upon the values of their physical constants. Since these are restricted in a problem involving laboratory experiments, the analytical question of convergence prescribes the amount of temperature difference which may be applied. In the numerical computation of the following cases, the physical constants of glycerine have been chosen. These examples have been set up so that the Z -axis is a line of symmetry, and all the equations have but two independent variables.

Whenever the liquid is assumed to be absolutely incompressible so that $\text{div } V = 0$, and cartesian coordinates are used, a "current function" Ψ is formed such that

$$u = \partial \Psi / \partial y, \quad v = -\partial \Psi / \partial x. \quad (13)$$

Eqs. (1), (2), (3), then become

$$h^2 \nabla^2 T = \frac{\partial T}{\partial x} \frac{\partial \Psi}{\partial y} - \frac{\partial T}{\partial y} \frac{\partial \Psi}{\partial x}, \quad (14)$$

$$\nabla^4 \Psi = \frac{\alpha g}{\nu} \frac{\partial T}{\partial x}, \quad (15)$$

subject to $\Psi = \partial \Psi / \partial n = 0$, and $T = T(x, y)$ at the boundary surfaces. Two such cases are studied in detail.

(A) A half-space above the plane $y = 0$ upon whose surface $T(x, y) = t \cos x$ is maintained. The following solutions are obtained:

$$T = te^{-y} \cos x + \frac{\alpha g t^2}{128 h^2 \nu} [2 + e^{-2y} \{ (2y^2 + y) \cos 2x - (4y^2 + 4y + 2) \}] \quad (16)$$

$$\Psi = -\frac{\alpha g t}{8 \nu} y^2 e^{-y} \sin x - \frac{\alpha^2 g^2 t^2}{24576 h^2 \nu^2} e^{-2y} \sin 2x (4y^4 + 4y^3 + 3y^2). \quad (17)$$

The temperature and velocity fields are shown in Figs. 3 and 4. The limiting temperature approached high up in the space is not zero, but a definite positive value, $\alpha g t^2 / 64 h^2 \nu$, the heat having been carried upward by the convection currents and not brought down again as rapidly.

(B) The space between two infinite horizontal plane plates whose equations are $y = \pm l$, upon both of which $T(x, y) = t \cos x$ is maintained. When l is chosen as 3, and t as 0.5, the principal temperature term is $0.0496 \cosh y \cos x$, and

$$u = -10^{-3} \sin x [0.28y^2 \sinh y - 1.08y \cosh y + 0.74 \sinh y], \quad (18)$$

$$v = 10^{-3} \cos x [0.28y^2 \cosh y - 1.64y \sinh y + 2.38 \cosh y]. \quad (19)$$

The temperature and velocity fields are shown in Figs. 5 and 6. In both these cases the velocity fields show a jet-like streaming above the warm portions of

Fig. 4. Velocity field.

Fig. 5. Temperature field and isothermal lines.

Fig. 6. Velocity field.

the boundary. This is of the same type as that observed by Nelson² in his experiments in convection. The boundary temperatures are different in his work, so that only a qualitative check is obtainable here.

Using polar coordinates, analytic solutions may be computed for impressed boundary temperatures more readily adaptable to laboratory conditions. In the following examples the container is assumed to be an infinite horizontal circular cylinder, the initial line chosen as the upward radius, the vectorial angle running counterclockwise. Eqs. (14) and (15) when transformed to this system of coordinates are

$$\frac{\partial T}{\partial \rho} \cdot \frac{\partial \Psi}{\rho \partial \theta} - \frac{\partial T}{\rho \partial \theta} \cdot \frac{\partial \Psi}{\partial \rho} = h^2 \nabla^2 T, \quad (20)$$

$$\nu \nabla^4 \Psi + \alpha g \left(\sin \theta \frac{\partial T}{\partial \rho} + \cos \theta \frac{\partial T}{\rho \partial \theta} \right) = 0, \quad (21)$$

² Nelson, Phys. Rev. 23, 94 (1924).

where the radial and tangential components of velocity are

$$R = \partial\Psi/\rho\partial\theta, \quad \Theta = -\partial\Psi/\partial\rho. \quad (22)$$

As usual, the boundary conditions prescribe the temperature maintained on the surface, and cause the velocity to vanish there.

(A) The first case discussed in this coordinate system is an impressed boundary temperature $T = t \sin \theta$. This may be considered as the temperature impressed in a large metal block, across which a linear horizontal temperature gradient is constantly maintained. Temperature within the block near the boundary has not been measurably changed by the convection within the cylinder.

The first approximation to the velocity is a pure rotation, the current function being

$$\Psi_1 = -\frac{\alpha g t}{64\nu}(1 - \rho^2)^2 \quad (23)$$

the same solution which was found by Love³ in the deformation of a circular plate clamped at the circumference under uniform pressure. The temperature and velocity fields, approximated to another term, are shown in Figs. 7 and 8. This velocity field shows regions of "dead water" which have been observed under similar laboratory conditions.

Fig. 7. Temperature field and isothermal lines.

Fig. 8. Velocity field.

Fig. 9. Temperature field and isothermal lines.

For this case, a complete solution which does not include an assumption of the incompressibility of the liquid shows that the difference between the two types of solution consists of terms occurring only after the second approximations to temperature and velocity, and that these differences are of relative magnitude 10^{-3} . The analytic solution in this case is much more tedious. The values of the fluid pressure due to the convection current must be found, and the added accuracy of the solution occurs only in those terms which are of such size as to be entirely outside the range of experimental observation. The full solution is then neither a necessary nor an efficient method of attacking the problem.

(B) If a pure vertical gradient of any sort is impressed in the boundary temperatures, no motion is determined from the analytic solution. This represents equilibrium in the liquid, which is stable or unstable if the sign of the

³ Love, *Mathematical Theory of Elasticity*, 3d ed., p. 490.

upward gradient is positive or negative. The body of liquid stratifies in horizontal layers. In order to consider an approximate solution, one of two choices must be made: (1) assume a form of initial velocity; (2) assume an initial temperature which does not have a pure vertical gradient such as $T_0 = (t\rho \cos \theta)/a + kf(\rho, \theta)$, where $f(a, \theta) = 0$ to satisfy the boundary conditions. Either of these choices is so arbitrary that the solutions obtained do not compare with facts which could be observed. Two choices for $f(\rho, \theta)$ are studied here, both of which have radial symmetry. These are (1) $f(\rho, \theta) = (kt/a)(a - \rho)$ and (2) $f(\rho, \theta) = (kt/a^2)(a^2 - \rho^2)$. The temperature and velocity fields are compared. The two sets are shown in Figs. 9, 10, 11, and 12. In both cases, the

Fig. 10. Velocity field.

Fig. 11. Temperature field and isothermal lines.

Fig. 12. Velocity field.

whole problem approaches a null solution as the parameter k is made infinitesimal, so that neither presents a satisfactory approximation to the desired result. There is, however, a tendency for the corrections to the temperatures to equalize and thus become independent of the specific form chosen for $f(\rho, \theta)$.

Since Eqs. (14) and (15) are non-linear, the sum or difference of two solutions is not a new solution. This prevents the use of the usual type of uniqueness proof to assume a second solution and show that the difference of the two solutions vanishes identically. The essential accuracy of the approximations must be checked through experiment.

In all the particular examples studied, it is, of course, necessary to study carefully the question of the convergence of the series obtained:

$$T = T_0 + \alpha T_1 + \alpha^2 T_2 + \dots, \quad (24)$$

$$\Psi = \alpha \Psi_1 + \alpha^2 \Psi_2 + \dots. \quad (25)$$

For a liquid having a low viscosity, like alcohol or water, the sufficient condition for convergence requires the amplitude of the impressed temperature not to exceed about 10^{-4} degrees per centimeter of the horizontal cylinder. Such values are useless for comparison with any type of experiment. For a much more viscous liquid, such as glycerine, the amplitude of the impressed temperature may be as large as 10^{-1} degrees per centimeter radius. Even this restricts the usefulness of the Oberbeck method to such an extent as to render it practically useless as a comparison with laboratory results. The computations here show the dependence of the analytic solution upon the physical constants of the particular problem. They also determine the small amount of error obtained by assuming the absolute incompressibility of the liquid and demonstrate the fact that these corrections may be neglected, thus materially shortening the computations, which are laborious under the most favorable conditions.

LETTERS TO THE EDITOR

Prompt publication of brief reports of important discoveries in physics may be secured by addressing them to this department. Closing dates for this department are, for the first issue of the month, the twenty-eighth of the preceding month; for the second issue, the thirteenth of the month. The Board of Editors does not hold itself responsible for the opinions expressed by the correspondents.

*On the Mechanism of "Atomization"

So far as the writer knows no adequate explanation has been offered of the phenomenon of liquid "atomization." Scheubel¹ has, indeed, given some interesting and instructive spark pictures of the process as it occurs in the carburetor throat, but not much direct information can be derived from them except at fairly low air speeds. The fact, however, that the phenomenon can be used with confidence in the design of many machine elements,—that certain results may be expected to attend certain conditions,—is tacit declaration that the process has a definite physical background.

If, given a quantity of liquid which at one time exists as a single comparatively large mass, and a moment later is observed to be in the form of a very great number of very small discrete drops, we merely make the assumption that there must be an intermediate stage in which fine ligaments are formed, of such diameter that they will disintegrate into drops of the observed size, we can account for this phenomenon on the basis of Rayleigh's theory of jet disintegration and certain recent observations of the size of the drops formed when a liquid is atomized. This assumption seems reasonable, since time and temperature considerations exclude the possibility of evaporation and subsequent recondensation; it seems necessary, since it will appear very improbable that the existence of such fine ligaments can ever be directly demonstrated; and it is hoped to show that it is sufficient.

Rayleigh² thus explained the disintegration of a jet which we shall identify with the ligament mentioned in the preceding paragraph: He considered the jet as an infinitely long cylinder of liquid initially in equilibrium under the influence of the tension of its

envelope, and investigated the efficiency of various types of disturbance in upsetting this equilibrium. He found that

$$\alpha = \alpha_0 e^{qt} \quad (1)$$

where α and α_0 are amplitudes, at times t and 0, respectively, of a disturbance symmetrical with reference to the cylinder axis; e is the Napierian base; and

$$q = \left(\frac{8T}{\rho D^3} \right)^{\frac{1}{2}} \cdot F \quad (2)$$

In Eq. (2), T and ρ represent the liquid's surface tension and density, respectively:

D is the diameter of the undisturbed filament; and F is a (dimensionless) function of Z , the ratio length/diameter. The denominator of this fraction is the same as D above, while its numerator is the distance along the jet between two adjacent points in the same phase of vibration.

When α grows to $D/2$ the filament breaks.

The function F has been investigated by Rayleigh² and by the present writer.³ As a result it follows that the effective value of F may be taken as about 0.34 at $Z=4.5$. For this value of Z it also follows that the diameter d of a spherical drop will be about twice D , the diameter of the cylindrical segment from which the drop is formed.

for water atomized in a high speed air stream, a mean value of d of about 6×10^{-4} cm, while Woltjen⁶ found about the same for oil atomized by "airless" injection into a high pressure bomb. Taking 10^{-3} cm as an upper limit, we have 5×10^{-4} cm for D , so that Eq. (2) gives $q = 740,000 \text{ sec.}^{-1}$ for water atomized in a high speed air stream.

Now, it is very difficult, if not impossible, to estimate the value of α_0 precisely. The molecular diameter is, however, of the order of 10^{-7} cm⁷ so it seems legitimate to place about 10^{-8} cm as a lower limit. To cut through a ligament 5×10^{-4} cm in diameter, α must grow to $D/2 = 2.5 \times 10^{-4}$ cm. The necessary time is, by Eq. (1), $t = (1/q) \ln \alpha/\alpha_0 = (1/M_q) \log_{10} \alpha/\alpha_0 = 1/73,000 \text{ sec.}$ (approx.). This would correspond to a motion of about

2 millimeters of the *air* stream in the throat of the carburetor of an automobile engine turning over at high speed; or of about 1 mm of the spray 0.0005 sec. after injection at 8000 lbs/in², into a chamber held at 200 lbs/in² (N.A.C.A. Report #268).

The above gives *upper* limits of the possible lengths of these fine ligaments. Small wonder that they have never been observed!

The Atomic Weights of Hydrogen and Helium.

Eddington (Proc. Roy. Soc. A126, 696, 1930) has obtained a new theoretical value of $1/137$ for the fine structure constant α . This agrees much better with observational data than his previous value of $1/136$. He also reaches the very interesting conclusion that in a *rigid system* of protons and electrons, there should be a proportional loss of mass equal to α . The most rigid system of this kind now known is the alpha-particle, and the loss of mass, assuming the alpha-particle to be absolutely rigid, agrees more closely with the theory than is indicated in Eddington's paper. In fact, on this assumption, an atomic weight of 1.00777 ± 0.00002 for hydrogen (see Birge, Phys. Rev. Suppl. 1, 1, 1929) leads to 4.00166 as the calculated atomic weight of helium. As I have noted (footnote 12a, page 21, loc. cit.) the best chemical value for this latter quantity is now 4.0018. Because of the newly discovered isotopes of oxygen, Aston's mass spectrograph value of 4.0022 should be lowered about one part in 10,000 (page 69, loc. cit.) and then agrees precisely with the chemical value. Hence the observed and calculated values of the atomic weight of helium differ by only one part in 30,000, and this may be

taken to indicate that the alpha-particle is in fact very nearly "rigid."

This correlation of the fine structure constant with the "packing effect" in an alpha-particle has already been suggested, on a purely empirical basis, by Lunn (Phys. Rev. 20, 1, 1922) and has been revived by Witmer (Nature 124, 180, 1929). In this earlier work, the predicted decrease in mass was given as $\alpha/(1+\alpha)$, but this differs by an entirely negligible amount from the present predicted decrease of α .

If the nucleus of the isotope oxygen "16" is a non-rigid system composed of four such "rigid" alpha-particles, the mass of this nucleus should be four times the mass of an alpha-particle, diminished by the mass-equivalent of the binding energy of the four alpha-particles. The atomic weight of the isotope oxygen "16" is 15.9984 (one part in 10,000 less than 16.0000), and one thus obtains 0.0082 atomic weight units (or one part in 1950 of the total mass) as the mass-equivalent of the binding energy. This seems to be a reasonable value.

RAYMOND T. BIRGE

A New Unified Field Theory and Wave Mechanics

In your issue of January 1st 1930, you published a preliminary notice of a paper on the above subject by the present writer. A few more words of explanation thereof, not included in the paper itself seem called for.

The fundamental postulate is that the unobservable is non-existent. This is familiar in wave mechanics, but is now applied for the first time to relativity.

Since the metric tensor of space time is

defined logically in terms of an unobservable N -dimensional pseudo-Euclidean space, for classical relativity, by our postulate the definition is impossible. For us the metric tensor becomes a perfectly arbitrary set of ten functions of the space-time coordinates, available for descriptive purposes. The old analogy with the intrinsic properties of two-dimensional curved surfaces can be dropped and surpassed. The metric tensor is defined only by transfer according to a certain rule from an initial point, and its increments are not perfect differentials; it depends upon the track along which the rule has been applied. Such a tensor is sufficient to give definite magnitude to the elements of the vector lines in the vector field defined by another transfer rule applied to a vector. As already pointed out these vector lines become the known orbit equations when the simplest derivable definite tensor function is used to describe the electric field.

This is a distinct improvement on the theory of Kaluza and Klein which introduces an unknowable fifth dimension directly into the equations, apart from the others required for the logical definition of the metric.

It has been found necessary to abandon the

hope that the theory might lead to quantised orbits round atomic nuclei; but this is not necessary, for there is no longer any inconsistency with wave mechanics. Thus classical electromagnetic theory was based on the concept of a local singularity with definite position and velocity; but no such singularity is at the basis of the present theory. The new point of view is this: If local singularities exist, then their tracks can be described by means of the vector line theory, but if the uncertainty in the position or velocity of such singularities becomes significant, the method will no longer be useful, and statistical methods appropriate to the case must be used. There is thus no longer any inconsistency, it is merely a matter of convenience in description.

We may finally claim to have cleared up the apparent inconsistencies between the field theory and the atomic theory, and set the former on the same satisfactory philosophical basis as the latter.

The Carbon Dioxide Theory of the Ice Ages

It was pointed out long ago by Tyndall, (Phil. Mag. 22, 277 (1861)), that changes in the carbon dioxide content of the atmosphere might be a controlling factor in the cause of ice ages. The suggestion was generally accepted for many years but more recently writers have denied its importance, for example Angström, Ann. d. Physik 6, 172 (1901), Humphreys, ("Physics of the Air," pages 564 and 602 (1929)), Abbot and Foule, (Smithsonian Institution, Annals Astrophys. Obs. 2, 172 (1908)), Jeffreys, ("The Earth," page 263 (1924)) and Simpson (Nature 124, 988 (1929)) and "Past Climates," page 9 (1929)). These writers have used the single blanket argument, which in its simplest form may be stated as follows: If all the energy leaving a hot body is absorbed by one blanket the cooling rate will not be reduced by increasing the number of blankets. Since water vapor is practically completely absorbant for the radiation in the CO_2 absorption bands, they argued that changing the amount of CO_2 in the atmos-

phere would not affect the climate of the earth.

The argument of course is not correct. For example, the temperature T degrees Kelvin of a body warmed by a constant supply of energy f ergs $\text{cm}^{-2} \text{sec}^{-1}$ and cooled by radiation through an absorbing sheath containing n molecules, in a 1 cm^3 column through the sheath, of atomic absorption coefficient α for the radiation, is given by

$$T^4 = f(1 + \alpha n) / a\sigma, \quad (1)$$

where a is the absorption coefficient of the surface of the body and σ is the Stefan-Boltzmann constant. From (1) it is seen that T increases with n for all values of n . Calculations for the carbon dioxide and the water vapor in the upper atmosphere, using (1) and taking into account the shift of the spectral distribution curve of the radiation as it passes through the atmosphere, etc., show that a 70 percent decrease in the carbon dioxide will cause a decrease of more than 6 percent in the radiation entering the lower atmosphere, (Terr. Mag. and Atmos. Elec.

33, 253 (1928)). This decrease alone will account for a temperature drop of about 6°C at the earth's surface. When to this 6° is added decreases associated with decreased humidity, decreased wind action in providing a cooled insulating layer and increased reflection of sun's rays accompanying the extension

of ice fields we would expect a temperature drop such as would be associated with an ice age. It is hoped to develop these ideas to some extent in a future paper.

BOOK REVIEWS

Magnetism. EDMUND C. STONER. viii + 117 pp. 20 figs. E. P. Dutton and Co., New York 1930. Price: \$1.10.

This little book is one of a series by English physicists which propose to supply the advanced student of physics in general with condensed accounts of recent progress in specialized branches of his subject. The general preface by O. W. Richardson emphasizes the utility of these monographs to those preparing for examinations. The present exemplar is well written and is thoroughly up-to-date in all that relates to the theory of magnetism and to the experimental basis upon which it rests, that is to theory and experiment in diamagnetism, paramagnetism and ferromagnetism in high magnetic fields. Ferromagnetism in weak magnetic fields—including the Barkhausen effect—is not so happily treated. This is no doubt because this part of the subject is still, as the author clearly states, almost without a theoretical structure to connect its phenomena. Aside from four misprints, a slight mistake regarding the magnetostriction of nickel-iron alloys on page 88, and a general tendency to use sub-visible subscripts, the reviewer finds nothing in which the author, editor, and publisher have been remiss. The practice of omitting the name of each investigator with whose conclusions the author disagrees is novel but commendable.

L. W. MCKEEHAN

Acoustics of Buildings. F. R. WATSON. Second Edition, Pp. 165, Figs. 69. John Wiley & Sons, New York, 1930. Price \$3.00.

This is a second edition of Professor Watson's book first published in 1923, and is intended for that rapidly growing group of persons who have to deal with the practical problems of architectural acoustics. For this reason the emphasis throughout is laid upon the application of the developments in this field during the last thirty years to the control of acoustic conditions rather than upon a detailed account of the underlying principles and theory.

The first section of the book concerns itself with the problems of Auditorium Acoustics, particularly with the calculation and control of reverberation. Numerous illustrations and examples of the use of the reverberation formula both in the design of new rooms and in the correction of existing rooms are given. The most important addition made in the revision of this section of the book is a table of sound absorption coefficients of commercial materials used for acoustical correction, and one giving the absorbing power of opera chairs of various types. The author's position on the question of optimum reverberation times as a function of the size of the auditorium is somewhat equivocal. Thus a graph is given showing what the author considers the optimum time computed by the well-known Sabine formula increasing linearly with the logarithm of the volume from 0.8 to 2.05 seconds as the volume is increased from 1,000 to 1,000,000 cubic feet. In a subsequent paragraph under the heading "Ideal Auditorium Acoustics" appears the statement "The second condition (for ideal acoustics) is that the auditorium should be made as dead as out doors for the benefit of the auditors." The reader interested in the acoustical design of a new room is left in doubt as to whether to install absorbent material so as to give the "optimum reverberation time," or to try to approximate the "ideal" condition of out of doors where sound reflection is nil. The difference is one of considerable practical importance.

There are no important additions to the material given in the earlier edition in the section devoted to sound proofing in buildings, although numerous references to recent original work on this phase of the subject are added.

Considered even as a vehicle for the conveyance of practical information, one feels that the author frequently errs on the side of brevity and over simplification. This is particularly true in some of the illustrative diagrams. Thus to represent sound of wave-length of the order of two feet as being reflected in a parallel beam from a parabolic mirror with an aperture of five feet and reflected again geometrically from a plain surface of small dimensions is to neglect the complicated standing wave pattern that must result in such a case from interference and diffraction, and measurements based on such a simplified picture of the phenomenon must be open to serious question.

Taken as a whole the book is a concise, almost summary, statement of the principal facts of architectural acoustics as they were known at the time of the publication of the first edition of the book. To include the considerable mass of data that have been accumulated in the last five years would call for more rewriting than could be included in a revision of the first edition.

PAUL E. SABINE

Molekelbau. F. HUND. Pp. 38, 7 figs. and 3 tables. Part of Band VIII, *Ergebnisse der exakten Naturwissenschaften*, Julius Springer, Berlin, 1929.

This is a valuable compact summary of the progress made to date (i.e., spring of 1929) in the theory of molecular structure from the standpoint of the wave mechanics. The emphasis is laid on the qualitative features of the problem and no attempt is made to consider the mathematical arguments involved. The bibliography is comprehensive. The attention of persons interested in this review may also be called to the "Zusammenfassende Bericht" on homopolar chemical binding by W. Heitler in the *Physikalische Zeitschrift* for March, 1930, and to the articles on the "Interpretation of Band Spectra" by Mulliken now appearing in *Reviews of Modern Physics*.

(Received March 16, 1930)

ABSTRACT

The *intensity of x-rays reflected* from powdered crystals of magnesium oxide was measured for all lines out to $\theta = 45^\circ$. The values of the structure factor, F , were calculated and plotted against $\sin \theta$. Using the values of F from this curve as coefficients in Compton's Fourier series, the *radial electron distribution for the atoms of magnesium and oxygen* was determined. The electron distribution curves for these atoms are very similar to Havighurst's curves for sodium chloride and sodium fluoride. Although it has been generally conceded that crystals of the magnesium oxide type are polar in form, the data here included are more in line with their being non-polar crystals. However, it is not believed possible from x-ray reflection data to prove definitely this point.

INTRODUCTION

THE intensity of reflection of the K_α line of molybdenum has been measured for powdered crystals of magnesium oxide. The structure factor curves have been calculated, and the electron density in the crystal and the radial electron distribution in the atoms of magnesium and oxygen have been determined, using the Fourier Series worked out by A. H. Compton.¹ Besides being able to determine the distribution of the electrons in the atoms, the total number of electrons associated with each point of the space lattice can thus be found. This should make it possible to decide whether the crystal is in a polar or non-polar form. In the work of Bragg, James, and Bosanquet, sodium chloride was concluded to be polar and Havighurst has concluded that several crystals with which he worked were of this form. In general the evidence seems to favor this view for crystals of the sodium chloride type, but it can hardly be said to be conclusive.

Magnesium oxide has been chosen for analysis, not only for the interest in determining the electron distribution in the atoms of magnesium and oxygen, but also because it is a very suitable substance for showing the state of ionization of the atoms in the space lattice.

¹ A. H. Compton, "X-Rays and Electrons."

EXPERIMENTAL PROCEDURE

The accuracy with which intensity measurements can be made with powdered crystals is limited to some extent by the difficulty of obtaining a strictly homogeneous beam of x-rays of sufficient intensity. It was found that the method used by Havighurst² was most suitable for obtaining accurate results, especially at large angles, where the intensity is very weak. This method is essentially that first used by W. H. Bragg,³ and consists in utilizing the focussing effect of randomly oriented crystals pressed into a flat plate, and the use of zirconium oxide filters for cutting out the K_β and K_γ lines and a greater part of the general radiation. The arrangement of the author's apparatus is shown in Fig. 1. A molybdenum target x-ray tube was operated at a potential of 35 kv and 35 m.a., supplied by a transformer with full wave rectification.

Fig. 1. Diagram of apparatus

The pure magnesium oxide powder was pressed into a brass ring two inches in diameter. The mass per cm² of the powder was made just great enough for practically total absorption of the K_α lines of molybdenum. In this way some of the general radiation of shorter wave-length was not effective in scattering and increasing the continuous background.

The slits used in front of the ionization chamber were accurately measured to be of such width that when the briquet was moved through some predetermined increment of arc (generally five to ten minutes) the slit, S₂, moved through its own width. In this way all the reflected energy was received in the ionization chamber.

The ionization current was measured with a Compton electrometer, having a sensitivity of from five to ten meters per volt. The rate of deflection of the electrometer needle was taken at each increment of arc corresponding

² R. J. Havighurst, Phys. Rev. **28**, 832, (1926).

³ W. H. Bragg, Proc. Phys. Soc. London, **33**, 222 (1921).

to the width of the slit, S_2 . The reciprocals of these readings were plotted as ordinates against the angle θ and the intensity of the line was taken as proportional to the sum of the ordinates above the base line. If the increments are small the intensity is also proportional to the area under the curve. Different widths of slits, S_2 , were found to give results in satisfactory agreement.

Table I, column three, gives the average of the relative intensity measurements where the intensity of the (200) reflection has been taken equal to 100.00. The measurements have been extended to about $\theta = 45^\circ$. This is as far as the spectrometer could conveniently be used.

STRUCTURE FACTOR DETERMINATIONS

Darwin⁴ and A. H. Compton⁵ have derived equations which relate structure factor and the integrated intensity of x-rays reflected from powdered crystals.

When the relative intensity measurements have been made by reflection from a briquet of powder as they were in this case, the equation for calculating the relative values of the structure factor, F , takes the simple form

⁴ C. G. Darwin, Phil. Mag. **43**, 827, (1927).

⁵ A. H. Compton, Phys. Rev. **9**, 29, (1917).

$$F^2 = \frac{P_s \sin \theta \sin 2\theta}{j (1 + \cos^2 2\theta)} \quad (1)$$

where P_s is the intensity of the reflected beam measured on some arbitrary scale, j is the number of planes cooperating in producing the intensity P_s , and 2θ is the angle between the primary and the reflected beam. F^2 is the square of the structure factor in which the Debye⁶ temperature factor, $\exp [(b^2 \sin^2 \theta) / \lambda^2]$, is included. The reasons for the inclusion of the Debye factor in the value of F have been pointed out by Havighurst.²

The relative values of F can be placed on an absolute scale by comparing the intensity of some line of the substance to be analyzed with the intensity

Fig. 2. Structure factor curve for MgO.

of a line of a substance for which the absolute value of F has been directly determined. The absolute value of F for the (220) reflection of sodium chloride has been measured by James, Bragg and Bosanquet⁷ on single crystals, and corrected for secondary extinction. Their value of $F=15.75$, has been used as a standard for placing the relative F values of magnesium oxide on an absolute basis.

Table I, column IV gives the absolute values of F for all the lines measured, where F (220) was found equal to 10.15 by comparison with the same reflection from sodium chloride.

⁶ P. Debye, *Verh. d. D. Phys. Ges.* **15**, 678, (1913).

⁷ W. L. Bragg, James, and Bosanquet, *Phil. Mag.* **42**, 1, (1921).

Fig. 2 shows the F curves plotted from the above values of F . The upper curve is due to even order reflections and corresponds to $F_{Mg} + F_O$, while the lower curve corresponds to $F_{Mg} - F_O$. The values of F for the separate atoms can be found from the relations

$$\begin{aligned} F_{Mg} &= \frac{1}{2}(F_{Mg} + F_O) + (F_{Mg} - F_O) \text{ and} \\ F_O &= \frac{1}{2}(F_{Mg} + F_O) - (F_{Mg} - F_O). \end{aligned} \quad (2)$$

Since magnesium and oxygen are bivalent and have atomic numbers of 12 and 8, respectively, the ions would have 10 electrons each. This means that for ions the lower F curve is dependent on the different electron distributions and not on the number of electrons in the two ions. If the scattering centers are neutral atoms this curve would be a function of both the distribution and the number of electrons.

ELECTRON DISTRIBUTION CURVES

For the determination of the radial electron distribution curves the equation derived by Compton was used. This is a one dimensional Fourier series and much easier to evaluate than the three dimensional series of Duane. The series has the form

$$U = \frac{8\pi r}{D^2} \sum_1^{\infty} n F_n \sin \frac{2\pi n r}{D} \quad (3)$$

where U is equal to the number of electrons per Angstrom and r is the distance from the center of the atom in Angstroms. If both sides of this equation are multiplied by dr and integrated from 0 to $D/2$ one gets an expression for Z , the total number of electrons in the atom included between these limits,

$$Z = -2 \sum_1^{\infty} (-1)^n F_n. \quad (4)$$

In calculating the electron distribution curves for magnesium and oxygen, spherical symmetry has been assumed in the atoms, and the values of F were read directly from the F curves, assuming a grating space of 2.5Å for the sake of convenience in calculations. This gives a series of only seven terms, but it was found that the distribution in the K and L shells was only very slightly different if a larger number of terms were used.

TABLE II. Values of F from F -curves on basis of $D=2.5\text{\AA}$.

Indices	Sin θ	$(F_{Mg} + F_O)$	$(F_{Mg} - F_O)$	F_{Mg}	F_O
111	0.142	15.00	2.92	8.96	6.04
222	.284	8.40	2.76	5.58	2.82
333	.426	5.10	2.00	3.55	1.60
444	.568	2.94	1.14	2.04	0.90
555	.710	1.94	0.44	1.19	0.75
666	.852	1.24	0.00	0.62	0.62
777	.994	0.60	0.00	0.30	0.30

Table II gives the values of $F_{Mg} + F_O$ and $F_{Mg} - F_O$ which have been taken from the F curves of Fig. 2 and the values of F_{Mg} and F_O , which have been calculated with the aid of Eq. (2). Using these values of F as coefficients in the series 3, given above, the electron distribution curves of magnesium and oxygen have been plotted in Figs. 3 and 4.

MAGNESIUM

Fig. 3 shows the curve for the radial electron distribution in magnesium. The area under the curve corresponding to the K and L shells is about 9.5 electrons, unless a part of the adjoining hump is included. If the distribution is calculated on the basis of $D = 5.00\text{\AA}$ the area under this part of the curve is 10 electrons and its distribution is very nearly the same with a slightly better resolution of the hump at $r = 0.5\text{\AA}$. The distribution in these shells is very similar to Havighurst's⁸ curves for sodium in NaCl and NaF, except that in this case the average distance of the electrons from the nucleus is less.

Fig. 3. Electron distribution in Mg.

This could be expected from the fact that magnesium has a higher atomic number and also that the grating space of Mg is less than for either of the other two substances mentioned.

In this curve there is also an indication of the two valence electrons, and these, as might be expected, are more loosely bound than the other electrons. Little significance can be placed in the positions of these humps, however, since they are not the same when calculated on the basis of $D = 5.0\text{\AA}$.

The total number of electrons in the atom, according to this analysis is 11.50. This is the area under the curve and also the value as given in Table II, calculated from Eq. (4). In all cases the area under the curve checks the value from Eq. (4) as, of course, should be the case if no error is made in working out the Fourier series. The existence of only 11.50 electrons using the F values corresponding to $D = 2.5\text{\AA}$ and 11.04 electrons for $D = 2.424\text{\AA}$ indicates that some of the electron atmosphere is at a distance greater than

⁸ R. J. Havighurst, Phys. Rev. **29**, 1, (1927).

$D/2$ from the nucleus, beyond which the series does not hold, since it drops to zero at this value.

OXYGEN

Fig. 4 shows the radial electron distribution curve for oxygen. Here the electron shells in oxygen have areas corresponding to 3, 3.5 and 1.5 electrons with a small erratic variation near $D/2$. The fact that the humps do not represent an integral number of electrons may be due to experimental error,

Fig. 4. Electron distribution in O.

but there is no reason, from the idea of elliptic and interpenetrating orbits, that the distributions should be made up of humps representing integral numbers of electrons.

The total area under the curve is equal to 8.7 electrons, which also checks the value in Table II, as calculated from Eq. (4). This curve for oxygen closely resembles Havighurst's curve for fluorine.

ELECTRON DENSITY IN THE MgO CRYSTAL

Compton has derived a series which represents the number of electrons in a plane at any height above some atomic layer. This series has the form

$$P = \frac{Z}{a} + \frac{2}{a} \sum_{n=1}^{\infty} \left(F_n \cos 2\pi n \frac{z}{a} \right) \quad (5)$$

where P is equal to the number of electrons per Angstrom, z is the distance above the reference plane in Angstroms, and Z is the total number of electrons per molecule of the substance.

Using the values of F_{111} , F_{222} , etc., given in Table I and the value of F_{666} extrapolated from the F curve, as coefficients in this series and plotting P against z/a , one gets the curve shown in Fig. 5.

It will be noticed that the electron density does not fall to zero between the atoms. This means that the atoms overlap, and in order to tell how many electrons belong to each atom it is necessary to extrapolate the curve of one atom into the space of the other. This, in general, can be only a good guess; but in this case there is considerable difference in the size of the humps, and the most obvious extrapolation would be to give magnesium more electrons

than oxygen. In Fig. 5 extrapolations have been made for the two extreme cases of the neutral atom and the ion. The broken line shows how the curve can be extrapolated to give Mg 12 electrons and oxygen 8 electrons, while the dot and dash line gives the ions with 10 electrons each. From the fact that the radial electron distribution curves for magnesium do not contain 12 electrons between 0 and $D/2$, however, one is led to the conclusion that the valence electrons of magnesium spend part of the time nearer to the nucleus of oxygen than to that of the magnesium atom. It is, however, probable that the distribution for large values of r in the radial distribution

Fig. 5. Electron density in MgO.

curves, is no more reliable than a logical extrapolation of the curves in Fig. 5.

Using the table of F values worked out by Havighurst as coefficients in series 4, the total number of electrons associated with the atoms in various crystals has been determined and the results are shown in Table III. It will be seen that the analysis of these data by the use of Compton's series leads to no definite conclusions regarding the state of ionization of the atoms in the crystals considered.

TABLE III.

Mg		O	
$D = 2.5\text{\AA}$	$Z = 11.52$	$Z = 8.70$	
2.424\AA	$Z = 11.04$	$Z = 8.42$	
5.00\AA	11.56	8.34	
Havighurst's Data			
NaCl	NaF	CaF ₂	LiF
$Z_{\text{Na}} = 10.82$	$Z_{\text{Na}} = 10.48$	$Z_{\text{Ca}} = 19.04$	$Z_{\text{Li}} = 1.42$
$Z_{\text{Cl}} = 17.54$	$Z_{\text{F}} = 9.12$	$Z_{\text{F}} = 10.46$	$Z_{\text{F}} = 8.38$

CONCLUSION

There seems to be fairly good agreement in the data of different observers for the distribution of the electrons in the *K* and *L* shells of various atoms. For magnesium there is no overlapping of these shells for neighboring atoms. In the shells of larger radius, where there is overlapping of the electrons for the two or more atoms considered, it is quite likely that the analysis of the distribution is less reliable.

From the data at hand, one is hardly justified in drawing definite conclusions regarding the location and the behavior of the valence electrons in the atoms of crystals. To say that an atom is ionized in the crystal presumably means that the electrons are revolving about the nucleus of the other atom. Since a large portion of each atom overlaps its neighbor, this implies that the analysis can detect whether an electron scattering at a point near the nucleus of one atom is actually revolving about the nucleus of the other. This can, at best, be only a good guess as to what is actually occurring.

The calculation of the distribution of diffracting power in some direction in the crystal is considerably more straightforward. Hence, a curve of the type of that shown in Fig. 5 would be more reliable than the radial distribution curves. In the case of magnesium oxide it would be easier to extrapolate this curve to give 12 and 8 electrons to the atoms of magnesium and oxygen, respectively, than to make an extrapolation giving these atoms each 10 electrons.

Since there is a considerable amount of overlapping of the neighboring atoms, it would be more reasonable to conclude from the data at hand that the valence electrons are shared by the atoms of magnesium and oxygen and that neither of the conclusions regarding the existence of ions or neutral atoms in the points of the crystal lattice is altogether correct.

In conclusion, the writer wishes to express his appreciation to Professor A. H. Compton for his helpful suggestions throughout the work.

PREDISSOCIATION OF DIATOMIC MOLECULES
FROM HIGH ROTATIONAL STATESBY D. S. VILLARS AND E. U. CONDON
UNIVERSITY OF MINNESOTA, MINNEAPOLIS

(Received March 12, 1930)

ABSTRACT

Instability of molecules in high rotational states, as observed especially in HgH and AlH, is a phenomenon whose quantum-mechanical explanation is closely analogous to that of the radioactive disintegration of atomic nuclei. The heat of dissociation of AlH from its normal state is estimated to be 3.07 volts.

THE observations of Henri¹ and his school, that certain band systems apparently pass progressively from a discontinuous to a continuous character in such a manner as to indicate that the emitting molecules lose their rotational quantization before they lose their vibrational quantization, has been ascribed to a "predissociation" by various writers. The generally accepted mechanism for this process is that proposed by Bonhoeffer and Farkas,² who assume, in accordance with quantum mechanics, that there may occur a radiationless transition of the molecule in a definitely quantized rotational and vibrational state, to another electronic state for which the same total energy places the molecule in the continuous energy range corresponding to dissociation. When the probability of transition from the quantized level to the dissociated state is high, the average life of the molecule may become less than a rotational period of the molecule so the corresponding band is diffuse. But there is an additional mechanism for predissociation which also is a consequence of quantum mechanics which has not been mentioned before, so far as we are aware.

It is known that the set of rotational quantum levels associated with the same vibrational quantum number may extend up to values of the total energy in excess of the amount necessary to dissociate the molecule in that electronic state. Such sets of rotational levels however do not extend upward indefinitely but are often observed to break off rather suddenly. In at least one instance, that of aluminum hydride, the last two or three levels broaden out so that lines involving them become faint because their energy is spread out more on the photographic plate. This phenomenon has been interpreted by Mulliken,³ Hulthén,⁴ and Ludloff⁵ as due to an instability of the molecule arising from the high rotation. What has been lacking is an

⁵ Ludloff, *Zeits. f. Physik* **39**, 526 (1926).

account of the nature of the instability and the reason that it sets in when it does.

Franck and Sponer⁶ have advanced the view that the phenomena both of the sudden termination of such sets of rotational levels and the broadening of the last few levels, are to be interpreted as Bonhoeffer and Farkas have suggested. Oldenberg,⁷ from classical ideas alone, has criticized this paper of Franck and Sponer. He points out that the potential energy governing the radial motion of a molecule that is rotating with quantum number, m , is equal to

$$U_m(r) = U_0(r) + \frac{h^2}{8\pi^2\mu} \frac{m(m+1)}{r^2}$$

where $U_0(r)$ is the potential energy for the non-rotating molecule and is determined by the electronic state. Since for large r , $U_0(r)$ becomes constant more rapidly than r^{-2} approaches zero, the function $U_m(r)$ is positive for large values of r and will show, for m not too great, a minimum followed by a maximum at greater nuclear separation. This behavior is illustrated by Fig. 1 which represents the curves (Morse⁸) for HgH.

The similarity of the curves with those that lie at the basis of quantum mechanics of radioactive disintegration⁹ is evident. Hence the general properties of the wave equation which were so successful in that field are applicable here. The formula for the mean time of remaining essentially in the range of the periodic classical motion near the minimum, before going over into the range of the aperiodic classical motion extending from beyond the maximum to infinity, there developed for the atomic nucleus, is here applicable to the dissociation of molecules by rotation. We do not expect accurate results from it, both because it is based on an approximate integration of the wave equation, and because it requires an accurate knowledge (which we do not have) of $U_0(r)$ for the larger values of r . In principle, however, we have the means of inferring from the $U_0(r)$ curve, which is inferred from the energy levels, the exact maximum value of the rotational energy which can give levels effectively sharp in radiative transitions. These are the ones for which the mean life, τ , of the molecule before it "leaks" through the hump in the potential energy curve is large compared with 10^{-8} sec, which is the mean life needed to provide a sharp line in spectroscopic instruments of the resolving power actually available to experimenters.

Oldenberg has shown that there will be no trace of any discrete level structure for any value of m greater than the one for which $U_m(r)$ has a horizontal inflection point. (An *integral* value of m may not give a horizontal inflection point, m is regarded here as a continuous variable). He also mentions that owing to the existence of the so-called zero-point vibration energy the actual

⁹ Gurney and Condon, *Phys. Rev.* **33**, 127 (1929).

values of m will not extend this far. But there is another factor to consider: the level in question must be sufficiently below the maximum of the $U_m(r)$ that the mean life before leakage is large compared to the mean life before radiation. It is clear why the rotational levels associated with the second vibrational quantum state cannot extend as high as those associated with the

Fig. 1. Rotational vibrational (Morse) curves for HgH (normal $^2\Sigma$ state.) The designation $F_2(30)$ refers to the upper of the two doublet levels on the $m=30$ curve.

first; they are always higher above the minimum of the $U_m(r)$ curve because of the extra vibrational energy and therefore the requirement that they be sufficiently below the maximum of $U_m(r)$ can only be satisfied for smaller values of m . This behavior is nicely illustrated by the levels of HgH plotted by Franck and Spomer in their Fig 2.⁶

This behavior is also shown by the excited electronic state of AlH concerned in the band system studied by Eriksson and Hulthén.¹⁰ Here only two vibrational levels are known so that the heat of dissociation cannot be found by the usual method of extrapolation of vibration levels, due to Birge and Sponer.¹¹ Fig. 2 shows the range of rotational energy associated with the zero and one vibrational levels of this electronic level. Comparing this figure with the analogous one for HgH, we do not hesitate to say that the dissociation energy for excited AlH must lie below the lowest fuzzy level and above the one quantum vibration level with zero rotation. This puts it probably within the range of the braces around "D" in the figure, that is,

Fig. 2. Predissociation levels in the excited $^2\Pi$ state of AlH.

it is close to 0.17 ± 0.02 volts. This is the quantity called "y" in Table I of Mulliken's¹² study of band spectra of diatomic hydrides. Hence the heat of dissociation from the normal state is 3.07 volts. This is essentially the conclusion of Franck and Sponer, though from different theoretical considerations.

Oldenberg¹³ is of the opinion that the radiationless transfers in the nuclear separation coordinate violate Franck's principle because they call for a fairly large "sudden" alteration in the nuclear separation. We feel that this is an attempt to push the Franck idea beyond the limits of its validity. The

¹³ Reference 7, p. 573.

principle is simply an easily visualized rule describing approximately what quantum mechanics will predict. The connection with quantum mechanics has already been developed.¹⁴ The principle has to do with the nuclear motions accompanying electron transitions and not with the nuclear motions when there is no change of electronic state.

A rough calculation for HgH was made, using a Morse function for $U_0(r)$,

$$U_0(r) = 2990 + 3592e^{-6.25(r-r_0)} - 7184e^{-3.125(r-r_0)},$$

where energy is measured in cm^{-1} and distance in 10^{-8} cm. The zero-point vibrational energy was arbitrarily taken as one-half the difference between the two lowest vibrational levels. The quantity ω_e was taken as 1528.8 cm^{-1} . These assumptions are somewhat arbitrary but are the best that can be made. The half-breadth of a line is given by

$$\Delta\nu/c = 1/4\pi\tau c,$$

(compare Pauli, *Handbuch der Physik*, vol. 23, p. 70). With the formula for mean life from Gurney and Condon¹⁵, the half-breadth of the line with rotation quantum number thirty and zero vibration comes out to be 39 cm^{-1} . Actually this level gives rise to a sharp line, but a slight change in the form of the $U_0(r)$ curve, entering the exponent of the formula for τ will make it be sharp, so we conclude that insufficient knowledge of the $U_0(r)$ function does not justify further calculations at present.

NEW MEASUREMENTS ON THE FOURTH POSITIVE
BANDS OF CARBON MONOXIDE

BY L. B. HEADRICK AND G. W. FOX

UNIVERSITY OF MICHIGAN PHYSICS LABORATORY

(Received March 19, 1930)

ABSTRACT

New measurements of that part of the fourth positive band system of carbon monoxide between 2174A and 1280A have been made from plates photographed with a one-meter vacuum spectrograph. Low voltage arc excitation was used. The densities of the band edges were determined from a microphotometric trace. A few new band edges lying below the fourth positive system are reported. In general the measurements here reported are in good agreement with the wave-lengths published by Birge.

INTRODUCTION

THE fourth positive band system of carbon monoxide extending from 2800A to about 1280A has been measured in parts by a number of investigators at different times. Birge¹ describes the work previous to 1926 and analyzes data taken by Deslandres, Bair, Duncan, Lyman and Leifson. Recently Estey² discusses the papers on CO subsequent to 1926 and reports new measurements on that part of the fourth positive system lying between 1970A and 2800A.

In the course of some work with a vacuum spectrograph, measurements were made on the part of the fourth positive system of CO lying between 1280A and 2174A. It seems advisable to report these results at this time to give a more complete set of new measurements for this important band system.

EXPERIMENTAL DETAILS

The bands were photographed with a one-meter vacuum spectrograph of the design described by Sawyer.³ Two plates were made; one of short exposure for microphotometer records and the other of longer exposure for wave-length determinations.

A low voltage arc in CO containing a trace of hydrogen was used to excite the bands. The gas pressure was 0.5 mm of mercury, current 10 to 12 m.a. and potential difference 22 volts. An enlargement of one of the plates extending from 2090A to 1150A is shown in Fig. 1. A microphotometric trace of the same plate, made on a Moll self-recording microphotometer is shown in Fig. 2. The densities of the band edges and lines given in Table II and

Fig. 2. A microphotometer record of part of the fourth positive band system of CO. from 2090.5A to 1280.6A. Including the hydrogen line 1215.78A, several carbon lines and bands of CO at 1179.3 and 1152.9A.

Table III were obtained from this trace by use of the relation,⁴ density = $\log d/(d-h)$, where d is the total galvanometer deflection in the absence of a line and h is the height of the peak on the trace corresponding to a band edge or line.

The carbon line 2479.29 was used as a standard for the measurements of the bands from 2173.8A to 1595.8A. The hydrogen line 1215.78A was used as a standard for the measurements from the lower wave-length end of the plate up to 1611.5A. The measurements from the two standard lines overlapped for several bands near 1600A. The two measurements obtained in this way for the same edges checked within 0.2A.

The grating constant varied somewhat over the region photographed. The best values for it were previously determined experimentally by Dr. J. E. Mack. Table I gives these values for the regions over which they may be applied.

TABLE I.

Grating constant Angstroms/mm	Wave-length range
17.49	2332.2A—1970.0A
17.47	1970.0A—1729.5A
17.46	1729.5A—1597.4A
17.44	1597.4A—1025.7A

RESULTS

The measurements on the band edges, their densities as obtained from the microphotometer record, and their identification as assigned by Birge¹ are given in Table II. Some of the weaker band edges could not be measured on the plate but they appear on the photometer record in Fig. 2. A few new unidentified bands which apparently belong to the fourth positive system of CO are included in Table II.

In Table III are given the wave-lengths of the C_I and hydrogen lines which were used as standards to measure the band edges. A few other C_I and C_{II} lines which were used to check the measurements are also given in this table. Measurements of four strong unidentified band edges below the fourth positive system are included. Three of these band edges may be seen

on the microphotometric trace, one just to the left of the hydrogen line. The other two at the right of this line are marked. The fourth one at 1025.7A is not shown on the trace. This was the shortest wave-length edge observed.

ABSORPTION BANDS OF AMMONIA GAS
IN THE VISIBLE

BY RICHARD M. BADGER

GATES CHEMICAL LABORATORY, CALIFORNIA INSTITUTE OF TECHNOLOGY

(Received March 4, 1930)

ABSTRACT

The article describes an investigation of the absorption spectrum of ammonia gas in the visible region. At 5490Å an absorption region was found which was too weak for a complete investigation with the means at hand. On a second band at 6474Å measurements on 57 lines are given, and the structure of the band is discussed. These two bands are the fifth and fourth overtones of an ammonia band at 3μ . Some interesting alternations of intensity are pointed out, and comparison is made with other ammonia bands of the same harmonic series. Some features of other portions of the ammonia spectrum are discussed in connection with the bands here investigated.

INTRODUCTION

IT WAS recently shown by Badger and Mecke¹ that molecular band spectra of the vibration-rotation type, corresponding to higher members of a harmonic series with a fundamental in the infra-red, may be photographed in the near infra-red or visible regions with the large dispersion of a long focus grating. In the case particularly investigated (ammonia gas) it was found that a complexity of structure was revealed which could only be surmised from the existing investigations on bands lying further in the infra-red and beyond the reach of photographic methods.

Recently, information concerning the spectra of diatomic molecules has been accumulating at a very rapid rate, so that the more important features of this type of spectrum are now quite well understood. Our knowledge of polyatomic molecules is in a much less satisfactory state, and up to the present only relatively small portions of the complete spectrum originating in any molecule of this type have been submitted to anything like a complete analysis.

The study of the vibration-rotation type of band with the relatively high resolution permitted by photography seems to offer important possibilities in the solution of the general problem, and a program for the investigation of a number of the simpler polyatomic molecules by this method has consequently been undertaken.

In the case of certain molecules it has been found that different vibration-rotation bands of the same molecule may have a very different appearance, even in the case of bands of the same harmonic series. Theoretical reasons for this on the basis of symmetry considerations have been discussed by Hund.²

¹ Badger and Mecke, *Zeits. f. phys. Chem.* **5**, 333 (1929).

² Hund, *Zeits. f. Physik* **43**, 805 (1927).

One of the most interesting cases of the kind mentioned is found in ammonia, which is a relatively simple molecule and one whose spectrum might be expected to be capable of treatment. At 3μ there is a band which has been investigated by Stinchcomb and Barker³ and has been interpreted by Dennison⁴ as due to a molecular vibration in which the change of electric moment is perpendicular to the symmetry axis. The harmonics of this band are relatively strong as shown by Badger and Mecke,¹ who investigated the fourth and located the fifth members of the series. The two bands of the series which have been studied present considerable difference in appearance and have several features of which the explanation is not immediately evident.

It is the purpose of the investigation described in this paper, as a part of the general program mentioned above, to extend the investigation of this harmonic series to higher members with the expectation that a comparison of several bands, and especially of the intensity alternation of each, will lead to an understanding of the nature of the various rotational and vibrational levels involved.

EXPERIMENTAL PROCEDURE

The ammonia gas used in the investigation was a synthetic product and was confined in a steel absorption tube 280 cm long, closed at the ends with plate glass windows. Gas pressures of from one to five atmospheres were employed, but increasing the pressure did not seem to have great advantage, probably due to a broadening of the absorption lines. The source of illumination was a tungsten lamp.

The majority of the exposures were made with a six inch grating of ten foot radius of curvature. This grating gives intense spectra in the first order in the red, and has great freedom from ghosts. Some exposures were also made using the second order of a twenty-foot grating.

When using the ten-foot grating the exposures were made on a process panchromatic film which was very contrasty and fine grained. The exposure times ranged from ten to thirty minutes. Development was carried as far as possible without introducing excessive developer fog. When using the second order of the large grating it was necessary to use a faster film, which unfortunately was less contrasty than the process film, so that only the stronger lines showed up in the exposures. An iron arc calibration spectrum was photographed on each of the films.

Since, at best, the absorption bands studied are very weak, and direct measurements on the films were difficult, as all but the most intense lines disappear under the microscope of a comparator, the following procedures were used in working up the results.

(1) Enlargements of several different films were made on contrast paper. Measurements were made on each with a scale, and the results compared.

³ Stinchcomb and Barker, *Phys. Rev.* **33**, 305 (1929).

⁴ Dennison, *Phil. Mag.* **1**, 195 (1926).

(2) The best film (most contrasty, free from blemishes) was microphotometered and measurements made on the record plate.

(3) Enlargements from four of the best films were made on contrast film and superposed (see Oldenberg, *Zeits. f. Physik*, **58**, 722 (1929)) and measurements made on the resulting composite picture. It is remarkable how this procedure averages out small defects in the plates and intensifies lines which on a single plate would be pronounced doubtful.

EXPERIMENTAL RESULTS

In this work two absorption regions were investigated corresponding to the fifth and sixth harmonics of the band at 3μ . At 6474A a band was found

with a broad *Q* branch, an *R* branch with four intense lines and several rather weak ones, and several irregularly spaced absorption maxima in a *P* branch. The most distinguishing features of the band are the four strong lines of the *R* branch.

In the region at 5490A, evidences of absorption were obtained in all of a number of exposures. The absorption lines were so weak, however, as to be of the same order as non-uniformities in the emulsion of the film, and although the center of the absorption band seemed to lie at about 5490A, the *Q* branch could not be identified with certainty. Consequently no data are given for this band.

In Table I is given a summary of the measurements on the ammonia band at 6474A. The lines for which an intensity is given are well assured as real by several measurements. The lines designated by a point of interrogation are very weak and are possibly somewhat uncertain. Included in braces are broader regions of absorption which are incompletely resolved into lines, but have maxima of absorption at the wave-lengths given. They have possibly a more complex structure than that indicated. All of the lines in the spectrum are rather broad, but this does not seem to be due to a lack of dispersion or resolving power in the means employed, since the spectrograms taken with the second order of the 20 ft. grating showed no better resolution than those taken with the first order of the 10 ft. grating. To secure complete resolution of the lines one would probably have to work at very low gas pressures and a correspondingly long absorption path.

DISCUSSION OF THE RESULTS

In Figure 1 is given for purposes of comparison a diagrammatic representation of three of the ammonia bands of the series with fundamental at 3μ . In the case of the band at 6474A the curve is adapted from a microphotometer investigation of the best spectrogram obtained. The vertical lines represent the position of absorption maxima as taken from the various measurements. The dotted lines indicate the less certain maxima. The band at 7919A is reproduced from the work of Badger and Mecke¹ and the curve for the band at 3μ is adapted from the figure given by Barker and Stinchcomb.³

Below the first two bands is indicated a provisional arrangement of the lines into "series." Each series includes all the lines where one of the quantum numbers characterizing the rotational states, say τ , makes the particular transition $\tau' \rightarrow \tau''$, the other quantum number, say j , making all possible transitions (with the restriction of course that $\Delta\tau$ and $\Delta j = 0 \pm 1$). In the case of the two harmonic bands all of the intense lines, at least, fit into five of these series. Higher series may also be present but the lines of these will nearly coincide with those of the series given, the first and sixth series coinciding, and so on. For the band at 6474A the assignment is possibly in some cases ambiguous owing to incomplete resolution of the lines.

From the figure the following characteristic features are evident. First of all one may note that the bands at 7919A and 6474A include many double

lines with a separation of the two components which is perhaps constant within experimental error, since the resolution is not complete. In general it seems to be the weaker lines which are so resolved, and it is not impossible that the broadness of the stronger lines conceals a similar structure, though in a few cases the stronger lines are relatively sharp and apparently single.

Fig. 1. Two harmonic bands of ammonia and the fundamental band at 3μ .

Badger and Mecke suggested as an explanation of the doubling that the ammonia molecule becomes slightly unsymmetrical as the amplitude of vibration increases. An alternative explanation has been offered by Barker⁵ on the basis of a slight difference in the energy values corresponding to the symmetric and anti-symmetric eigenfunctions representing an oscillational state, this

⁵ Barker, *Phys. Rev.* **33**, 684 (1929).

difference arising from the possibility of the nitrogen atom passing through the plane of the three hydrogen atoms. Barker interprets the bands here considered as due to an oscillation in which all the atoms of the molecule approach each other simultaneously. As the amplitude of this vibration increases the potential energy increases, as the nitrogen atom approaches the plane of the hydrogen, also rises, and the difference between energy levels corresponding to the two types of eigenfunction should decrease. Consequently the doubling of levels might be appreciable only in the lowest energy state, and the doubling of the bands would thus be nearly constant through the harmonic series. This is indeed in agreement with the data. However, it seems very questionable whether the bands here under consideration are due to the type of oscillation mentioned, first on account of the great intensity of transitions in which $\Delta\tau \neq 0$, and secondly on account of the convergence of the bands. An extrapolation of the harmonic series yields a dissociation energy of 6.0 volts, which is much less than that required for the complete separation of the molecule into its atoms (about 12 volts) which would result from the vibration in question. Dennison⁴ in a treatment of the vibrations of the ammonia molecule by means of normal coordinates, concluded that the 3μ band arose from an oscillation perpendicular to the symmetry axis. But it is possible that even for this kind of oscillation one should expect a similar situation for the doubling of the vibrational levels.

It is striking that no very appreciable convergence in any series in any of the bands is observed. Furthermore, as one must expect from this fact, the spacing of the lines in a series is sensibly constant for all of the bands, having the approximate mean value 19.88 cm^{-1} for the band at 7919A and 19.74 cm^{-1} for the band at 6474A, corresponding to a moment of inertia of $2.78 \times 10^{-40} \text{ gm. cm}^2$ or $2.80 \times 10^{-40} \text{ gm. cm}^2$, respectively, about an axis perpendicular to the axis of symmetry. It would be very interesting to observe whether the other moment of inertia (about the symmetry axis) is not appreciably changed by the oscillation, as seems not improbable, but the accuracy of measurement scarcely suffices for this. The probable value for this quantity is $3.49 \times 10^{-40} \text{ gm. cm}^2$ if one assumes a flat pyramidal structure for the ammonia molecule.

A particularly striking feature of the two harmonic bands is the alternation of intensity in each series. There seems to be a great tendency for alternate lines to be weak or to fall out altogether, and an alternation is also observed for corresponding lines through successive series. The irregularity of spacing in the *P* branch of the 3μ band suggests that the strong lines here do not all belong to the same series, and that greater resolution would disclose a similar condition in this case. Indeed this band seems quite similar to the harmonic at 6474A except that certain series which in the former are quite weak have in the latter become of intensity comparable with the strongest series.

For purposes of clarity the five series of the two harmonic bands have been represented in Figure 2 by means of a scheme similar to that which is frequently used in representing electronic bands. The diagonal lines sloping

to the left indicate the transitions giving rise to the P branches, and those sloping to the right to the R branches. J' and J'' are the probable values of the quantum number associated with the larger spacing of the band structure, in the normal and excited states respectively. The absolute values of the other quantum number τ for the several series are somewhat in doubt. The thickness of the diagonal lines represents roughly the intensity of the observed transitions, and as in Figure 1, broken lines indicate doubtful cases. At the bottom of the figure are shown the kinds of transitions which are especially characteristic of the two bands.

In the case of the band $N, 0 \rightarrow 4$ the results indicate that the rotational levels are alternately of two kinds in both lower and upper states, one of these kinds being considerably the more probable. For the band $N, 0 \rightarrow 5$ the

Fig. 2. Scheme of transitions in the ammonia harmonic bands.

situation seems to be quite different and the explanation is not obvious. In neither case is the condition quite what would seem to be predicted by the considerations of Hund.²

In this connection it is not out of place to make some remarks on certain other ammonia bands. At 10μ there is an absorption region which is produced by another type of molecular vibration. This band has been investigated by Barker,⁵ who finds a double band of apparently simple structure. According to Barker's analysis this band comprises two component bands, each of which consists of a Q branch and simple P and R branches corresponding to the transitions $\Delta j = \pm 1, \Delta \tau = 0$. There is no appreciable convergence of the lines, and one component has a spacing of 20.2 cm^{-1} the other of 18.7 cm^{-1} . This would mean that the band is produced by two kinds of ammonia mole-

cule whose moments of inertia are the same in the upper and lower states but appreciably different from that of the lower state involved in the bands at 3μ etc. In other words these bands do not have a common lower level.

It seems to the writer, however, that the absorption curve may equally well be interpreted in a slightly different way, but one which is much more satisfactory when one considers its connection with the other data. The following analysis of the 10μ band is accordingly suggested.

TABLE II. *The ammonia band at 10μ . (from the data of Barker⁶).*

Mean $\Delta\nu = 19.6\text{ cm}^{-1}$					Mean $\Delta\nu = 19.3\text{ cm}^{-1}$			
Weighted mean $\Delta\nu = 19.83\text{ cm}^{-1}$					Weighted mean $\Delta\nu = 19.66\text{ cm}^{-1}$			

There is only one region of the absorption curve which does not fit this analysis as well as that given by Barker, and that is the weak maximum at 981 cm^{-1} which should include two maxima at about 975 cm^{-1} and 987 cm^{-1} . It seems, however, that a more complete resolution of this region is necessary to decide definitely which interpretation is the correct one.

In the interpretation here suggested, the band at 933 cm^{-1} converges slightly in the P branch, which indicates a decrease of moment of inertia perpendicular to the symmetry axis, in the activated state. This is not surprising if one considers the type of vibration probably responsible for this band. The three hydrogen atoms are presumed to separate at the same time as the nitrogen atom is approaching their plane. The oscillation should be considerably nonharmonic with a tendency for the nitrogen atom to linger near the plane of the hydrogen atoms, causing a decrease of average moment of inertia as the amplitude of vibration increases.

The suggested interpretation of this band gives within experimental error the same moment of inertia for the normal state as that obtained from the other data.

In a study of the pure rotation spectrum of ammonia Badger and Cartwright⁶ found an apparent convergence of the lines toward shorter wave-

⁶ Badger and Cartwright, *Phys. Rev.* **33**, 692 (1929).

lengths. This spectrum consists of lines produced when j increases by unity, τ remaining constant. If this convergence is not real the molecular moment of inertia calculated from the lines of shorter wave-length, which were those most accurately measured, is the same as that calculated from the vibration rotation bands. But if the interpretation given for the doubling of these bands is the correct one, one should expect that the pure rotation lines are all double with components of perhaps unequal intensity. In this case it could appear that the unresolved lines were somewhat unequally spaced. A similar effect would not be observed, of course, in the case of the Raman spectrum.

At this point the author wishes to express his thanks to Professor J. Anderson of the Mount Wilson Solar Observatory of the Carnegie Institution for the loan of the ten-foot grating which made the investigation possible; and to Dr. Edison Pettit of the same institution for the microphotometer measurements.

EVIDENCE FOR QUANTIZATION FROM THE ELECTRIC POLARIZATION OF ACETIC ACID VAPOR

BY C. T. ZAHN

PALMER PHYSICAL LABORATORY, PRINCETON UNIVERSITY

(Received March 24, 1930)

ABSTRACT

The dielectric constant of acetic acid vapor was measured at various pressures and temperatures. The results indicate a departure from Debye's theory which suggests an internal transition, with respect to temperature variation, from one type of single molecule to another. Near saturation there was detected a small amount of association of a kind increasing the molecular polarization. The anomaly is discussed from the point of view of the new quantum mechanics and it is suggested as an explanation that the effect is due to a transition from one state to a higher state of vibration associated with the OH group. The data are interpreted in terms of the proposed extension of Van Vleck's theory given in the following note. The Raman frequencies given by Dadiou and Kohlrausch indicate that the fundamental vibration frequency due to the OH group is of such a value as to produce transitions of quantum state in precisely the observed region of temperature. This is in agreement with the proposed theory, particularly since molecular polarization measurements in general indicate that the OH group always has associated with it a large electric moment.

The electric moment of the acetic acid molecule cannot be calculated accurately but the data indicate roughly a transition from 1.4×10^{-18} in the ground state to an average value greater than 1.7×10^{-18} c.g.s. e.s.u. in the upper states.

A discussion is given of the anomalous behavior of other physical properties of the vapor, regarding it as a statistical distribution of molecules, surrounded by different force fields associated with the change in electric moment. The possibility of attributing previously observed discrepancies between refractivities and the optical parts of the dielectric polarization to the above mentioned type of quantization is suggested.

IN THE measurement of the dielectric constant of vapors there have occurred occasional apparent deviations¹ from Debye's theory. These deviations are detected by a departure from linearity of the curve obtained by plotting the product of the molecular polarization and the absolute temperature against the absolute temperature itself. They occur always near the saturation point of the vapor, i.e., at low temperatures or high pressures. For this reason they have been attributed to association or adsorption on the condenser material. An associated molecule would give an increased contribution to the "optical" term of Debye's equation and a change in the "orientational" term corresponding to either an increased or a decreased electric moment.² The existence of association is to be detected by studying

² L. Ebert, *Zeits. f. Physik. Chem.* **113**, 1 (1924).

the variation of the polarization with pressure. Absorption could be detected in the same manner, but there is sometimes introduced a complication due to accompanying conductivity between the condenser plates. An anomaly of the latter type was observed by the author³ in the case of water vapor at room temperature. The effect seemed to set in sharply at about one-third the saturation pressure. This adsorption was explained qualitatively by the attraction of the dipole molecule for its image in the adsorbing surface. As the molecule approaches the surface its potential energy is lowered until it touches the surface. The ratio of the pressure at the surface to that far from the surface is obtained by the Boltzmann distribution law. When the pressure in the body of the vapor reaches a certain value, that on the surface reaches saturation and adsorption follows. Originally it was thought that the observed effect was due to the direct dielectric effect of the layer of water on the condenser plates. This required about 200 layers of water. Later experiments were made by K. Wolf on this effect, and it was shown that there is considerable conductivity between the plates of the condenser. The author has also made measurements of this conductivity which show that the observed apparent increase in dielectric polarization may be largely due to the indirect effect of conductivity across the thin layer of water adsorbed on the quartz insulators used. It is impossible to say how much of the effect is due to each of the three causes, association, adsorption layer on the plates, and conductivity across the insulators. Fraser⁴ has shown by measurements of the polarization of light reflected from the adsorbing surface of glass that about 5 layers of water are present at saturation. Therefore in the case of water vapor the effect must be almost entirely due to conductivity and possibly association. Only in case there is no observable conductivity can one be sure that a variation in molecular polarization with pressure is due to association (or chemical reaction).

All the above effects can usually be eliminated by working at pressures considerably below saturation, when one is interested in the polarization of single molecules.⁵ In cases where there is no appreciable leakage in the condenser the anomalies can be used to obtain information concerning the forces causing association.⁶ On account of the general anomalous behavior of the physical properties of acetic acid vapor it was thought that measurements of its dielectric constant might prove of interest, particularly since it is known definitely to associate in the gaseous state. By making pressure runs at each temperature and using only the linear, or low pressure parts, the polarization corresponding to the single molecules can be obtained. The Debye line obtained from these data should enable one to calculate the electric moment of the molecule and thus to obtain an idea of the magnitude of the moment characteristic of the carboxyl group. The upper or high pressure parts of the curves should give an idea of the nature of the association.

EXPERIMENTAL RESULTS

The experiments here described were made by the same method used by the author in a series of previous investigations.⁷ Pressure curves were obtained at eleven different temperatures in the range 20–220° C. In Fig. 1 are shown two typical pressure curves, one for a high temperature, and the other for a low temperature where the gas was nearer saturation. The high temperature curve shows no departure from linearity and therefore no as-

Fig. 1.

sociation. The low temperature curve has a linear portion at the lower pressures and an anomalous increase of the polarization for the higher pressure, near saturation. Leakage tests showed no appreciable conductivity. Therefore there is association of such a nature that the electric moment is increased.

A more interesting feature of the results is seen when an attempt is made to plot a Debye line. In Table I are given the data taken from the lower portions of the pressure curves where the effect of association is negligible. For economy in space the individual pressure data are not included. In

⁷ C. T. Zahn, Phys. Rev. **24**, 400 (1924), C. T. Zahn, Phys. Rev. **35**, 848 (1930).

column III is given the limiting slope of the pressure curve in the lower part for pressures expressed in atmospheres. This gives the value of $(\epsilon-1) 10^6$ corresponding to an atmosphere of single molecules. Column IV gives values of $3(\epsilon-1/\epsilon+2) (1/p_{at})$; and column V, values of $3(\epsilon-1/\epsilon+2) v \cdot 10^6$ where

v is calculated from the ideal gas law $v = T/273.13 p_{at}$. The van der Waal correction would probably amount to about one percent. This correction was not made because of the lack of data. Column VI gives the ordinates for the Debye line:

$$3 \left(\frac{\epsilon-1}{\epsilon+2} \right) vT = AT + B.$$

Column VII gives values of the molecular polarization P , i.e., the value of $(\epsilon-1/\epsilon+2)$ corresponding to a gram molecule of single acetic acid molecules.

In Fig. 2 are plotted the values of columns VI and VII of the table. According to Debye's theory the upper curve should be a straight line of slope A and intercept B . The lower curve should be of the form:

$$P :: A + (B/T).$$

It is obvious that this is far from the case and that there is here represented a departure from Debye's theory which is due neither to association nor to conducting layers. Apart from the linearity of the pressure curves in their lower parts, if there were association, it would be practically absent at the higher temperatures and the upper portion of the curve of Fig. 2 would approach the supposed true Debye line. Then the anomalous *decrease* of $3(\epsilon-1/\epsilon+2)vT$ for the lower temperatures would have to be attributed to association corresponding to *reduced* electric moment. On the other hand the pressure curves near saturation indicate that association occurs in such a way as to *increase* the electric moment of the molecule. Therefore an explanation of the departure from the Debye line based on the assumption of association leads to a contradiction.

The values for the lowest temperature, given in the table and shown in Fig. 2, were obtained under very difficult experimental conditions because of

the low vapor pressure, and are therefore subject to a much greater probable error. Association may not be completely eliminated. The slight rise in the upper curve is probably not correct, but the rise in the lower curve is probably only a little too great but definitely existing.

During the investigation it was thought that the observed anomalies could be due to an indirect effect of a small amount of water in the acid specimen. In order to test this supposition an especially pure specimen, of

Fig. 2.

fusion point 16.6°C , was prepared and measurements were repeated at extreme temperatures. No appreciable difference was observed between the two specimens. In any case if the effect of water vapor is only its direct effect it would require a considerable amount to produce an appreciable change in the dielectric constant, since the two substances have nearly the same dielectric constant.

EVIDENCE FOR QUANTIZATION

The curves in Fig. 2 indicate roughly a transition from one value of A and B in the Debye equation to another. Since the pressure curves are linear this must correspond to an internal change in the molecule. On the quantum theory such a change would be a change from one stationary state to another, or to a redistribution among several states, according to the Boltzmann theorem. Van Vleck⁸ has given a general derivation of the Debye formula in the new quantum mechanics. The Debye formula is found

⁸ J. H. Van Vleck, *Phys. Rev.* **29**, 729 (1927); *Phys. Rev.* **30**, 31 (1927).

to hold for temperatures such that $h\nu \ll kT$ where $h\nu$ is the energy spacing of the rotational levels or other low energy levels. This means that deviations due to rotational quantization are small when T is such that the above inequality holds. To a second approximation the effect of rotational quantization gives the formula:

$$3 \left(\frac{\epsilon - 1}{\epsilon + 2} \right) = A + \frac{B}{T} - \frac{C}{T^2}$$

Van Vleck has calculated the constant C in terms of the moments of inertia of the molecules and the components of the electric moment along the principal axes of inertia. When $T = h\nu/k$ the deviations are considerable and the above second approximation is not sufficient, of course. Debye⁹ calls this latter temperature the "characteristic" temperature and finds that for HCl it is 14.7°K. At 0°C the correction due to rotational quantization is only about 2 percent, and it would be difficult to detect departures from the Debye formula unless measurements could be made near the characteristic temperature.

One can let each energy transition $h\nu$ define a temperature such that $h\nu = kT$. In this sense a transition in the region of $T = 400^\circ\text{K}$ could certainly not be attributed to rotational quantization since it would require a moment of inertia many times smaller than that of HCl. Van Vleck in his derivation of the Debye equation assumes that the electric moment of the molecule is invariant with respect to all quantum numbers producing low or medium frequency transitions. There are many substances which have vibrational energies in the region of measurable temperatures. If one admits the possibility of different "fixed" electric moment in different vibrational states the general behaviour of the curves in Fig. 2 can be explained as due to the statistical distribution in these states. In a note to follow Van Vleck's theory has been generalized to include such an assumption and Debye's formula is replaced by:

$$3 \left(\frac{\epsilon - 1}{\epsilon + 2} \right) = A + \frac{[\sum_v B_v e^{-h\nu_v/kT}]/[\sum_v e^{-h\nu_v/kT}]}{T}$$

This does not include the small correction due to rotational quantization. The B of Debye's equation is replaced by a statistically averaged B over all vibrational states. The same is true of the square of the electric moment since it is proportional to B .

In case the changes in the electric moment μ are due to a single type of vibration the various overtones ν_v will be spaced relatively far apart on the temperature scale, and in the region of temperature around a particular value of ν the transition will be roughly as from one value of ν to one other value. The higher energy states will exist in only small amounts. The general shape of the distribution curve in the two states according to the Boltzmann theorem is like the upper curve of Fig. 2. If the overtones be taken into

⁹ P. Debye, "Polar Molecules," p. 150.

account the shape of the curve is only slightly changed in this region. Judging from such a distribution curve one would expect the transition frequency $h\nu$, to correspond to a temperature in the region from 420–450°K.

RELATION TO RAMAN SPECTRUM

Dadiou and Kohlrausch¹⁰ have investigated the Raman spectrum of acetic acid in the liquid state and give lines of the following wave-numbers: 440 (0); 618 (1); 890 (4); 1430 ($\frac{1}{2}$); 1656 (1); and 2935 (4). Salant and Sandow¹¹ have shown that for HCl there is a small shift of the infra-red lines on passing from the liquid to the vapor states on account of the Lorentz force in the liquid. The frequency in the gaseous state was found to be of the order of 4 percent higher. This would not alter the following qualitative discussion. In the sense defined by $h\nu = kT$ these lines lie at temperatures: 307; 432; 622; 998; 1157; and 2050°K. Of these lines the only one definitely in the region of observed temperatures is the second at 432°K. This is a moderately strong line and is attributed by the above mentioned authors to the OH group of the molecule. This is in excellent agreement with what would be expected from the existing data on electric moments.¹² The OH group is known to have associated with it a large electric moment and therefore the Raman line associated with this group would be the most likely to produce changes in electric moment. The other lines in the Raman spectrum excepting the overtones of the OH line which are not sufficiently strong to appear, would probably cause only very small changes in electric moment. There may be also a small effect on the electric moment due to vibrations associated with the CO group, if the corresponding value of $h\nu$ is near the observed temperature region.

If the potential energy function associated with the vibration is unsymmetrical about the minimum point, the average nuclear separations may be quite different for the different quantum states. Accompanying this the electric moment might have quite different values, particularly in cases of weak bonds such as exist in large organic molecules. On the other hand it is just here that one would expect interaction between rotation and vibration or centrifugal expansion; and that the sum rules, discussed by Van Vleck in connection with the high frequency or optical part of the susceptibility, might be invalidated. It does not seem impossible that such disturbing effects might be small even if the electric moment is altered by the vibration. As another possibility, in a complicated organic molecule there might be more than one minimum value of the potential energy of vibration with fairly strong binding forces around each one of them. For example, in the case of the ammonia molecule, the potential energy of the nitrogen nucleus along the axis of the molecule is probably symmetrical, or nearly symmetrical, with respect to the plane of the hydrogen triangle and there exist two minima

¹⁰ A. Dadiou and K. W. F. Kohlrausch, *Monatsch. f. Chem.* **52**, 220 (1929).

¹¹ E. O. Salant and A. Sandow, *Phys. Rev.* **35**, 214 (1930).

¹² H. A. Stuart, *Phys. Zeits.* **31**, 80 (1930).

on opposite sides of the triangle. In an organic molecule such a bond might be unsymmetrical and hence give rise to two distinct energy levels.

In connection with the above mentioned high frequency part of the dielectric susceptibility there are in progress in this laboratory observations of the refractivity of acetic acid vapor under the same conditions of pressure and temperature as the present observations. These observations may indicate whether any of the temperature variation is due to the failure of the sum rules which are called upon to prove the invariance of the high frequency term with temperature. They should also be of interest in connection with the association of the vapor near saturation. An observed variation with temperature could also be due to a variation in refractivity from one vibration state to another.

ELECTRIC MOMENT

On account of the inability to resolve completely the effects of the different states and of the lack of accurate knowledge of the Raman frequency for the vapor, it is impossible to obtain from the present observations an *accurate* knowledge of the electric moment in either state. Using a value of the refractivity obtained from the liquid one can calculate roughly the effective electric moment at the various temperatures. This is, of course, the root mean square electric moment. The calculation indicates that the average moment varies from 1.4 to 1.7×10^{-18} c.g.s. e.s.u. The lower value is probably not far from the value corresponding to the ground state. At the highest temperature there are still present a considerable number of the molecules in the ground state, which would necessitate a moment still greater than 1.7×10^{-18} for the upper state.

C. P. Smyth has recently made measurements¹³ of the molecular polarization of acetic acid solutions in benzene and in ether from 0 to 30°C. The values for the solution in benzene are in general abnormal. A calculation using the refractivity of acetic acid as above indicates an average moment of 0.7×10^{-18} . This may be due to a special type of association in the liquid state. For the solution in ether the behavior is normal and there is probably very little association as indicated by partition coefficient measurements. The value of the moment calculated by Smyth for this solution is 1.40×10^{-18} . At temperatures from 0 to 30°C all the molecules are probably in the ground state of vibration, judging from the curve of Fig. 2. The lower limit previously calculated from this curve, 1.4, is in good agreement with Smyth's value.

PHYSICAL PROPERTIES

In addition to the anomalous behavior here described acetic acid has long been known to behave anomalously with respect to van der Waal's equation. The value of $(RT_k d_k)/(Mp_k)$, which for most vapors is around 3.88, is abnormally high for acetic acid vapor, 4.99. Also Nasini¹⁴ has recently measured

¹³ To be published in the Jour. Amer. Chem. Soc.

¹⁴ A. G. Nasini, Phil. Mag. 52, 596 (1929).

the viscosity of acetic acid vapor at pressures of the order of 5 mm Hg and at temperatures from 90 to 250°C. At such low pressures there is no appreciable association, yet the temperature-viscosity curve shows at lower temperatures an opposite shape to those of other non-associated compounds.

If the interpretation of the behavior of acetic acid here suggested is correct it seems that the above mentioned deviations could be explained by the fact that such a vapor must be considered as a mixture of molecules surrounded by different force fields and distributed statistically. Any physical property depending on these force fields, such as van der Waal forces, mean free path, mobility, viscosity, etc., would be expected to behave abnormally with respect to temperature variation.

This effect of the variation of electric moment with vibrational state may be of some small importance even in molecules such as HCl where Debye's theory is apparently obeyed. If the vibration frequencies are not near the observed temperature region and if the moment is slightly different for different quanta of vibration, there may still be a first order linear correction to be applied. This would not alter the linearity of the Debye line but would give a slightly erroneous electric moment, and an erroneous value of the "optical" part, A , of the susceptibility. In a number of cases¹⁵ where the electric moment is large there have been discrepancies between the value of A and the refractivity. A is usually higher than the refractivity. In the case of the halogen hydrides the discrepancy is larger the larger the electric moment. These discrepancies have been discussed by various authors, notably Van Vleck,¹⁶ without obtaining a satisfactory explanation. For the case of HCl Van Vleck has made calculations to show that the effect of the vibrational spectrum on the dielectric constant is negligibly small. It should be noted in this connection that he has assumed an electric moment fixed with respect to the vibrational quantum number. In the case of CO₂ Fuchs¹⁷ has shown that the atomic vibration frequencies are necessary for the extrapolation of the refractivity to infinite wave-length, and that the value so extrapolated agrees well with the polarization obtained from electrical measurements. The discrepancies then may be due either to an error in the refractivity by the failure to include the atomic vibration frequencies when they are important, or to an erroneous value of A caused by vibrational quantization, when there is a variable electric moment, and possibly to a much smaller extent by the rotational quantization. There may also be a temperature effect on the high frequency part A caused by the failure of the sum rules for molecules with loose bonds; and the value of A obtained from dielectric constant data on the assumption that it is constant would be in error.

AN EXTENSION OF VAN VLECK'S THEORY OF DIELECTRIC POLARIZATION

By C. T. ZAHN

PALMER PHYSICAL LABORATORY, PRINCETON UNIVERSITY

(Received March 24, 1930)

ABSTRACT

The experimental data in the preceding paper show a departure from the Debye equation:

$$\left\{ \frac{\epsilon - 1}{\epsilon + 2} \right\} \frac{1}{d} = A + \frac{B}{T}$$

suggesting an effect of vibrational quantization where the electric moment depends on the vibrational quantum number. Van Vleck assumed the electric moment fixed for all states of low energy and thus did not admit the above possibility. In the following note it is shown that Van Vleck's theory can easily be extended to include the effect of such vibrational quantization which may occur in the region of observed temperatures. Debye's equation no longer holds in its simple form. In a sense it can be regarded to hold if the vapor be considered as a mixture of molecules statistically distributed in the vibration states.

THE following is simply an extension of Van Vleck's¹ theory of dielectric polarization and differs from his treatment only in the degree of restriction of the assumptions. He considers all the quantum numbers effective on the molecule to be divided into three classes, n , j , and m . The index n includes all quantum numbers whose effect is such that $h\nu \gg kT$; the index j , such that $h\nu \ll kT$, excluding the axial quantum number; and m , the axial quantum number for which also $h\nu \ll kT$. n may include electronic and vibrational quantum numbers; j , inner, rotational, and spin; and m , axial. In many vapors there are vibrational states for which $h\nu \sim kT$. As Van Vleck states, under his assumption of invariant "fixed" moment, these states, which correspond to linear oscillators, would cause no temperature variation; but they will be important under the present assumptions. For this reason there will be included an index v for the cases where $h\nu \sim kT$. This will be considered to correspond to some of the vibrational states.

Considering, as did Van Vleck, the electric moment matrix of typical element,

$$M_z(nvj m; n'v'j'm') e^{2\pi i \nu(nvj m; n'v'j'm') t}$$

the dielectric susceptibility can be written:

$$\chi = \frac{N}{F} \frac{\sum_{vj m} M_z^{(F)}(nvj m; nvj m) e^{-W^{(F)}(nvj m)/kT}}{\sum_{vj m} e^{-W^{(F)}(nvj m)/kT}} \quad (1)$$

where all the molecules are assumed to be in the ground state indicated by n . The perturbation theory gives, to the first power in F :

¹ J. H. Van Vleck, Phys. Rev. **29**, 727 (1927).

$$M_z^{(F)}(nvjm; nvjm) = M_z(nvjm; nvjm) - \frac{2F}{h} \sum_{n'v'j'm'} \frac{M_z(nvjm; n'v'j'm')^2}{\nu(nvjm; n'v'j'm')} \quad (2)$$

and

$$W^{(F)}(nvjm) = W(nvjm) - FM_z(nvjm; nvjm). \quad (3)$$

Substituting (2) and (3) in (1) gives:

$$\left\{ \begin{aligned} \chi &= \frac{N}{F} \frac{\sum_{vjm} M_z(nvjm; nvjm) e^{-W(nvjm)/kT}}{\sum_{vjm} e^{-W^{(F)}(nvjm)/kT}} \end{aligned} \right. \quad (a)$$

$$+ \frac{B}{kT} \sum_{vjm} |M_z(nvjm; nvjm)|^2 e^{-W(nvjm)/kT} \quad (b) \quad (4)$$

$$- \frac{2B}{h} \sum_{vjm; n'v'j'm'} \frac{|M_z(nvjm; n'v'j'm')|^2 e^{-W(nvjm)/kT}}{\nu(nvjm; n'v'j'm')} \quad (c)$$

where:

$$B \equiv N / \sum_{vjm} e^{-W(nvjm)/kT}. \quad (5)$$

4(a) vanishes because there is no residual electrifications for the field intensity $F=0$. (4) can now be written:

$$\left\{ \begin{aligned} \chi &= \frac{B}{kT} \sum_{vjm} |\mu_z(vjm; vjm)|^2 e^{-W(nvjm)/kT} \end{aligned} \right. \quad (a)$$

$$- \frac{2B}{h} \sum_{vjm; v'j'm'} \frac{|\mu_z(vjm; v'j'm')|^2}{\nu(nvjm; nv'j'm')} e^{-W(nvjm)/kT} \quad (b) \quad (6)$$

$$- \frac{2B}{h} \sum_{vjm; n'v'j'm' (n', v' \neq n, v)} \frac{|M_z(nvjm; n'v'j'm')|^2}{\nu(nvjm; n'v'j'm')} e^{-W(nvjm)/kT} \quad (c)$$

where for the low frequency elements $M_z(nvjm; nv'j'm') \equiv \mu_z(vjm; v'j'm')$ for separate treatment. For a fixed value of v 6(b) can be grouped in pairs and by approximate expansion put into the same form as 6(a) and included under a general summation (c.f. Van Vleck). Then (6) becomes:

$$\left\{ \begin{aligned} \chi &= \frac{B}{kT} \sum_v \sum_{jm; j'm'} |\mu_z(vjm; v'j'm')|^2 e^{-W(nvj)/kT} \end{aligned} \right. \quad (a)$$

$$- \frac{2B}{h} \sum_v \sum_{jm; n'v'j'm' (n', v' \neq n, v)} \frac{|M_z(nvjm; n'v'j'm')|^2}{\nu(nvjm; n'v'j'm')} e^{-W(nvjm)/kT} \quad (b) \quad (7)$$

where $W(nvjm) \equiv W(nvj)$ since the m separations are small.

On account of the high degree of spectroscopic stability $\sum_{mm'} |\mu_z(vjm; v'j'm')|^2$ is invariant of the direction of space quantization and can be written $\frac{1}{3} \sum_{mm'} |\mu(vjm; v'j'm')|^2$. If the energy spacings due to j and m are small compared to those associated with v and n then for 7(b) $\nu(nvjm; n'v'j'm') \rightarrow \nu(nv; n'v')$ and $W(nvjm) \rightarrow W_v$. This latter requirement may not always be satisfied in actual cases, particularly with reference to the index v , but will

probably be met in most cases. Also $\sum_{jm} |\mu(vjm; vj'm')|^2$ is the diagonal element $\mu^2(vjm)$ of the μ_v^2 matrix. This fixed moment is assumed independent of (jm) , but not of v as in Van Vleck's treatment.

All these facts together with (7) and (5) give:

$$\chi = \frac{\sum_v N \{ \alpha_v + (\mu_v^2/3kT) \} e^{-W_v/kT}}{\sum_v e^{-W_v/kT}} \quad (8)$$

where

$$\alpha_v \equiv -\frac{2}{3h} \sum_{jm; n'v'j'm' (n', v' \neq n, v)} \frac{|M_z(nvjm; n'v'j'm')|^2}{\nu(nv; n'v')}$$

represents the high frequency terms. As Van Vleck has shown α_v will be independent of temperature if the sum rules for absorption are applicable. These rules, according to Dirac, should be easily extended to any molecules for which the internal coupling forces give rise to pure precessions and not to distortions such as centrifugal expansion. On the other hand it is in just such molecules where the binding is weak and the electric moment depends on the state of vibration that the effects of centrifugal expansion would be expected. Therefore it is possible that each α_v depends on the temperature to a small extent in case the sum rules break down. The high frequency term then is subject to three possible causes of small temperature variation: redistribution amongst the α_v for different vibration states, a breaking down of the sum rules, and the effect of j quantization which was neglected in setting $W(nvjm) = W(nv)$ and $\nu(nvjm; n'v'j'm') = \nu(nv; n'v')$.

Further α_v is probably nearly independent of v for the following reasons. It has long been known that the law of additivity of atomic refractivities holds fairly well except in molecules with polar bonds. Therefore one would expect that α_v would not change very much in going from one vibration state to another if the accompanying changes in electric moment were only a small fraction of the total fixed moment. Still this effect might be much greater than that due to the breaking down of the sum rules or to the j quantization. If we do make the assumption that α_v is independent of v (8) becomes:

$$\chi = N \left\{ \alpha + \frac{\sum_v (\mu_v^2/3kT) e^{-W_v/kT}}{\sum_v e^{-W_v/kT}} \cdot \frac{1}{T} \right\} \quad (9)$$

or:

$$\chi = A + \frac{\sum_v B_v e^{-W_v/kT}}{\sum_v e^{-W_v/kT}} \cdot \frac{1}{T} \quad (10)$$

where the constants A and B_v correspond to those in Debye's equation. In these equations the effect of rotational quantization is neglected. This has been discussed by Van Vleck, Debye, and others for the low frequency term. As a first approximation there is introduced a term $(-C/T^2)$ in the expression for χ .

In conclusion the author wishes to express his indebtedness to Dr. G. Breit for the opportunity to discuss with him several aspects of this problem.

ON A NEW PHOTOELECTRIC EFFECT
IN ALKALI CELLS

BY ERICH MARX

DEPARTMENT FOR RADIOPHYSICS, PHYSICAL INSTITUTE, UNIVERSITY OF LEIPZIG

(Received March 13, 1930)

ABSTRACT

If two monochromatic beams fall simultaneously on an alkali electrode, a new photoelectric effect is shown as follows: If the intensity of the high frequency light ν_1 is sufficient to establish the limiting potential corresponding to the Einstein law, the presence of any component of lower frequency ν_2 diminishes the potential according to the following equation

$$R = c (n_2/n_1) \cdot (\nu_1/\nu_2)(\nu_1 - \nu_2)h/e$$

where R is the potential decrease and n_2/n_1 the ratio of the electronic emission of the two components, measured by the test cell itself. A tentative explanation of the phenomenon is advanced.

I.

IN A preliminary note to *Die Naturwissenschaften*¹ I have described a new photoelectric effect in alkali cells. The existence of this effect was denied by Olpin.² In the present article we present the essential experiments on which the original note was based.

The effect is as follows. If light of frequency ν falls on a potassium surface the limiting potential V is given by Einstein's law $h(\nu - \nu_0) = e \cdot V$, where ν_0 is the long wave limit and h the Planck constant; $h\nu_0$ is equal to the contact potential of the potassium in the cell. If the insulation of the electrodes is sufficient, and the light intense enough, the limiting potential should depend only on the shortest radiation which is contained in the incident beam.

Our experiments show conclusively that if white light falls on a highly evacuated potassium cell, which is so constructed that the anode is shielded from all light, direct as well as reflected, a limiting potential is reached. If now a blue glass filter is put in the path of the incident light, the limiting potential is increased. Since the filter cannot possibly add light of higher frequency, it is obvious that we are dealing with a new phenomenon. The limiting potential is consequently diminished by the presence of the long wave radiation.

At the Breslau meeting of the Deutschen Physikalischen Gesellschaft in January of this year, I demonstrated this effect by two different experiments. In the first experiment light passing through a small diaphragm was permitted to fall on the photoelectric cell, until a constant potential was shown by the string electrometer connected to the cell. A neutral gray

¹ Marx, *Die Naturwissenschaften* 17, 806-807 (1929).

² A. R. Olpin, *Phys. Rev.* 35, 112 (1930).

filter was then interposed. No change was shown by the electrometer demonstrating that the conditions of light intensity and insulation were fulfilled. When I replaced the gray filter by a blue filter the electrometer showed an increased potential, although the intensity of the incident light was diminished to $1/5$ by the blue filter. In the second experiment the incident

Fig. 1. Dependence of electrometer potential on the wave-length.

light was split into two beams. In the path of one beam an orange filter (Schott filter OG 2) was placed and in the path of the other a blue filter (BG 4) was placed. When the blue beam alone was permitted to fall on the cell, the electrometer showed a constant potential, but when the orange beam also was permitted to fall on the cell the electrometer potential decreased to a new constant value.

Fig. 2. Compensation device for measuring the limiting potential.

In my first experiment I demonstrated the effect by subtracting long wave-length light from the original beam; in the second experiment I demonstrated the same effect by adding orange light to the beam.

II. The effect shown by the above qualitative experiments has been investigated completely and quantitatively by A. H. Herbert Meyer and myself using a double monochromator in place of the glass filters. We found without exception that whenever the cell is illuminated simultaneously with a shorter and a longer wave-length beam, that the electrometer potential is less than if the cell is illuminated by a shorter wave-length beam alone.

We next investigated our photoelectric cell. Fig. 1 shows the dependence of electrometer potential on the wave-length. The linear dependence and the slope of the line are completely in agreement with the best experimental

Fig. 3. Diagram of cell.

values of h and e . We used two different methods for these investigations both of which were different from the known pioneer method of Millikan. In the first method we measured the deflections of a string electrometer, in the second method, we used a compensation device, shown in Fig. 2. V is a precision voltmeter. The two methods were in complete agreement, but the compensation method has the advantage of introducing a guard ring. This compensation method is superior to the other mentioned with respect to accuracy and rapidity of measurement. The cell used for this purpose was of the kind sketched in Fig. 3. The tube was evacuated as well as could be done in the presence of potassium. The potassium layer

K was deposited on the platinized front of the glass mushroom P . The contact was established by the wire D . The anode AA formed an almost complete annular ring, with contacts by the lead wire Z_1Z_2 . This arrangement permitted us to heat the anode. The shield G was made of black glass which protected the anode from all reflected and scattered light. The interior surface of the bulb was covered with a very thin potassium layer. B was a tin

Fig. 4. Dependence of limiting potential for three different intensities of 4358 Å when mixed with various intensities of 5461 Å.

foil covering on the outer surface, in which a rectangular opening was cut. It was electrically connected with the interior surface and the cathode K , all of which was kept at earth potential. The compensating potential was applied to the anode only. This form of cell gave the very satisfactory results of Fig. 1.

Fig. 5. Dependence of limiting potential upon the ratio of the intensity of the components.

Although it is not necessary to shield the anode in order to demonstrate the qualitative effect of light mixtures, it is necessary to do so if we wish to obtain quantitative results. The precautions which must be taken in order to obtain results of highest accuracy will be discussed by Mr. A. H. Herbert Meyer in his thesis, which will soon be published.

III. After obtaining the results plotted in Fig. 1 we then investigated the effect of light mixtures.

Fig. 4 shows the dependence of the limiting potential for three different intensities of the blue line 4358 Å, when mixed with various intensities of

the green line 5461A. By intensities we mean the amount of light which results in electronic emission. The three blue intensities were 139 erg/sec, 11.4 erg/sec and 5.8 erg/sec. It is to be noticed that when no green light was admitted, the electrometer showed exactly the same potential. When green light was admitted the limiting potential depends not only upon the intensity of the green line but also upon the intensity of the blue line. The

Fig. 6. Dependence of limiting potential of $\lambda 4047$ when mixed with various intensities of different longer wave-lengths.

Fig. 7. Dependence of the limiting potential of $\lambda 4047$ upon the intensity of $\lambda 4358$ up to very high intensities.

dependence is linear. This can be more conveniently shown in Fig. 5 by plotting the potential against n_2/n_1 as is done for all data contained in Fig. 4.

IV. We next tried the effect of varying the frequencies of the long wavelength component, keeping the frequency and intensity of the high frequency component constant. For a high frequency component we chose the line 4047A, since this is the highest frequency in the mercury spectrum which glass transmits with sufficient intensity.

Fig. 8. Dependence of limiting potential of $\lambda 4351$ when mixed with various intensities of different longer wave-lengths.

Fig. 9.

In Fig. 6 we have plotted the limiting potentials for this line when mixed with various intensities of the lines $\lambda\lambda 4358, 4916, 5461$ and $5790-5771A$. It is evident that in all cases we get a linear dependence. The intensities were determined by a helium cell before and after measurement of the limiting potential in our test cell. This helium cell had already been compared with our test cell and a thermocouple at various frequencies.

If the intensity of the low frequency components is increased still more, keeping the intensity of the short wave component constant, a point is reached where the linear dependence ceases. The curve approaches asymptotically to the value it would have for the pure low frequency component (Fig. 7).

Fig. 8 is exactly the same as Fig. 6 except that in this case we used the line $\lambda 4358\text{\AA}$ for high frequency component in place of $\lambda 4047\text{\AA}$.

V. As may be seen from the linear form of the curve of Fig. 9, all our observations can be fairly well represented by a straight line. The lowering of the limiting potential is therefore given by

$$R = \text{const.} \frac{n_2 \nu_1}{n_1 \nu_2} (\nu_1 - \nu_2) \frac{h}{e}$$

where n_2/n_1 is the ratio of the intensities of the components and ν_1 and ν_2 are the frequencies of the shorter and longer wave-length components, respectively.

VI. In the Einstein law the $h\nu_0$ term which represents the work of emission is independent of the frequency of the light which falls on the photoelectric substance for a given substance. We could therefore expect this work

Fig. 10.

to be constant for light mixtures. The obvious explanation of the effect which we have observed would be that the anode is emitting electrons and therefore the equilibrium potential is lowered. This was the first point that we tested by constructing a cell, in shape of a dumbbell, in one side of which was the anode ring and in the other the potassium. The diameter of the anode was so large, that none of the light which passed through the connecting tube could fall on the anode. It was therefore completely shielded from both direct and reflected light. The possibility of explaining the observed effect by assuming an electron emission on the anode is very nearly excluded. In order to make absolutely certain of this point we constructed the cell shown in Fig. 10. In this cell the anode lies behind the cathode and is still further shielded from it by black glass which half incloses the anode. This cell gives exactly the same results as the cell which was used in this

investigation. Due, however, to the unfavorable form of the field in the cell it took too long actually to use this cell in the investigation. We have, however, tried such a cell in which potassium was replaced by sodium. This sodium cell behaves exactly like the potassium cell. This does not agree with the results in the letter mentioned above.

VII. The explanation of the determination of the limiting potential by light of long wave-length is the following. As a result of the general distribution of velocities, as given by Ramsauer, it follows that in the case of limiting potential there must be, even with monochromatic light, a distribution of space charge extending over the whole distance between anode and cathode. The magnitude of the space charge is determined by capacity and limiting potential. This gives all the conditions necessary and sufficient for the theory.

The integration of the Poisson equation gives the variation of the distribution of the space-charge as a function of the frequency. Now, if long-wave light is incident along with short-wave light, then the space charge resulting from the long-wave light (just as the charging of the illuminated electrode) can only be generated at cost of the electrons, set free by the short-wave light. Since each electron which is released returns to the illuminated electrode, the number of electrons produced by light of frequencies ν_1 and ν_2 is equal to the number n_1 and n_2 respectively which is present in the space between anode and cathode. The ratio n_1/n_2 of the electrons, produced per second from frequencies ν_1 and ν_2 , determines therefore the proportion in which the electrons generated by these frequencies take part in the emission and are present in the space charge. If by illumination with short-wave light alone the limiting potential was attained, then this will sink, when the repressing of the electrons generated by short-wave light has advanced to such a degree, that the number of electrons released per second is no longer sufficient to charge up the illuminated electrode to the limiting potential. The limiting potential then approaches asymptotically the limiting potential of the long-wave light as in diagram 7.

The publication of the complete theory follows in the near future.

OSCILLATIONS IN THE GLOW DISCHARGE IN NEON

BY GERALD W. FOX

DEPARTMENT OF PHYSICS, UNIVERSITY OF MICHIGAN

(Received February 26, 1930)

ABSTRACT

Radio-frequency oscillations consisting of one or two fundamentals together with a series of harmonics for each fundamental have been observed in large current glow discharges in neon. The observed frequencies lie in the range from approximately 1.5×10^4 to 2×10^5 cycles per second. The oscillations are very sensitive to pressure changes, their frequency increasing rapidly with decreasing gas pressure. The oscillation frequency also increases markedly with increasing current. The frequency is quite independent of resistance in series with the discharge.

The suggestion is made that the oscillations are due to the presence of a reversed electric field in the negative glow of the discharge.

INTRODUCTION

OSCILLATIONS in gaseous discharges have been observed for many years. As far back as 1876, Spottswode¹ reported observing intermittent electric discharges in gas filled tubes. More recently the work of Whiddington,² Appleton,³ Penning,⁴ Webb and Pardue,⁵ Tonks and Langmuir,⁶ and others have brought this phenomenon to the fore, with the result that many new and interesting data have come to light. The present paper deals only with glow discharges in neon.

APPARATUS AND METHOD

The discharge tube is shown in Fig. 1. The over all length was approximately 50 cm, of which the central section was a quartz tube 22 cm long and 2 cm in diameter. The two Pyrex bulbs contained respectively the heavy copper anode, *P* and the barium-oxide coated cylindrical nickel cathode, *C*. The cathode was indirectly heated by radiation from a 20 mil tungsten spiral inside. A close fitting glass sleeve diminished gas diffusion to the back of the anode so that only the front was effective. Ground joints, deKhotinsky sealed, connected the central quartz section to the two end bulbs. These joints were water cooled. The tube voltage was supplied through series resistance by a 600 volt storage battery.

The usual arrangement of pressure gauges and pumping equipment made up the vacuum system. The discharge tube itself was at all times isolated

from the pumping system by a liquid air immersed charcoal trap close to the anode bulb, and a second liquid air trap nearer the pumps. At no time throughout the period of the experiments did the discharge show the presence of mercury vapor.

The detection scheme was essentially the same as that used by Webb and Pardue.⁵ A regenerative detector circuit and a one stage audio amplifier worked admirably. The current through the discharge tube flowed through a

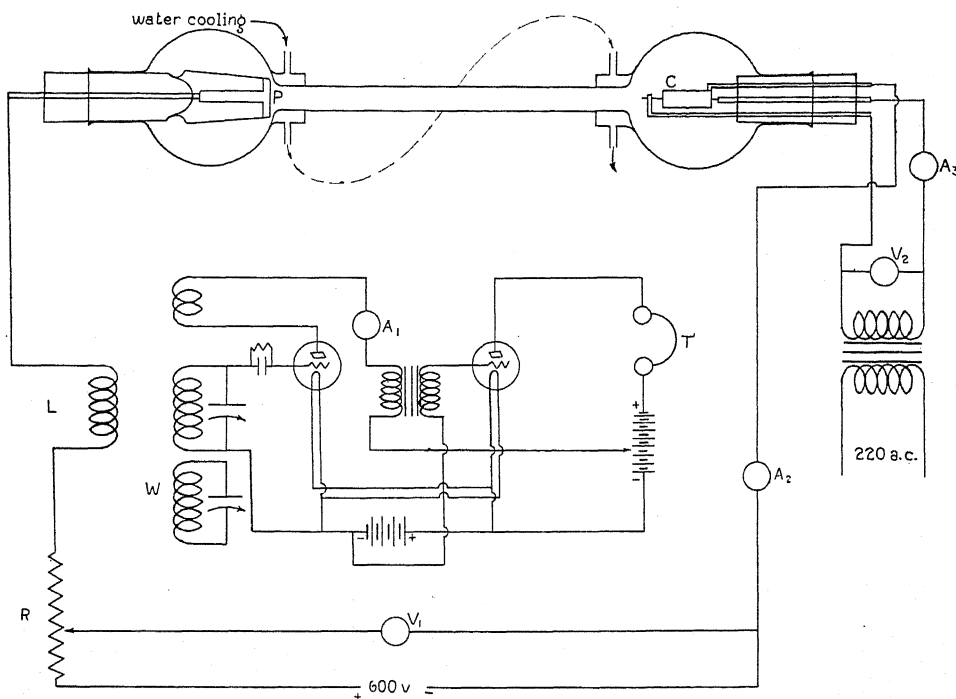

Fig. 1. Diagram of apparatus.

five turn coil of heavy wire which was very loosely coupled to the input of the detector tube. The frequency of the discharge was determined through the method of beats. On zero beat the frequency was measured by a loosely coupled wavemeter.

RESULTS

1. *Frequencies present at a given pressure.*

Data taken in a large number of runs show that several frequencies were present in the discharge at the same time. These frequencies appear to be multiples of a fundamental frequency. The pick up circuit allowed complete covering of a wave-length range of 24000 meters to 100 meters. Throughout this range a large number of frequencies were found. Table I shows one typical run and Table II another. It will be noticed that these are for different tube currents and gas pressures.

Fig. 2. Typical curve showing variation of oscillation frequency with tube current in neon.

2. Variation of frequency with tube current.

The curve shown in Fig. 2 is typical of the frequency variation with tube current. The frequency at first rose rapidly with the increase in current; then more slowly. However, it never reached a condition where it no longer changed with increase in current. At some current value there was always an abrupt change, the frequency stopping suddenly and some other fundamental appearing with its corresponding series of harmonics.

3. Variation of frequency with pressure.

The discharge frequency was extremely sensitive to pressure changes. Even the slight pressure fluctuations caused by raising or lowering the mercury in the McLeod gauge were enough to vary the beat note as heard in the

Fig. 3. Variation of oscillation frequency with gas pressure in neon.

telephone receivers as much as a thousand cycles. Fig. 3 shows typical frequency-pressure curves. The frequency rose very rapidly as the pressure was lowered to 0.2 mm of mercury. Below 0.2 mm it became increasingly difficult to maintain oscillations. Their regularity disappeared and, although even at 0.01 mm for some current values the discharge could be made to oscillate, conditions were very uncertain.

4. Oscillations independent of series resistance.

Table III shows that the oscillation frequency is not a function of the series resistance.

TABLE III. Independence of oscillations of series resistance. (Tube current = 3 amperes, pressure = 0.57 mm).

Total voltage	Tube voltage	Series resistance (ohms)	Frequency
500	175	108	88495
325	175	47	88235
230	175	18	87915
190	165	8	88626

These data were taken within a period of five minutes. The discharge was off only long enough to allow decreasing the total battery voltage.

DISCUSSION

The oscillations here investigated exist only when the discharge is perfectly steady with a uniform positive column. They are entirely unaffected by any capacitance or inductance in parallel with the discharge. In Appleton's³ work on ionic oscillations the inference is made that oscillations occur in sharply defined striae. In the work of Webb and Pardue⁵ the oscillations do not exist so long as sharply defined striae are present but begin when diffusion between adjacent striae takes place and continue until a uniform glow fills the tube. In both the investigations mentioned the tube currents were small, of the order of a few hundred milliamperes at most, while in this investigation the tube currents varied from one ampere to as much as twenty amperes. Oscillations consisting of one or two fundamentals and numerous harmonics were present for any current in this range providing the pressure was not too low.

In their theory of plasma-ion oscillations Tonks and Langmuir⁶ have developed an expression for the frequency of ionic oscillations. The limiting value is given by:

$$\nu = e^2 \left(\frac{n}{\pi m} \right)^{1/2} . \quad (1)$$

Under the conditions of their experiments the limiting value for mercury vapor comes out to be about 1.5×10^6 cycles per second. According to their theory the plasma-ion type of oscillation is likely to go over into electric-sound waves, whose frequency may extend up to 6.5×10^5 per second. The frequencies observed in this investigation fall in this range. The variation of frequency with gas pressure is in general agreement with the curves of Webb and Pardue.⁵

It seems very certain that the type of oscillation herein described does not depend on series resistance. As shown in Table III there is a negligible frequency change for different values of series resistances. In fact the discharge has an entirely positive characteristic since it will run steadily with no series resistance at all, except the very small value due to lead wires from the storage batteries, provided the total voltage across the tube does not exceed by more than a few volts the usual drop across the tube (about 170 volts for this tube). The cathode temperature is not affected appreciably by positive ion bombardment but is wholly controlled by radiation from the heater coil.

Compton and Eckert⁷ have shown that oscillations may exist in discharges of the low voltage arc type when there is a high resistance in series with the arc. As the voltage across the tube increases to the ionization potential of the gas, the arc strikes. The negative space charge surrounding the filament is at once neutralized by the positive gas ions. Bombardment of the filament in-

⁷ Compton and Eckert, *Phys. Rev.* **24**, 97 (1924).

creases its temperature, thereby further increasing the emission and hence the arc current. But the resulting large IR drop in the series resistance lowers the voltage across the tube. This constitutes one type of oscillation. The glow discharge is not greatly different from a low voltage arc except for the long positive column. One might expect, therefore, a similar explanation of the origin of the oscillations, but the evidence is against this.

At all times during the experiments, the interesting flashes described by Aston and Kikuchi⁸ and Whiddington² were present. The suggestion is made that the ionic high frequency oscillations are modulated by these rather low frequency pulsations, since on zero beat a note of about 150 cycles was always

Fig. 4. The effect of increasing amounts of ionization on the distribution of potential between two parallel electrodes one of which is a source of electrons. Curve 1 shows the electrostatic distribution, curve 2 the distribution in the presence of space charge from electrons, and the remaining curves the distribution in cases of successively increasing amount of ionization at the ionizing potential V_i . (From Compton, Turner and McCurdy.)

heard. This is roughly the frequency of the flashes. It is to be noted also that these flashes only occurred in the positive column. Examined by the aid of a rotating mirror they appeared very bright from anode to Faraday dark space, where they disappear. The light of the negative glow is entirely uniform.

The question of the origin of the oscillations is a puzzling one. It seems possible that they originate in the Faraday dark space. A small bar magnet moved about in the vicinity of the discharge had very slight effect except in the region of the Faraday dark space where its motion changed the oscillation frequency very markedly.

⁸ Aston and Kikuchi, *Proc. Roy. Soc. A* **98**, 50 (1920).

In their theory of the glow discharge, Compton, Turner, and McCurdy⁹ have shown the possibility of a reversed field in the region of the negative glow, especially in cases where there is large ionization. As shown in Fig. 4, increasing ionization leads finally to the potential distribution shown in curve 7. There is no reason to suppose conditions should not become even more exaggerated until the potential of the gas in the negative glow should actually be higher than the potential of the gas in the negative end of the positive column. Compton and Eckert¹⁰ have shown this possibility for the case of the low voltage arc. The suggestion seems reasonable that this reversed field is the cause of the ionic oscillations. The positive ions fall through the potential gradient at the cathode end of the positive column with gradually increasing speed, in spite of numerous collisions, until they run into the reversed field which sends them back toward the anode. A back and forth motion of the positive ions results which constitutes the ionic oscillation.

THE CONDUCTIVITY OF A HIGH FREQUENCY DISCHARGE IN HYDROGEN*

BY CHARLES J. BRASEFIELD
UNIVERSITY OF MICHIGAN

ABSTRACT

Measurements were made of the voltage between electrodes necessary to produce a current of 100 milliamperes in the discharge for gas pressures between 0.005 mm and 1.0 mm and for frequencies of oscillation between 1.25 and 20 million cycles per second (wave-lengths between 240 and 15 meters). It was found that the discharge has its maximum conductivity when operated at a frequency of 15 million cycles (20 meters) and a pressure of 0.015 mm. A theory of the mechanism of the high frequency discharge indicates that under these conditions, an electron makes an inelastic collision with a gas molecule every electronic mean free path having been under the influence of the electric force for one half cycle. The theory also indicates that for any frequency of oscillation greater than 15 million cycles, both the electric force and the gas pressure for which the conductivity is a maximum, will increase directly with the frequency of oscillation.

INTRODUCTION

THERE are essentially two methods by which a high frequency discharge can be obtained in a rarefied gas without the use of internal electrodes. The first method consists in surrounding the discharge tube by an inductance coil through which high frequency currents are passed. In the second method, high frequency voltages are applied to external electrodes of sheet metal which are attached to the outside of the discharge tube. As for the first method, it has been shown ^{1,2,3} that unless the high frequency currents in the inductance coil are very large, (such as are obtained with damped oscillations), the electric forces producing the discharge are principally the electrostatic forces between the ends of the coil. In other words, for small currents the two methods of excitation are fundamentally the same. On the other hand, the second method has the advantage of greater simplicity and flexibility. For this reason, the second method was used in the work about to be described.

It is well known that a high frequency discharge is profoundly affected by changes in gas pressure and frequency of oscillation. It therefore should be of interest to discover at what pressure and frequency of oscillation the discharge will function most efficiently. One way of doing this would be to study the variation in the striking potential or the minimum maintaining potential of the discharge as the pressure and frequency of oscillation are

varied. Hayman⁴ has made such measurements for helium and neon while C. and H. Gutton⁵ have done the same for hydrogen. In some preliminary experiments the writer attempted to reproduce Guttons' results, but found that it was practically impossible to make any reliable measurements of the striking potential of the discharge because of the difficulty in determining at just what potential the discharge struck. In an effort to obtain results which would have more significance, the problem was attacked from a different angle. It was proposed to study the conductivity of the discharge, that is, the voltage between electrodes necessary to produce a given current in the gas. Such an investigation would clearly show under what conditions the high frequency discharge operates most efficiently.

APPARATUS AND PROCEDURE

The apparatus used to produce the high frequency oscillations was essentially the same as that described in a previous paper.⁶ The discharge tube was 90 cm long, 4.5 cm internal diameter while the electrodes surrounding it were of sheet copper 4 cm wide. It was found that the conductivity of the discharge could be measured with greatest accuracy when the distance between electrodes was 40 cm. If the electrodes were much farther apart than this then there was an appreciable leakage current between the high potential electrode and the standard used to support that end of the tube. On the other hand, if the electrodes were too close together, the capacity current between electrodes became appreciable. For pressures below 0.2 mm a continuous flow of pure hydrogen was maintained through the tube while above 0.2 mm the gas was stagnant.

Instead of applying the total voltage of the high frequency generator to the electrodes, one electrode was connected to ground through a 0-120 high frequency milliammeter. The experimental procedure consisted simply in measuring the voltage between electrodes which was necessary to produce a current of 100 milliamperes through the tube, for different frequencies of oscillation and different gas pressures. The voltage between electrodes, which is equal to the voltage across one of the condensers of the tank circuit, was calculated from the formula $E = I/2\pi fC$ where I is the tank current in amperes, f the frequency of oscillation and C the capacity in farads of one of the two equal tank condensers. The tank current was measured by a 0-10 Weston radio frequency ammeter (thermocouple type) which is guaranteed by the makers to be accurate within one percent of full scale deflection. The amplitude of the electromotive force between electrodes is $E(2)^{1/2}$. Measurements were made for frequencies of oscillation corresponding to 15, 20, 25, 30, 40, 50, 60, 80, 100, 120, 160, 200, and 240 meters.

RESULTS

Fig. 1 shows, for a few typical frequencies of oscillation, the relation between gas pressure, and the voltage between electrodes which is necessary to

⁴ R. L. Hayman, *Phil. Mag.* 7, 586 (1929).

⁵ C. and H. Gutton, *Comp. Rend.* 186, 303 (1928).

⁶ C. J. Brasefield, *Phys. Rev.* 35, 92 (1930).

produce a current of 100 milliamperes through the tube. Fig. 2 shows the variation with frequency of oscillation of the minimum voltage necessary to produce a current of 100 milliamperes. It can be seen from Fig. 2 that the high frequency discharge in hydrogen has its maximum conductivity at frequencies of oscillation between 10 and 15 million cycles (i.e. between 20 and 30 meters) and at gas pressures between 0.035 and 0.015 mm. Operating the discharge under these conditions of maximum conductivity, it was possible to obtain a current as large as 300 milliamperes at 20, 25, and 30 meters. This current was, of course, limited only by the output of the high frequency generator.

Fig. 1. Variation with gas pressure (in mm of mercury) of the voltage between electrodes necessary to produce a current of 100 milliamperes.

It can be seen from Fig. 1 that at very low pressures, the discharge is most conducting when operated at 20 meters. Using this frequency of oscillation and applying the full voltage of the high frequency generator to the electrodes it was found possible to obtain a faint white luminous discharge at pressures even as low as 10^{-6} mm. This discharge was accompanied by a blue fluorescence of the glass at the ends of the tube and by a red fluorescence of the glass at irregular spots along the tube. These spots were evidently due to bombardment of the walls of the tube by a stream of electrons for they could be shifted by moving one's finger in their neighborhood or by the presence of a magnet. The discharge itself at these low pressures seemed to be due to a beam of electrons moving along the axis of the tube, for it could be deflected by the presence of one's finger. However, no peculiarly shaped luminous bodies of gas such as Wood⁷ observed using ultra high frequencies, were ever seen.

⁷ R. W. Wood, Phys. Rev. **35**, 658 (1930).

DISCUSSION

It is not difficult to explain, qualitatively, the shape of the curves of Fig. 1. In order to maintain a stable high frequency discharge, the electrons in the discharge must satisfy two conditions. In the first place, they must produce positive ions by collision with gas molecules within a distance which is in general not greater than a few electronic mean free paths and within a time which is not greater than one-half the period of the oscillation. The second condition is, of course, that at the time of collision, the electron must have a

Fig. 2. Variation with frequency of oscillation of the minimum voltage necessary to produce a current of 100 milliamperes. Numbers along curve represent the pressure corresponding to the minimum voltage.

velocity sufficient to ionize a gas molecule. Now at relatively high pressures, the mean free path of the electron is small. Hence if an electron is to attain ionizing velocity in this small distance, the applied electric force must be large. On the other hand, at low pressures the mean free path of the electron is large, so that the electric force must be large in order that the electron can make a collision with a gas molecule within one-half the period of the oscillation. Between these two extremes will be a pressure at which a smaller electric force will enable the electron to satisfy the two conditions simultaneously. These points of maximum conductivity are shown in Fig. 1.

To explain the variation in the conductivity with the frequency of oscillation (Fig. 2) requires a more detailed study of the mechanism of the high

frequency discharge. The motion of an electron in a high frequency electric field can be represented by the equation

$$mx'' = eE_0 \sin 2\pi ft \quad (1)$$

where E_0 is the amplitude of the electric force and f is the frequency of oscillation. Integrating, we get the velocity at any time t ,

$$v_t = \frac{e}{m} \frac{E_0}{2\pi f} (1 - \cos 2\pi ft) \quad (v_0 = 0). \quad (2)$$

Integrating once again, we get the distance the electron goes in time t

$$d = \frac{e}{m} \frac{E_0}{4\pi^2 f^2} (2\pi ft - \sin 2\pi ft). \quad (3)$$

From Eq. (2) it is evident that for a given E_0 and f , the electron will have its maximum velocity after a time $t = 1/2f$, that is, after it has been under the influence of the electric force for one half cycle. If this terminal velocity is sufficient to ionize a gas molecule and if the distance which the electron has gone in one half cycle (given by Eq. (3)) is at least one mean free path, then the high frequency discharge will be operating under the most favorable conditions possible.

Let us consider the mechanism of a high frequency discharge operating at a frequency of 20 million cycles per second (15 meters). The electron velocity given by Eq. (2) must also satisfy the equation

$$\frac{1}{2}mv^2 = eV \quad (4)$$

where V is at least 16 volts. As a matter of fact, a previous investigation⁶ has shown that to maintain a stable high frequency discharge in hydrogen, the electron velocity must probably be at least 21 equivalent volts. Assuming this value for V and substituting the corresponding value of v in Eq. (2), we find that an electric force of amplitude $E_0 = 9.7$ volts per cm acting on an electron for one half period ($t = 1/2f$) will give it enough energy to ionize a hydrogen molecule. This, then, is the minimum electric force capable of maintaining a discharge at 15 meters; moreover, a discharge will not occur for this value of E_0 unless the distance gone by the electron is at least one mean free path. Substituting $E_0 = 9.7$ in Eq. (3) we find that the distance which the electron goes in one half period is 3.39 cm. From Fig. 2 we see that the pressure corresponding to maximum conductivity at 20 million cycles is 0.02 mm. The electronic mean free path at this pressure is 3.5 cm, which compares favorably with the distance 3.39 cm which the electron goes in one-half period.

Hence we have shown that at 20 million cycles the high frequency discharge in hydrogen has its maximum conductivity at 0.02 mm pressure because at this pressure a minimum electric force of amplitude 9.7 volts per cm is sufficient to allow an electron to make an inelastic collision with a hydrogen molecule in one mean free path having been under the influence of the elec-

tricfield for onehalf cycle. At this point of maximum conductivity the potential difference between electrodes is 505 volts. Dividing this by the distance between electrodes, 40 cm, and multiplying by $2^{1/2}$ we get an apparent electric force of amplitude 17.8 volts per cm. This is entirely compatible with the theoretical value of 9.7 volts per cm. For the potential difference between electrodes consists of two parts. The first is the drop in potential in the body of gas and the second is the drop in potential at the electrodes. Since there is at present no means of estimating the magnitude of this second factor, all that can be said is that the apparent electric force represents the upper limit of the true electric force in the gas.

Let us now consider a high frequency discharge operating at 15 million cycles per second (20 meters). Assuming as before $V=21$ volts, we find that a minimum electric force of amplitude $E_0=7.3$ volts per cm acting on an electron for one half period will give it enough energy to ionize a hydrogen molecule. Substituting this value of E_0 in Eq. (3), we find the distance which the electron goes in one half period is 4.53 cm. This compares favorably with the electronic mean free path of 4.65 cm at the pressure corresponding to maximum conductivity at 15 million cycles. Moreover, the electric force at 15 million cycles is less than the electric force at 20 million cycles. This explains why the conductivity of the discharge is greater at 15 million cycles.

At both 20 and 15 million cycles, we have seen that the mechanism of the high frequency discharge under conditions of maximum conductivity consists in an electron making an inelastic collision with a gas molecule every electronic mean free path having been under the influence of the electric force for one half cycle. If this were also the mechanism of the discharge at frequencies less than 15 million cycles, then we would expect to find that both the voltage and pressure corresponding to maximum conductivity would be less than at 15 million cycles. Since Fig. 2 shows that at frequencies less than 15 million cycles, both the voltage and pressure corresponding to maximum conductivity are greater than the voltage and pressure at 15 million cycles, we must conclude that the mechanism of the discharge at frequencies less than 15 million cycles is different from the mechanism at frequencies greater than 15 million cycles. Using Eqs. (2) and (3) we find that the difference in mechanism is due primarily to the fact that below 15 million cycles, the electron makes an inelastic collision before it has been under the influence of the electric force for an entire half period. The shape of the curve of Fig. 2., combined with a rough calculation, suggests that between 15 and 12 million cycles the electron makes an inelastic collision having been under the influence of the electric force for one third cycle; between 12 and 10 million cycles for one fourth cycle; between 10 and 7.5 million cycles for one fifth cycle; between 7.5 and 6.5 million cycles for one sixth cycle; between 6.5 and 5 million cycles for one seventh cycle; between 5 and 3 million cycles for one eighth cycle; and between 3 and 1.25 million cycles the electron makes an inelastic collision having been under the influence of the electric force for only one ninth cycle. Since the time during which the electron is under the influence of the electric field is becoming shorter, the electric force must be increased in order

that the electron can attain ionizing velocity. On the other hand, it is evident that the even fractions of a cycle will be more efficient in producing ions than the odd fractions. This explains the maxima and points of inflection of Fig. 2.

If the conditions described in the last paragraph give a true picture of the mechanism of the discharge at frequencies below 15 million cycles, then the number of electronic mean free paths involved in an inelastic collision increases as the frequency of oscillation decreases. Thus for maximum conductivity at 10 million cycles, the electron makes an inelastic collision in a little more than one mean free path; at 5 million cycles in about 3 mean free paths; and at 1.25 million cycles in about 15 mean free paths.

The reason for the sharp break in the curve at 15 million cycles is probably due to the fact that 0.015 mm pressure is the lowest pressure at which sufficient ions can be produced to sustain a current of 100 milliamperes. Hence if the current through the tube were decreased, we might expect to find maximum conductivity at some frequency less than 15 million cycles and some pressure less than 0.015 mm. As yet, experiments have not been undertaken to verify this.

In conclusion, it has been shown that the conductivity of a high frequency discharge in hydrogen is greatest when the frequency of oscillation is 15 million cycles per second and the gas pressure is 0.015 mm because the discharge is operating most efficiently under these conditions. For, under these conditions, an electron is undisturbed for one complete half cycle of the electric field, and at the end of this time it has gone exactly one mean free path so that it can make an inelastic collision with its maximum velocity. Moreover, even though at 20 million cycles and 0.02 mm pressure, the mechanism of the discharge is the same (i.e. the electron goes exactly one mean free path in one half cycle) the electric force required is greater than at 15 million cycles. Finally, at frequencies of oscillation greater than 20 million cycles, if the mechanism of the discharge is the same as at 15 and 20 million cycles (which appears very probable), it is possible to predict from Eqs. (2) and (3), first, that the electric force at maximum conductivity will increase directly with the frequency of oscillation and second, that the gas pressure at maximum conductivity will also increase directly with the frequency of oscillation.

The writer wishes to express his appreciation to the Grigsby-Grunow Company of Chicago, Illinois, for whom this investigation has been carried out. He is also indebted to several members of the Department of Physics for their interest in this work and especially to Mr. J. S. Owens who assisted in the experimental work.

ON THE CATHODE OF AN ARC DRAWN IN VACUUM

BY R. TANBERG

RESEARCH DEPARTMENT, WESTINGHOUSE ELECTRIC AND MANUFACTURING CO.
EAST PITTSBURGH, PA.

(Received December 23, 1929)

ABSTRACT

It has been found that the cathode is the only electrode which contributes vapor for the maintenance of an electric arc under very low gas pressure.

The velocity of this vapor was determined by two methods. Method 1 consisted of measuring the force of reaction of the vapor on the cathode and the rate of vaporization of the cathode material. Method 2 consisted of determining the force exerted by the vapor on a vane suspended in front of the cathode spot and the rate of vapor condensation on the vane.

Both these methods gave a vapor velocity of the order of 16×10^5 cm/sec. A temperature of around $500,000^\circ$ K results when this value for the cathode vapor velocity is substituted for c in the equation: $\frac{1}{2}mc^2 = 3KT/2$.

INTRODUCTION

A SERIES of experiments with electric arcs drawn in vacuum indicated that a jet of high-speed vapor is ejected from the cathode region of such an arc.¹ A description will be given in the following paper of an attempt to obtain quantitative data on the velocity of this cathode vapor.

For the sake of simplicity the word "vacuum arc" will be used as representing an electric arc under an air pressure of the order of a few microns. The exact pressure will be given in each particular case wherever this is of interest.

DESCRIPTION OF EXPERIMENTS

An electric arc can be drawn even in very high vacuum by separating two metal contacts carrying current of the order of a few amperes.

The arc is drawn initially in the vapor given off by the vaporization of the metal at the point of last contact² and may be maintained by the vapor which after contact separation continues to be given off from the contact surface.

A number of preliminary experiments suggested that a jet of metal vapor with considerable velocity was emitted from the cathode region. A knowledge of the velocity of this vapor jet is not only of value in connection with the determination of the temperature of the cathode region, but will also enable us to get a better quantitative picture of the conditions in the vacuum arc in general. Accordingly an investigation was undertaken based upon the following experiments:

1. Measurement of the force of reaction of the vapor on the cathode. Knowing the amount of metal vapor evaporated per unit time the velocity can be calculated.

¹ R. Tanberg, *Nature*, Sept. 7, 371 (1929).

² J. Slepian, *Journ. A.I.E.E.*, October, 1926, p. 930.

2. Determination of the momentum imparted by the vapor to a vane suspended in front of the cathode. Knowing the amount of vapor condensed on the vane per unit time the vapor speed can be obtained.

In Fig. 1 is shown the apparatus used for the tests outlined under #1 above. The copper cathode, *c*, consisted of a short copper cylinder, 0.6 cm

Fig. 1. Apparatus for determination of cathode vapor speed.

diameter, on the end surface of which the cathode spot was located. A quartz tubing fitted tightly around the copper cylinder in order to limit the motion of the cathode spot. The cathode was fastened to a strip of aluminum which was suspended by two fine molybdenum wires from a suitable supporting frame mounted directly on the negative terminal leading through the wall of

* Based upon figures in column 8 and 9.

the arcing chamber. The pressure in the arcing chamber varied between 0.2×10^{-3} mm Hg at the beginning of the arcing to around 10×10^{-3} mm Hg at the finish. The arc current was supplied to the cathode through an iron wire which dipped into a pool of mercury, *P*, electrically connected with the negative terminal.

Thus the cathode was suspended so it would swing freely back and forth in a plane vertical to the cathode surface. The deflection was measured on a scale, *S*, located underneath the cathode. The instrument was calibrated for cathode deflection against the corresponding force on the cathode surface.

The arc was formed by contact between the cathode and anode as indicated in Fig. 1b. As soon as the arc was playing the anode was moved to about 1.5 m away from the cathode. The deflection of the cathode during the arcing was of considerable magnitude and quite steady and could, therefore, be read with good accuracy on the scale provided for that purpose.

The results of a series of typical tests are compiled in Table I. Column 3 gives the force on the cathode as a function of the arc current given in column 2. Column 9 gives the amount of vapor in grams per second leaving the cathode during the arcing.

Fig. 2. Vaporization of copper cathode by arc in vacuum.

These last values are taken from the curve in Fig. 2 which is based upon a separate series of tests made under identically the same conditions as those existing during the measuring of the cathode reaction force. The cathode was weighed before and after each test and the time duration of the arcing was noted, thus determining the rate of vaporization of the cathode material.

Column 10 contains the root mean square velocities of the vapor leaving the cathode, calculated from the data given in columns 8 and 9 using the formula:-

$$(C^2)^{1/2} = 1.39K/m$$

where

K = force in dynes on cathode.

m = mass in grams per second of metal evaporated from the cathode.

$(C^2)^{1/2}$ = root mean square velocity in cm/sec. of vapor leaving the cathode.

The development of this formula will be found in the appendix to this paper.

Considering the conditions under which the tests were made it is evident that the results should be corrected for possible radiometric, electrodynamic and electrostatic forces. A discussion of these corrections can also be found in the appendix.

The values of the cathode reaction force obtained when the above mentioned corrections are taken into account will be found in column 8 in Table I.

As will be seen later by the calculation of the corresponding temperature, the vapor velocities obtained are very high compared with what could be expected from conservative estimates of the temperature existing at the cathode. It was, therefore, thought desirable to check the results by the vane deflection method already referred to.

This was made with the apparatus shown in Fig. 3a and b. The cathode, *c*, was of the same design (copper cylinder surrounded by quartz tube) as

Fig. 3. Apparatus for measuring cathode vapor speed.

used in the previous experiments. It was fastened to a metal rod which could be moved from outside the vacuum by means of the flexible bellows, *B*. The same pressure was maintained during these experiments as during the cathode reaction tests just described. The arc was formed by moving the cathode to touch the anode as indicated in Fig. 3b. As soon as the arc was playing, the cathode was moved back in front of the glass vane, *v*, consisting of a square piece of Pyrex glass. This was suspended by two fine silk threads from a supporting frame indicated in the figure. The deflection of the vane was read directly on the scale, *S*, and the force necessary to deflect the vane as a function of the deflection was determined.

During a test the arc would play between the cathode and anode as indicated in Fig. 3b, while the vapor would be projected from the cathode spot directly against the vane deflecting this according to the momentum imparted to it by the impinging molecules.

The presence of this jet of high-speed vapor was not only evident from the definite deflection of the vane, but could also be realized visually by the sharply defined, faintly luminous, cone-shaped region, extending from the cathode spot to the vane. The results of these tests are given in Table II.

TABLE II. Results of vapor speed determination by deflecting vane method.

1 Test	2 Arc current (amps.)	3 Force on vane (gm)	4 Vapor condensed (gms/sec.) on vane	(C ²) ¹ / ₅ cm/sec. R.M.S. vapor velocity
366	14.2	64×10^{-3}	42.6×10^{-6}	20.8×10^5
369	16.0	64×10^{-3}	53.7×10^{-6}	16.6×10^5
367	18.0	94×10^{-3}	65×10^{-6}	20.1×10^5

The velocities in column 5 in this table were calculated by the same formula as previously used for calculating the vapor velocities from the cathode reaction tests, while m (column 4), representing the amount of metal vapor condensed on the vane per second, was obtained from the curve in Fig. 4, which is based upon direct measurements. It will be seen that the values for the cathode vapor speed obtained by this method agree quite well in the order of magnitude with the values obtained by the previous method.

Fig. 4. Condensation of copper vapor on collector 2 cm from cathode.

When judging these results it must be remembered that it is practically impossible to prevent the cathode spot from traveling on the cathode surface. The amount of vapor hitting the vane may, therefore, vary somewhat with the location of the cathode spot.

The discussion in the appendix of possible corrections to these measurements will show that the effects from radiometric pressure, electrostatic fields etc., can be entirely neglected.

CALCULATION OF TEMPERATURE CORRESPONDING TO THE MEASURED VAPOR VELOCITIES

The knowledge of the speed with which the metal vapor is ejected from the cathode region enables us to calculate at least the order of magnitude of the temperature at the cathode by the well-known relations between the average

kinetic energy and the absolute temperature of the molecules in a gas. It is believed to be justified to use in this connection the equation applying to three degrees of freedom of the molecule:

$$\frac{1}{2}m' \cdot C^2 = 3kT/2 \quad (1)$$

where m' is the molecular mass in grams; C^2 is the mean square of the velocity of the molecules in cm/sec.; k is Boltzmann's gas constant in erg/°Abs. and T is the absolute temperature.

The justification for using this form of the temperature-kinetic energy equation is the good agreement it gives with experimental results when applied to Stern's³ and Eldridge's⁴ measurements on velocities of molecules emitted from a hot metal surface under low gas pressure.

Substituting in Eq. (1) the values for the molecular velocities given in Table I give temperatures as shown in column 11.

GENERAL DISCUSSION OF RESULTS

As will be realized, these temperatures are far in excess of even the most extreme temperatures ever measured in connection with any physical phenomenon of any duration. One must, however, remember that the space close to the cathode of an electric arc constitutes a very small volume with a large energy input where one, from only conservative estimates, could expect exceedingly high temperatures.

A similar case with large energy input into a small space constitutes the interesting experiments made by J. A. Anderson⁵ with electrically exploded wires, during which he obtained estimated temperatures of 300,000°C.

CONCLUSION

The temperature existing at the cathode spot determined from the velocity of the cathode vapor is of the order of 500,000°K.

If this extreme temperature is confirmed by other investigators, our present ideas of what takes place at the cathode of a vacuum arc must be revised. The cathode region would then offer an excellent opportunity to study the very interesting physical conditions which must exist in a location with such an enormous temperature.

The writer wants to express his thanks to Dr. J. Slepian for the encouragement he has received from him during the preparation of this paper.

APPENDIX

Calculation of vapor velocities. A molecule will exert an impulse

$$\int K' dt = m' \cdot u \quad (2)$$

³ Stern, Zeits. f. Physik 2, 49 (1920).

⁴ Eldridge, Phys. Rev. 30, 931 (1927).

⁵ J. A. Anderson, Astrophys. J. p. 37. Jan. (1920).

on any surface which it is either leaving or striking. In this equation:

K' = force in dynes.

m' = mass in grams of the molecule.

u = component of velocity of molecule in cm/sec. perpendicular to surface.

The probability that a molecule in the vapor shall have a velocity component lying between u and $u+du$ is: $f(u) \cdot du$ assuming a certain velocity distribution. If n is the number of molecules per cm³ of the vapor, the number of these which has a velocity lying between u and $u+du$ is: $n \cdot f(u) \cdot du$. The total number of molecules per cm² per second leaving the cathode region with velocities lying within this particular interval must therefore be:

$$\Delta\gamma = u(n \cdot f(u) \cdot du) \cdot \text{molecules/sec.} \quad (3)$$

where u = velocity perpendicular to the surface in cm/sec.

The force exerted by these molecules on the cathode per cm² is (from Eqs. (2) and (3)). $K' = (m' \cdot u) \cdot (u \cdot n \cdot f(u) \cdot du)$.

$$K' = m' \cdot n \cdot u^2 \cdot f(u) \cdot du. \quad (4)$$

The total force per cm² of molecules leaving the cathode:

$$K = m' \cdot n \int_0^{\infty} u^2 \cdot f(u) \cdot du. \quad (5)$$

By changing integration limits:

$$K = m' \cdot n \cdot \frac{1}{2} \int_{-\infty}^{+\infty} u^2 \cdot f(u) \cdot du.$$

If u^2 denotes the mean square of the velocity component perpendicular to the surface:

$$K = \frac{1}{2} m' \cdot n \cdot u^2. \quad (6)$$

Since the vapor density $m' \cdot n$ is not practical to determine it is necessary to express this term by the amount of vapor leaving the cathode. The total number of moles per cm² leaving the cathode per second is found by integrating Eq. (3) from 0 to ∞ : $\gamma = n \int_0^{\infty} u \cdot f(u) \cdot du$. if $|\bar{u}|$ denotes the average numerical value of the perpendicular component of velocity we have: $\gamma = \frac{1}{2} n \cdot |\bar{u}|$. Thus the total mass of the atoms leaving the cathode per second is: $A \cdot m' \cdot \gamma = A \cdot m' \cdot (\frac{1}{2} n \cdot |\bar{u}|) = m$ or

$$A \cdot m' \cdot n = 2 \frac{m}{|\bar{u}|} \quad (7)$$

where m is total loss of cathode material during one second of arcing and A is the area of the cathode spot in cm². Making Eq. (6) apply to the whole

⁶ Richardson, "The Emission of Electricity from Hot Bodies" Edition 1921, pages 155 and 177.

cathode spot by multiplication with the cathode spot area "A" and combining it with Eq. (7) gives

$$K = (\bar{u}^2 / |\bar{u}| m). \quad (8)$$

There is reason⁶ to believe that the fundamental equations of Maxwell's velocity distribution theory can be used in connection with the conditions considered here. We can, therefore, substitute in equation (8) $\bar{u}^2 = \frac{1}{3} \bar{C}^2$ and $|\bar{u}| = \frac{1}{2} \bar{C}$ which gives: $K = \frac{2}{3} C^2 / C (C^2)^{1/2} m$ according to the Maxwellian velocity distribution function:

$$(C^2)^{1/2} / C = 1.08.$$

Hence:

$$(C^2)^{1/2} 1.39 K / m \quad (9)$$

which is the formula used for calculating the values given for the root mean square velocities in columns 10 and 5 in Tables I and II respectively.

The conditions at the vane are somewhat more complicated than assumed above because the existence of a Maxwellian velocity distribution in the gas at the vane surface may be questioned. However, the application of Eq. (9) to the data obtained from the vane deflection experiments will undoubtedly give values representing the correct order of magnitude of the R. M. S. velocity of the vapor striking the vane.

The values given in column 5 Table II which are calculated from Eq. (9) must therefore only be considered as serving the purpose of a rough check on the velocity values given in Table I.

DISCUSSION OF POSSIBLE CORRECTIONS TO VANE DEFLECTION TESTS

a. Radiometric effect—Due to the brilliancy of the cathode spot it was thought possible that the deflection of the vane during the experiments may have been affected by radiometric pressure. The tests recorded in Table III indicate, however, quite conclusively that the effect of radiometric pressure on the vane deflection must be of such small magnitude as to be negligible.

TABLE III. Showing that variations in gas pressures do not affect the deflection of the vane.

457	"	"	63×10^{-3}	64×10^{-3}	130×10^{-3}	did not vary
458	"	"	0.2×10^{-3}	13×10^{-3}	130×10^{-3}	with press.
459	"	"	0.2×10^{-3}	12×10^{-3}	94×10^{-3}	increase
460	"	"	0.2×10^{-3}	16×10^{-3}	130×10^{-3}	
461	"	"	0.2×10^{-3}	8.5×10^{-3}	130×10^{-3}	

During these experiments the gas pressure was measured by a McLeod gauge before and after each test allowing sufficient time for the pressure to equalize all through the vacuum system. The time required for equalization

was very short since all tube connections were dimensioned so as to give a large ratio of diameter to tube length.

The pumps were shut off during each experiment. Since the leakage of the system was found to be negligible, the increase in pressure during each test represents gas given off from the electrode during the arcing.

Thus during test #456 which lasted several seconds the pressure increased from 0.9×10^{-3} mm Hg to 56×10^{-3} mm Hg but the deflection of the vane remained constant around the value given in column 5 in spite of the fact that the radiometric effect within the same pressure interval according to data by Westphal⁷ should be expected to increase ten fold.

The difference in pressure at the end of tests 460 and 457 in Table III does not reveal any change in the force on the vane while the corresponding change in radiometric pressure according to Westphal's experiments should be about 28 percent.

A similar analysis of the other tests recorded in Table III points just as conclusively to the fact that the radiometric pressure on the vane can be entirely neglected during the writer's experiments.

b. Accumulation of charge on vane. If the vapor consisted of ions of one sign it would charge the vane up to a potential of the same sign as the charge on the vapor particles. The magnitude of this charge would increase until a sufficient field was set up to reflect the vapor particles back against the cathode. The momentum imparted to the vane by the vapor under such conditions would be about twice the momentum delivered to the vane if the particles condensed. It is, therefore, necessary to determine if such a reflection actually can have taken place during the tests recorded in the Tables I, II and III.

During a series of experiments the vapor from the cathode spot was made to condense on a metal plate which was kept under different potentials relative to the cathode. The metal plate was located in the same relative position to the cathode and anode as the vane during the previous experiments. The potential was varied between 0 and +60 volts without producing any effect upon the amount of condensed vapor.

Since the R. M. S. velocity of the vapor (15×10^5 cm/sec.) corresponds to about 74 volts assuming singly-ionized Cu atoms, this potential interval should have been sufficient to show some changes in condensation had the vapor when reaching the vane been charged.

CORRECTIONS TO CATHODE REACTION TESTS

a. Radiometric effect: From the discussion in connection with the vane experiments it is probably safe to assume that the radiometric effect is negligible also at the cathode outside of the cathode spot proper. This assumption is justified on account of the extremely steep temperature gradient existing at the cathode spot which will limit the high temperature area to the spot itself.

⁷ Westphal, Zeits. f. Physik 1, 92 (1920).

It remains, however, to be proved that the radiometric pressure at the cathode spot also will be of such small magnitude as to be negligible.

Knudsen⁸ gives the following formula for the radiometric force as a function of temperature and gas pressure:

$$K = \frac{1}{2}p \cdot \left(\frac{T_1}{T_2} - 1 \right) \quad (10)$$

where K is the radiometric force in grams/cm²; p is the gas pressure in grams/cm², and T_1 and T_2 are absolute temperatures.

The good agreement obtained by Knudsen between experimental and calculated values within the pressure range existing during the writer's arcing experiments justifies the use of this formula in calculating the radiometric force at the cathode of the vacuum arc.

Assuming a temperature at the cathode of 700,000°K and a temperature of the surrounding parts of 300°K gives:

$$K = 328 \times 10^{-3} \text{ grams/cm}^2$$

from Eq. (10) for a pressure equal to 10×10^{-3} mm Hg. If we assume that the current density of 7200 amp/cm² found by Güntherschultze⁹ for cathode spots on iron under atmospheric pressure also holds for a vacuum arc the cathode spot of a 20 amp. arc will have an area of 2.8×10^{-3} cm². Thus the total force on the cathode spot due to radiometric effects under the conditions specified will not exceed 0.92×10^{-3} grams/cm².

A comparison with the forces actually measured on the cathode spot shows that the radiometric effect also in this case can be entirely neglected.

b. Electrostatic force on the cathode. On account of the cathode drop an electrostatic force will be exerted on the cathode during the arcing in such a direction as to tend to move it into the arc. Since the cathode drop is known to be concentrated in a very small distance from the cathode surface the electrostatic force may be of such magnitude that it can not be neglected.

If S is the area in cm² over which the electric field extends at the cathode and E the field strength in absolute units per cm, the force in dynes exerted on the cathode is (assuming a dielectric constant = 1) $F = S \cdot E^2 / 8 \cdot \pi$.

Observations of the Stark effect¹⁰ indicates a field strength at the cathode surface of the order of 10^5 volts/cm. Since the field at the edge of the cathode spot probably falls off very rapidly it should be correct to substitute for S in the above equation the area of the cathode spot determined from the current density observed by Güntherschultze.⁹ The values thus obtained are given in column 4 Table I.

c. Electrodynamic forces. Due to the form of the current path in the apparatus shown in Fig. 1 an electrodynamic force can be expected to act upon the suspended cathode during the arcing, tending to increase its deflection. The correction for this will be found in column 5, Table I.

THE REFLECTION OF LITHIUM IONS FROM METAL SURFACES

BY R. B. SAWYER

RYERSON PHYSICAL LABORATORY, UNIVERSITY OF CHICAGO

(Received March 22, 1930)

ABSTRACT

A study has been made of the reflection of lithium ions from reflectors of platinum foil and of nickel crystals deposited on tungsten foil. Movable ground joints in the tube were completely eliminated in order to prevent contamination of the reflector surfaces by grease. Readings were taken with both cold and hot reflectors. Spodumene was used as a source of ions and reflection was studied in the meridian plane only.

Superposed on a diffuse scattering of ions were two reflected beams. One was reflected nearly specularly, as found by Read and by Gurney, the angle of maximum reflection, however, being independent of accelerating potential. The other beam appeared only at voltages above 200 and was composed of ions most of which had retained 80 percent or more of their original energy. This beam was found between the incident beam and the normal to the surface, at angles independent of the accelerating potential up to 700 volts. This independence of angle on voltage forbids diffraction interpretations. A tentative explanation consists in supposing specular reflection from the (110) planes of the nickel crystals, but the agreement is not entirely satisfactory.

THE reflection of lithium and potassium ions from a platinum surface has been investigated by Read,¹ and that of lithium, potassium, and caesium from platinum by Gurney.² Both found considerable reflection from a clean platinum surface, the maximum occurring at an angle somewhat larger than that corresponding to specular reflection. Since an extremely clean reflector seemed to be necessary in order to obtain appreciable reflection, it was desirable to continue the study, making every effort to avoid contamination of the reflector, especially by grease vapor. The discovery of electron diffraction by crystals³ and the work of Ellett and Olson⁴ on reflection of neutral atoms by crystals suggested a trial of crystal surfaces as reflectors of positive ions.

APPARATUS

The tube used is shown in Fig. 1 and Fig. 2. A tiny crystal of spodumene, *S*, on an electrically heated platinum strip was used as a source of lithium ions.⁵ These were accelerated to the drum, *B*, and a portion passed through holes 1 mm in diameter, and entered the cylinder, *A*, which had a 3 mm slot cut around it to admit them. After striking the reflector, *T*, those ions which

were reflected at any given angle could be caught by the collector, *C*, which was a 2 mm \times 7 mm nickel strip rigidly fastened by means of a Pyrex bead to the axis of the cylinder, *A*. The collector-cylinder system was mounted in a supporting framework (not shown in the figure) so that it could be rotated from the outside of the tube by an electromagnet applied to the soft iron armature, *D*. The angle at which the collector was set was indicated by a pointer, *E*, moving over a graduated circle, *F*. The collector was connected to a string electrometer by a flexible lead. The positive ion current from the collector was balanced by a negative current from an ionization chamber.⁶ The central part of the tube was shielded by a gauze, *G*, and an additional screen, *H*, of sheet metal was placed around the bottom part of the tube in order to prevent the escape of any positive ions from the source except

Figs. 1, 2. Construction of tube.

through the holes in the top of the drum, *B*. The cylinder and framework supporting it were grounded through the same lead as the screen, *H*, but the gauze, *G*, had a separate ground connection. Neither of these ground leads is shown in the figure. Tungsten wires were used for sealing through the Pyrex.

The reflector was either a 5/16 in. \times 3/8 in. strip of platinum-iridium foil (10 percent iridium) 0.0005 in. thick, or a 1/8 in. \times 3/8 in. strip of tungsten foil, kindly supplied Dr. W. E. Forsythe, upon which nickel crystals had been deposited by evaporation, according to the method of Rupp.⁷ He states that the minute crystals so formed are oriented with their (111) planes parallel to the surface of the backing foil. The platinum foil was mounted so as to be kept always under slight tension by a tungsten spring, while the heavy nickel wires supporting the nickel crystal reflector had enough elasticity to keep the tungsten foil taut. In either case the reflector could be heated electrically to any temperature desired. Except as otherwise noted, all metal parts were made of nickel.

⁶ Read, reference 1, p. 630.

⁷ Rupp, *Ann. d. Physik* 1, 801 (1929).

Spodumene proved to be so satisfactory a source of lithium ions that the stem supporting the source and drum was sealed permanently into the side tube. A useful life of from 75 to 100 hours for one crystal was not unusual. One end of the main tube was ground off and closed by a glass plate waxed on with ordinary red sealing wax, care being taken to keep the wax on the outside of the tube. Contamination by grease vapors was thus entirely eliminated and that by vapors of wax reduced to a very small amount.

Originally a small Faraday cylinder was used as a collector. It was found that the measured ion current to such a cylinder was sensibly the same no matter whether the ions struck the inside of the cylinder or the bottom outside. It has been noted by others⁸ that the reflection of positive ions almost disappears at normal incidence. Furthermore, a particularly clean surface seems to be necessary to secure much reflection at any angle, and no pains were taken to secure this degree of cleanliness of the collector. Hence, since the ions would be incident normal to the collector and the collector was not especially cleaned, one would not expect loss of ions by reflection even from a simple strip. Experience bears out this conclusion. The cylinder was later replaced by a strip because it took up less space.

METHOD

The accelerating potential could be applied in two parts: one between the source and the drum, the other between the cylinder and the reflector, drum and cylinder both being grounded. The field between cylinder and reflector served both to accelerate primary ions moving toward the reflector and to retard reflected ions leaving it. Thus by making the source 30 volts positive and the reflector 20 volts negative with respect to the drum and cylinder, the ions caught by the collector would have struck the reflector with an energy of 50 volts and would have retained 20 volts or more after impact. These will be designated as 50-20 volt ions.

It is true that with this arrangement the ions are in a field of force while they are being reflected and this may conceivably influence the reflection somewhat. The geometry of the tube was such that the field between the cylinder and the reflector was, to a rough approximation, radial, and the velocities of the reflected ions should not have been greatly altered by it as regards direction. Furthermore, when a reading was being taken the field around the cylinder was not distorted by the presence of the collector, since its potential at such a time was always zero. One disadvantage of this method is that the field between the cylinder and the reflector focuses the incident beam to some extent, so that even though the ion current getting through the holes in the drum remains constant, the number of ions striking the reflector is greater the greater the potential difference between it and the cylinder. Thus for the higher retarding potentials, i.e., larger fractions of total accelerating potential applied between cylinder and reflector, the current to the reflector is actually increased.

⁸ Gurney, reference 2, p. 472, and his quotation of Jackson, *Phys. Rev.* **28**, 524 (1926).

An alternative method would be to keep the drum, cylinder, and reflector all at ground potential, applying the whole accelerating field between the source and the drum, and the retarding field between the cylinder and collector. This has two disadvantages. In the first place, the field in the immediate vicinity of the collector tends to change the direction of approaching ions, deflecting them so that some which should strike the collector now miss it entirely. In the second place, this method involves placing the whole collector-electrometer system at a positive potential, sometimes comparatively high, with the consequently greater likelihood of insulation leaks. All of the data in this paper were obtained with the first arrangement.

The procedure in taking a series of readings was as follows. The desired accelerating and retarding potentials were applied and the source was heated for several minutes until the emission became steady. The total ion current getting through the holes in the drum was measured by turning the collector so as to cover the holes. This current was kept as nearly constant as possible and was checked occasionally during a run, little difficulty being found in maintaining constancy. The heating current through the reflector was adjusted to give the desired temperature and the collector then rotated so as to collect ions reflected at various angles. The width of the collector subtended an angle of about 9.5° at the center of the reflector, and in taking readings settings were made at 10° intervals. The pressure was kept as low as possible, being of the order of 10^{-6} mm. If the reflector were at any temperature higher than that of a just visible red heat, it was found necessary to apply to it a negative potential of 2 or 3 volts in order to suppress positive ion emission from the reflector itself.

RESULTS

In general, the reflector gave more intense reflection when hot than when cold, though little change was observed as the temperature was raised beyond a medium red. In most of the following work a medium red heat was used. It is probable, as Read and Gurney suggested, that the increased reflection when hot was due to the removal of surface films of gas or grease. Read reported that within a few seconds after the heating current was turned off no reflection could be detected, while Gurney publishes a curve showing that the intensity of reflection decreased to 0.4 of its initial value during the first minute after heating was stopped. With the tube used in this investigation it was found that the intensity was 0.9 of its original value after an interval of 8 minutes, in one instance, and even after 20 minutes it had sunk only to $0.86 I_0$.

When only small retarding fields were applied so that ions of all but the very lowest velocities were collected, reflection was found as shown in Figs. 3-6. The figures show the incident beam coming from the right, and the length of the radius vector from the center of the reflector to any point on a curve is proportional to the intensity of reflection at that angle. The broken lines marked *N* and *S* show, respectively, the normal to the surface and the angle of specular reflection.

The reflection from platinum, Fig. 3, shows much the same sort of distribution as reported by Read and Gurney, but there are several points of difference. Apparently there was considerably more diffuse scattering at small

Fig. 3. Reflection from platinum, angle of incidence 43°. Small retarding potentials.

Fig. 4. Reflection from nickel, angle of incidence 51.5°. Small retarding potentials.

Fig. 6. Reflection from nickel, angle of incidence 69°. Small retarding potentials.

angles than was found by either Read or Gurney. There is a rather broad peak in each curve, the maximum falling at a larger angle than specular reflection would give. Contrary to the findings of Read, the position of this maximum did not change with a change in the accelerating potential.

Fig. 7. Reflection from nickel, angle of incidence 62.5°.

The curves for a nickel crystal reflector, Figs. 4-6, show hardly any peaks in some cases. Where they do occur they are not as prominent as with the platinum reflector, and fall much more nearly at the specular angle.

The relation between the intensity of the maximum and the accelerating potential is shown in Fig. 7 for a nickel reflector with a primary beam incident at 62.5° . The maximum in the neighborhood of 40 volts agrees with the results of Read and Gurney for platinum.

Figs. 8-13 are curves for larger retarding potentials. These curves show directly the angular distribution of all reflected ions having more than a certain amount of energy. For instance, the 50-20 volt curve of Fig. 8 shows the distribution of ions which originally had an energy of 50 volts and which retained 20 volts or more after reflection. For low accelerating potentials these curves show a progressive shift of the maximum toward larger angles as the retarding potential is increased, indicated in Fig. 8. This shows that the ions which were the least deviated from their original directions were apt to have higher velocities than those which were deflected through larger angles. This corroborates the result obtained by Gurney.

From a set of curves such as Fig. 8 or Fig. 9 it is possible to get some idea of the velocity distribution of the ions as well as their distribution in angle.

Fig. 8. Reflection from platinum, angle of incidence 43° . Large retarding potentials.

Fig. 9. Reflection from nickel, angle of incidence 51.5° . Large retarding potentials.

Thus in Fig. 9 it is seen that there is a fairly well-defined beam of ions coming off at an angle just inside the normal to the surface, and the ions composing the beam seem to have retained a large part of their original energy. The fact that some of the curves for large retarding potentials show a greater intensity than those for smaller retarding potentials at a given angle may be explained by the focusing effect of the field between the cylinder and the reflector, as before mentioned. Increasing the retarding potential accentuates the specularly reflected peak, though reducing its intensity, at the same time bringing into marked prominence the high velocity beam which must previously have been obscured by general, low velocity scattering. It should be noted that the position of this new peak, as shown in Figs. 10-13, is unaffected by a change in the accelerating potential of the incident ions up to 700 volts, the largest used. This is not particularly apparent in Fig. 11. While the number of voltages used for an angle of incidence of 62.5° was not as large as might be desirable to locate accurately the position of the new peak, careful examination of all the data taken leads to the conclusion that the maximum was located at about 5° inside the normal, as shown by the 250-150 volt curve.

However, the accuracy of measurement was hardly sufficient to locate the maximum within 5° .

The peak near the normal was not observed with accelerating voltages below 200 volts and increased in prominence as the accelerating potential was raised. Its position so near the normal to the surface at once suggested that it might be due to the condensation of ions upon the surface and their subsequent evaporation, according to the theory of Langmuir⁹ and Frenkel.¹⁰ This would result in a cosine distribution with a maximum along the normal. However, it would hardly be expected that the ions would evaporate with such high velocities as were observed, if, indeed, they evaporated as ions at

Fig. 10. Reflection from nickel, angle of incidence 51.5° . Large retarding potentials.

Fig. 12. Reflection from nickel, angle of incidence 69° . Large retarding potentials.

Fig. 13. Reflection from platinum, angle of incidence 59° . Large retarding potentials.

all. The sharpness of the peak, too, did not suggest a cosine law. As a further check on the adsorption—re-evaporation idea, the effect was tried of changing the density of the ion stream, since the work of Cockcroft¹¹ indicated that stream density was an important factor in molecular condensation. However, it seemed to be impossible to make the peak either appear or disappear simply by changing the ion current. In one trial, using a voltage below that at which the peak appeared, an increase in the current by a factor of thirty failed to produce a peak.

A hot reflector gave the effect better than a cold one. It was not observed

at all with a nickel crystal reflector at an angle of incidence of 42° or with platinum at 44° .

When the larger accelerating potentials were used there sometimes appeared to be an emission of secondary electrons from the reflector. It was usually possible, by the application of a suitable magnetic field, to prevent these from reaching the collector and yet to leave the positive ions practically unaffected.

DISCUSSION

The reflected beam of ions coming off near the normal to the surface and having nearly the same velocity as the incident ions is the most interesting result of this study. It would be most natural to try to attribute it to positive ion diffraction were it not for the fact that the position of the beam is independent of the accelerating potential. The wave-length associated with a 200 volt lithium ion would be expected to be approximately 0.01A. Although it is difficult to predict the behavior to be expected of a complex ion when it strikes a crystal surface, specular reflection would seem to be as likely as anything else. A consideration of the possibilities of such reflection from various planes in the nickel crystals shows that, of those having the largest atom densities, only the (110) planes could give specular reflection at approximately the observed angles. Table I shows the angles observed and calculated. Having no accurate knowledge of the crystal structure of the platinum reflector, it is impossible to calculate the reflection as in the case of the nickel crystals.

TABLE I. *Reflection from nickel crystals. All angles measured from the normal to the surface.*

Angle of incidence on (111) planes	Angle of Reflection		Difference
	Calculated from (110) planes	Observed	
51.5°	19.5°	8.5°	+11.0°
62.5°	8.5°	5.5°	+3.0°
69.0°	2.0°	9.0°	-7.0°

One argument against the hypothesis of reflection by the (110) planes is that the differences between observed and calculated values of the angles show a systematic trend in one direction. However, the number of different angles tried was not sufficient to permit drawing a definite conclusion. The reflected beam was so nearly normal to the surface as to suggest the possibility that more accurate measurements might show it to lie exactly along that direction. A rough test of the relative satisfactoriness of the two suppositions—reflection by the (110) planes or reflection along the normal—is found by applying the method of least squares, though here again a greater number of angles would be desirable. This method gives little choice between the two hypotheses, the slight difference being in favor of the first mentioned.

The writer wishes to acknowledge his indebtedness and express his appreciation to Professor A. J. Dempster, who proposed the problem and whose suggestions proved extremely valuable, and to Mr. K. S. Woodcock, who assisted in taking some of the data and making the drawings.

THE ZODIACAL LIGHT AND THE GEGENSCHN AS
PHENOMENA OF THE EARTH'S ATMOSPHERE.*

BY E. O. HULBURT

NAVAL RESEARCH LABORATORY

(Received March 14, 1930)

ABSTRACT

A quantitative atmospheric theory of the zodiacal light and the gegenschein is developed. Neutral particles sprayed out in all directions from the earth's atmosphere are ionized at 50,000 to 70,000 km levels by the ultra-violet light of the sun. Because of the wobble of the earth's magnetic field with the rotation of the earth ions near the equatorial plane stay for some time at these high levels to form a ring around the earth, ions at high latitudes fall quickly back to the earth to give aurorae. The gravitational magnetic drift of the ions forces the ion ring into a long oval stretching out away from the sun to 10^6 km. The pressure of the sunlight warps the oval into the plane of the ecliptic and makes the ions stream out like a comet's tail. The ions are fluorescent; they absorb the sun's ultra-violet light and emit a part of the absorbed energy as visible light. The oval ring is the zodiacal light; the comet tail ion stream is the gegenschein. The zodiacal cones in December are somewhat to the south of the cones in June; the evening cone is south and north of the morning cone in March and September, respectively. These theoretical inferences are in qualitative accord with observation. The theory suggests that the spectrum of the zodiacal light and the gegenschein be different from that of sunlight.

Quantitative estimates lead to a low ion density in the zodiacal ring, less than 10^3 ions cm^{-3} and to a rate of escape of the terrestrial atmosphere of 10^6 particles $\text{cm}^{-2} \cdot \text{sec}^{-1}$ or 10^{-6} of the entire atmosphere in 10^6 years. These are perhaps under-estimates. The theory indicates that helium escapes more rapidly than the other gases because of its lightness and higher ionization potential. This may account for the small amount of helium in the atmosphere, which is regarded as being surprisingly low in the face of the estimated large rate of supply from the earth.

Variations in the zodiacal light, from the observations of Jones in 1853-1855 and of more recent observers, are shown to occur usually during magnetic storms. Similarly Barnard's observations of the variations in the gegenschein fall in with magnetic disturbances, although more data are needed to establish the connection clearly. The variations are in accord with the atmospheric theory.

INTRODUCTION

SHORTLY after sunset when the evening twilight has gone the zodiacal light appears as a faint cone of light in the west rising upward from the horizon, with a similar cone in the east before dawn.¹ At their apexes the cones narrow to a band which extends across the sky from one apex to the other. Thus the phenomenon is spoken of as a "band" of luminosity. The

* Published with the permission of the Navy Department.

¹ For general descriptions of the zodiacal light and the gegenschein see Newcomb, *Encyclopaedia Britannica*, 13th ed., Vol. 28, page 998; Schmid, "Das Zodiakallicht," Hamburg, 1928; Bayldon, *Pub. Ast. Soc. of the Pacific* 12, 13 (1900); and references cited throughout the present paper.

band lies closely, but not exactly, along the plane of the ecliptic. It is usually less bright than the milky way and may be seen on any clear night when there is no disturbing illumination such as the moon, planets, the milky way, artificial lights, etc. At an angle of 30° from the sun, the closest angle to the sun at which the light can be seen when observed in the eastern or western sky, the band is about 40° wide.² The width of course is rather indefinite for the band is brightest near its center and fades into obscurity at the edges. Newcomb³ and Barnard⁴ in north latitudes around 45° during the midnight hours of the summer solstice observed a glow passing from the west to the east along the north horizon. They concluded that this was the zodiacal band, for it could not have been ordinary twilight because the sun was more than 18° below the horizon, and that therefore the band was about 70° wide along the sun's axis. With increasing angular distance from the sun the band decreases in width and in brightness. At 90° from the sun it is about 20° wide and at 150° about 10° wide. At 180° , the point directly opposite the sun, there is a faint knot of luminosity, sometimes appearing as a swelling in the zodiacal band, called the "gegenschein"⁵. Attempts to measure the parallax of the zodiacal band have always led to values close to zero, but, what is very curious, often negative. The parallax of the gegenschein, as determined by simultaneous observations in the northern and southern hemispheres, was found⁶ to be zero within an error of 1° or 2° . Therefore the zodiacal light and the gegenschein have been considered to be far away, beyond the moon, or farther.

The zodiacal light is supposed to be sunlight scattered or reflected or emitted by particles in the plane of the ecliptic. Whether the particles come from the atmosphere or the earth or are planet dust widely scattered through the solar system is an unsettled question, although probably the planet dust theory is more generally held at the present time. Recently the physics of the outer fringe of the atmosphere⁷ of the earth was developed, primarily for the purpose of the theory of aurorae and magnetic storms. At the time it was realized that the ideas might be brought to bear on the zodiacal light. Just how this was to be done was not clear until it was noticed (Hulburt, Amer. Phys. Soc. Bul. Dec. 30, 1929) that the fluctuations in the zodiacal light occurred at the same time as the magnetic disturbances. This indicated at once that the planet dust theory was open to objection and pointed the way to the development of the atmospheric theory. It is the purpose of this paper to give the evidence for the connection between the zodiacal light changes and magnetic storms and to describe a theory of zodiacal light based on the action of molecules and ions in the outer fringe of the terrestrial atmosphere. The theory offers an explanation of many features of the zodi-

acal light and the gegenschein which the planet dust theory is inadequate to explain.

In company with almost all who have written about the zodiacal light we shall use extensively the classical observations⁸ of Reverend George Jones USN, made for the most part in north latitudes 10° to 30° while on a voyage on the Pacific Ocean. From April, 2, 1853, to April 22, 1855, he observed the light every night, weather and other things permitting, and sketched on a chart of the heavens the zodiacal light as he saw it. The drawings, 341 in number, and their descriptions were published; they are by far the most complete and extensive series available. The observations are of gold, and whereas some writers, among them Jones himself, have wondered at apparent inconsistencies we have found that it is just these variances which fall in with the pattern of the theory, Jones wrote in his introduction, "I have put down all, exceptions and incongruities as well as others, not feeling authorized to omit any portion; for who can say, in a new science, that what seem to be exceptions are not a part of the general rule."

2. *Abnormalities in the zodiacal light and magnetic storms.* It was recognized long ago by Humboldt, Arago, Birt and others^{8,9} that the zodiacal light is at times variable in intensity the entire body of the light alternately weakening for a few minutes and strengthening again. That the zodiacal light is often unusually intense during epochs of strong aurorae has been known for a long time. For example, in 1881 Groneman⁹ referred to the fact as of common knowledge. Aurorae are known to occur in general during periods of magnetic disturbance, but no one has been interested in examining the exact relations with the zodiacal light. Turning to Jones' observations we find that occasionally he noticed and commented on fluctuations in the intensity of the zodiacal light; the entire body of the light grew brighter and dimmer in a period of two or three minutes. In a few cases he recorded an unusually wide spread of the zodiacal luminosity. One of his descriptions is as follows, "The changes were a swelling out, laterally and upwards, of the Zodiacal Light, with an increase of brightness in the Light itself; then, in a few minutes, a shrinking back of the boundaries, and a dimming of the Light; the latter to such a degree as to appear, at times, as if it was quite dying away; and so back and forth for about three quarters of an hour;" We have plotted these abnormalities on a qualitative scale in dots as ordinates against the dates as abscissas; a portion of the plot is given in Fig. 1. The magnetic storms observed at The Greenwich Observatory¹⁰ are plotted as short lines in the figure; 1, 2, and 3 mean a storm of moderate, strong and very strong intensity respectively. It is seen that the zodiacal light abnormalities occurred, usually during magnetic disturbances. To summarize the data: There were 27 magnetic storms, or groups of storms, in the period of Jones' observations, 17 of which were followed by cases of unusual zodiacal

⁹ Groneman, Archives Néerlandaises, Tome XVI.

¹⁰ Maunder, Monthly Notices, Roy. Ast. Soc. 65, 2 and 540 (1904-5).

light. There were 10 storms with no zodiacal light observations because of clouds, etc., and 10 instances when the zodiacal light might be regarded as abnormal with no accompanying magnetic storms.

A few more recent observations may be mentioned. Pachine¹¹ in Russia observed the zodiacal light to be remarkably brilliant and to exhibit fluctuations on January 28, 1911 at 6:30 p. m. The light appeared normal during the following days. The preceeding days were cloudy but the clouds were unusually illuminated and he concluded that the exceptional zodiacal brilliance began on the 25th. We do not know whether or not the illumination of the clouds might have been due to an aurora. A four-day magnetic storm of intensity 2 began at 4 hr, G. M. T., on January 24, 1911. Fluctuations in

Fig. 1. The dots are the zodiacal light observations of Jones, the vertical lines are the magnetic storms.

the zodiacal light were observed by Hanahan¹² in South Carolina on February 4 and 13 and on March 5, 1913. The storms in this period were January 29 (1), February 13 (1), 24 (1), and March 13 (2). The fluctuations on February 13 fall in with a magnetic storm, the others do not. The zodiacal light was very brilliant on March 21, 1927, according to a photograph by Graff¹³. The period was one of magnetic activity, a seven-day magnetic storm lasting from March 13 to 20 of intensity 2 on March 16 and 1 on March 20. Fluctuations in the zodiacal light were seen simultaneously by two observers Kamei and Oraki¹⁴ at widely separated points in Japan on November 3, 1929, at about 3 A. M. local time. A magnetic disturbance set in on November 2 at 23 hr,

¹⁴ See note by Glanville, *Pop. Ast.* 38, 124 (1930).

G. M. T., rose to intensity 2 on November 3 and continued with decreasing violence through November 6.

Of course abnormalities in the zodiacal light may at times be due to local causes, such as variations in haze, etc., rather than to changes in the light itself, and in such cases there would be no connection between the zodiacal light behavior and magnetic disturbances. The foregoing facts, however, support the conclusion that the connection is genuine and this suggests that the zodiacal light is influenced by the same solar emission which gives rise to magnetic storms. All in all, the data indicated that the zodiacal manifestation occurred within less than two days after the storm began, sometimes it was observed a day or a few hours before the storm (see the theoretical discussion of section 13).

3. *The energy, polarization and spectrum of the zodiacal light.* The energy $\cdot \text{cm}^{-2} \cdot \text{sec}^{-1}$ received at the earth from all the stars, from the total night sky (the non-polar aurora) and from the total zodiacal region was found¹⁵ to be equal to that of 1440, 0.08 and 0.08 stars, respectively, of magnitude 1 on the Harvard visual scale. The energy of starlight at the earth is $3 \times 10^{-3} \text{ erg} \cdot \text{cm}^{-2} \cdot \text{sec}^{-1}$ and therefore that of the night sky and the zodiacal luminosity each amounts to $0.08 \times 3 \times 10^{-3} \div 1440 = 1.7 \times 10^{-7} \text{ erg} \cdot \text{cm}^{-2} \cdot \text{Sec}^{-1}$. Assuming the zodiacal region to occupy 10^{-1} of the area of the sky, the energy emitted per $\text{cm}^{-2} \cdot \text{sec}^{-1}$ from the zodiacal region on the average is of the order of $10^{-6} \text{ erg} \cdot \text{cm}^{-2} \cdot \text{sec}^{-1}$. This means that the zodiacal region is ordinarily about 10 times as bright as the sky would be if there were no stars.

The zodiacal light was observed to be partially polarized,¹⁶ about 15 per cent. Early observers¹⁷ found that the spectrum of the zodiacal light was similar to that of sunlight, as well as could be judged from visual observations. More recently Fath¹⁸ photographed the spectrum with a 12 hour exposure, from 3 to 4 A. M. for 12 days. The spectrum from $\lambda 5000$ to 3900\AA was 2.2 mm long. Two absorption lines could be seen on the plate. Fath wrote, "A comparison of this plate with one of the sky spectrum taken with the same slit-width shows these lines to be *G* and the blend of *H* and *K* of the solar spectrum. These are the only two lines shown on the sky comparison plate within the limits of the spectrum obtained on the zodiacal light plate. There is no indication of bright lines on any of the spectrograms of the zodiacal light. Thus insofar as spectra of such low dispersion and resolving power can be trusted, we would seem to have good evidence to support the claim that the zodiacal light is reflected sunlight."

4. *The planet dust theory of the zodiacal light.* This theory assumed that there are dust particles in a flat lens shaped region with the sun at the center spreading out in the plane of the ecliptic well beyond the orbit of the earth. The particles were not molecules of a gas, for due to diffusion and light pressure molecules would not stay near the plane of the ecliptic. The particles

¹⁸ Fath, *Lick Obs. Bul.* 5, 141 (1909).

were considered to be small solid bodies each moving in its independent orbit around the sun. It was suggested that they were small meteoroids of the solar system, possibly remnants of the spray and dust from the large splash which inaugurated our planet system.¹⁹ The particles were assumed to reflect the sunlight, particles 1 mm in diameter and 5 miles apart of albedo 0.07, the albedo of the moon, being sufficient to account for the observed zodiacal luminosity.²⁰ Light reflected from minerals such as granite, clay, etc., was found to be partially polarized.¹⁶

Since the zodiacal light undergoes fluctuations in intensity it follows that all of the light can not be reflected sunlight. For the sunlight, at least in that portion of the spectrum accessible to us, does not fluctuate very much, the short period (a few hours or a day) variations²¹ of the solar constant being usually less than 10 per cent, whereas the variations in the zodiacal light intensity, although not measured, would perhaps be of the order of hundreds of percent. Therefore the planet dust theory, if it be retained at all, requires some fundamental modification not heretofore contemplated.

5. *The atmospheric theory of the zodiacal light.* As described in the following pages the atmospheric theory assumes that fast flying atoms or molecules are sprayed out in all directions from the sunlit hemisphere of the earth which, after a number of hours, are ionized by the ultra-violet light of the sun. Under the action of solar radiation pressure and the earth's magnetic and gravitational fields ions at levels beyond 30,000 km form a sort of oblong ring around the earth approximately in the plane of the ecliptic. The ions absorb sunlight in the far ultra-violet region of the spectrum and re-emit a portion of the absorbed energy as visible light. This is the zodiacal light. This view encounters two difficulties at the outset, namely, the light might be expected to be unpolarized and the spectrum should be different from that of sunlight. The first difficulty may be got round for the present by suggesting that the fluorescence radiation might be polarized to some extent and by expressing the wish that the polarization observations be repeated. The difficulty with the spectrum is more serious, so serious in fact that if future observations show that the zodiacal spectrum is that of sunlight the atmospheric theory in the form given here will fall to the ground. We may remark that the solar corona and certain comet tails exhibited a spectrum more of less continuous which, in part at least, was not that of sunlight.²²

6. *The ion spray to distances of 70,000 km.* In the earlier paper, reference 7, paragraph 3, it was shown that beyond 450 km above sea-level there were about 10^{-16} molecules and atoms in a 1cm^2 column of the atmosphere. These dance up and down, being knocked upward by thermal impacts from below and falling back under gravity, with practically no collisions except at the 450 km level where they experience 10^{14} collisions per sec. The thermal ve-

locities are hardly greater than 2 km sec^{-1} and the levels reached by the particles are on the average not above 2000 km. It was assumed that 2×10^6 of the collisions were of the second kind, *i. e.* collisions with excited atoms or molecules, which gave the particles velocities as great as $10 \text{ km} \cdot \text{sec}^{-1}$ (See reference 7 for a more detailed discussion.) In the present case the assumption is extended to include 2×10^7 collisions which result in velocities as high as 12 or 13 $\text{km} \cdot \text{sec}^{-1}$. Thus $10^7 \text{ cm}^{-2} \cdot \text{sec}^{-1}$ fast moving atoms or molecules move out from the earth. They are ionized by the ultra-violet light of the sun in a time t given by the relation $t = a/I_0 (1 - e^{-\beta})$, (reference 7, equation (1)) where a is the ionization potential of the atom or molecule, I_0 is the energy of the sun in the ionizing wave-lengths and β is the atomic absorption coefficient. β is defined in the usual way by

$$I = I_0 e^{-\beta y x}, \quad (1)$$

where I is the intensity of the light after passing through x cms of atoms or molecules of density y . It is assumed that the sun is quiet, *i. e.* no aurorae or

Fig. 2. The rate of supply q_z of ions as a function of the distance from the earth.

magnetic storms, and that its spectrum is that of a black body at 6000°K . The energy in the region from 725 to 750A of the solar spectrum falling $\text{cm}^{-2} \cdot \text{sec}^{-1}$ on the earth is 10^{-4} erg. With this value for I_0 , with $\beta = 3 \times 10^{-11}$ and with $a = 3.1 \times 10^{-11}$ ergs, corresponding to 20 volts, t is 3 hours.

Assuming always 3 hours for the time of ionization, the heights z where the neutral atoms were ionized were calculated for various values of v the velocity of projection from the 300 km level of the earth's atmosphere. For example, an atom with $v = 9.7 \text{ km} \cdot \text{sec}^{-1}$ reaches $z = 31,800 \text{ km}$ in 2.6 hours and falls back to 31,400 km in 0.4 hours where it is ionized; with $v = 10, 10.3$ and $11 \text{ km} \cdot \text{sec}^{-1}$ the atoms are ionized at $z = 39,800, 48,000$ and $70,000 \text{ km}$ respectively. The v, z curves were plotted for $t = 3$ hours and $t = 2$ hours. Assuming that the velocities are equally distributed among the high flying atoms, in which case the number of atoms with a specified energy is proportional to the square root of the energy, the rate of production q_z of ions cm^{-3} was determined from the slopes of the v, z curves. The q_z, z curves are given

in Fig. 2 for $t = 2$ and 3 hours, q_z being in arbitrary units; the numbers written along each curve are the values of v of the atom which became ionized at the ordinate z . It is seen that q_z is greater at heights above 50,000 km than at lower heights. Since v can not go on increasing indefinitely q_z must grow less somewhere and we may assume that q_z reaches a maximum between 50,000 and 80,000 km and falls to low values at greater distances. The foregoing calculations can only be regarded as illustrative, but they serve to show that hypotheses, perhaps not unreasonable ones, of the sort which have been made lead to a rate of ion production which does not fall off rapidly with increasing z and which may even increase with z for a time.

In order to determine the distribution of the high flying ions around the earth it is assumed that the number of fast moving atoms or molecules emitted from each cm^2 of the surface of the high atmosphere in a direction ϕ is proportional to $\cos \phi \cos i$, where ϕ is the angle with the normal to the surface

Fig. 3. Cross section of the zodiacal ion ring in the plane of the earth's equator.

and i is the angle of incidence of the sunlight on the surface. Let q_θ be the total number of fast moving particles emitted from the day hemisphere in a direction at an angle θ with the sun's rays. The relation between q_θ and θ is thus the same as that which expresses the distribution of light reflected from a perfectly diffusing hemisphere or the variation of the intensity of moonlight with the phase of the moon. The relation is

$$q_\theta = q_0(1 + \cos \theta)/2, \quad (2)$$

where q_0 is the value of q_θ for $\theta = 0$. The q_θ, θ curve is a cardioid. In Fig. 3, $abcde$ is a circle around the earth in the plane of the equator with a radius of 50,000 km. From this circle as a base q_θ , calculated from (2), is measured outward and forms the curve ABD . This curve represents the rate of supply of high flying atoms and molecules, and hence of ions, at the high levels in the plane of the equator. Rotating the curve about AK as an axis forms a figure which represents the rate of supply of the high flying ions around the

earth. Although (2) is an approximation, it is exact enough for our purposes. It assumes that the radius of the earth is small compared to 50,000 km, thereby neglecting the earth's shadow and giving values of q_0 greater than zero in the shadow, except for $\theta = 180^\circ$. No ions can be formed in the shadow but ions can get there because some fast flying atoms shoot over the poles of the earth, become ionized and follow along a magnetic line into the shadow.

7. *The ion ring around the earth.* It is assumed that the earth is electrically neutral at all points. Therefore any electric fields which exist are generated by the ions themselves and the motions of the ions at distances beyond several radii of the earth are approximately independent of the rotation of the earth on its axis²³, i.e. are the same whether the earth rotates or not. The centrifugal force due to the motion of the earth in its orbit around the sun is small and is neglected. When the neutral particles are ionized the ions and electrons thus formed are guided by the earth's magnetic field. They fall

Fig. 4. A section in the plane through the center of the earth normal to the sun's rays; kk or $k'k'$ is the zodiacal ion ring.

toward the earth along the magnetic lines of force under gravity and they drift across the magnetic field because of gravity, the positive ions going east and the negative electrons west. Dealing first with their fall we take into account the wobble of the magnetic field with the rotation of the earth. The magnetic axis makes an angle of about 20° with the geographic axis; the fact that the magnetic pole does not pass exactly through the center of the earth is of no consequence in the present discussion. In Fig. 4 PP is the geographic axis, AA is the magnetic axis with its magnetic lines given by curves a and BB is the magnetic axis 12 hours later with its magnetic lines b . The figure is in the plane through the center of the earth normal to the sun's rays. EE marks the plane of the earth's equator, and FF and EE mark the plane of the ecliptic at equinox and solstice, respectively; the angle between EE and FF is 23° . At equinox PP is in the plane of the drawing of Fig. 4, at solstice PP is tilted 23° out from the plane of the drawing.

An ion at c , Fig. 4, with an initial zero velocity component along the magnetic field H , falls under gravity along a number of slightly different curved

²³ Page, Phys. Rev. 33, 823 (1929).

paths depending on the time of day at which it starts to fall. One of the curved paths is given by cde , Fig. 4; the ion reaches e after about a day, and takes roughly a week to fall 20,000 km. Although the general path is cde , the actual path may be a spiral with a radius ρ which depends upon v , the velocity component across H , according to

$$\rho = mv/He. \quad (3)$$

m and e are the mass and charge of the ion, respectively; electromagnetic units are used throughout the paper. At 50,000 km with $v = 10 \text{ km} \cdot \text{sec}^{-1}$ ρ is 50 km for a nitrogen atomic ion, and is less for lighter ions as helium. Therefore ρ is small compared to the distances under consideration and in general the ions move along their paths in relatively tight spirals. An ion at f , Fig. 4, falls along the path fg reaching g in 1 day; an ion at h falls along hi and reaches the earth in less than a day. Thus the speed with which ions leave any level is a minimum on the earth's equator EE and increases rapidly on either side of EE . Since the rate of supply of ions at any level in the plane of Fig. 4 is constant the ion density y at a given level is a maximum at EE and falls off on either side by perhaps an order of magnitude or more at 20° from EE . Further, ions formed at the, say, 30,000 km level will remain there a shorter time than those formed at the 60,000 km level because of the greater gravitational attraction of the earth at the lower levels. This combined with the rate of supply curves of Fig. 2 indicates that the ion density y in the levels below 50,000 km down to perhaps 20,000 km may be much less than from 50,000 to 70,000 km.

Therefore the ions congregate into a ring around the earth lying roughly in the plane of the equator on the daylight side of the earth; on the night side, as is shown in sections 9 and 10, the ring is warped off the equatorial plane approximately into the plane of the ecliptic and is stretched out into a long oval by light pressure and by magnetic gravitational actions. Illustrative equivalent cross-sections of the ring at $\theta = 90^\circ$ are shown by kk , Fig. 4. These are sketched 20° wide and 20,000 km deep, the actual cross-section is perhaps more like $k'k'$, Fig. 4; at $\theta = 0^\circ$ the width is about 70° (section 9).

The total number of ions y_1 in any cross-section of the ring 1 cm thick is equal to $q\theta t$, where t is the time the ions remain there. Since t is a constant with respect to θ we have from (2)

$$y_1 = y_0(1 + \cos \theta)/2, \quad (4)$$

where y_0 is the value of y_1 at $\theta = 0$. An outflow of 10^7 high flying atoms $\text{cm}^{-2} \cdot \text{sec}^{-1}$ from the earth means a supply of 10^5 ions and electrons $\cdot \text{cm}^{-2} \cdot \text{sec}^{-1}$ into the portion of the ring nearest the sun, i.e. $q_0 = 10^5$. If t is ten days or 10^6 sec. there are 10^{11} ions in an average 1 cm^2 column out through the ring. With an equivalent cross section 20,000 km wide and 20,000 km deep the average ion and electron density y is 50, and y_0 is 2×10^{20} . At $\theta = 90^\circ$ $y = 25$ and $y_1 = 10^{20}$. With such low densities there are practically no collisions, for the free path of an ion is 10^{14} cm. The ion densities are so low that it seems doubtful that the presence of the ions and electrons could be detected by experiments

with wireless waves. It also seems doubtful that the diamagnetism²⁴ of the ions has any great effect upon the earth's magnetic field in the zodiacal region, although the field may be distorted to some extent.

It is assumed that ions absorb the solar ultra-violet radiation from $\lambda 900$ to 1000\AA , or an equivalent amount. The energy received at the earth in this spectrum region is $1 \text{ erg} \cdot \text{cm}^{-2} \cdot \text{sec}^{-1}$, as calculated for a quiet sun at 6000 K . Assuming the atomic absorption coefficient β for the radiation to be 10^{-12} , the energy absorbed by the 10^{11} ions is $10^{-1} \text{ erg} \cdot \text{sec}^{-1}$. If 10^{-5} of the absorbed energy is emitted as visible light the ion ring emits $10^{-6} \text{ erg} \cdot \text{cm}^{-2} \cdot \text{sec}^{-1}$, which is the observed value of the zodiacal luminosity (section 3).

8. *Radiation pressure.* The numerical assumptions of section 7 lead at once to a value for the radiation pressure on the zodiacal ions. The force of the radiation on y ions of mass m is $my\dot{p}$, where \dot{p} is the acceleration. If the energy flux of the radiation is I_0 the energy absorbed by the y ions is $I_0\beta y$ and the energy density of the absorbed radiation is $I_0\beta y/c$, where c is the velocity of light. Then $my\dot{p} = I_0\beta y/c$, or

$$\dot{p} = I_0\beta/mc. \quad (5)$$

With $I_0 = 1 \text{ erg} \cdot \text{cm}^{-2} \cdot \text{sec}^{-1}$, $\beta = 10^{-12}$ and $m = 2.3 \times 10^{-23}$ grams, as for a nitrogen atomic ion, \dot{p} is $1.5 \text{ cm} \cdot \text{sec}^{-2}$. For helium and hydrogen atomic ions \dot{p} is 5.2 and $20.8 \text{ cm} \cdot \text{sec}^{-2}$, respectively. The solar gravitational acceleration g_s is $0.6 \text{ cm} \cdot \text{sec}^{-2}$ at the earth. Therefore \dot{p} is greater than g_s by perhaps an order of magnitude. This is keeping with the observed streaming away in the direction of the sun's rays of the particles in comets' tails. The motion indicated that in some cases the radiation repulsion was 12 times the solar gravitational attraction.²⁵

In this paper we do not encounter any ionic velocities so great that the absorption coefficients and radiation pressure are influenced by Doppler effects, as Milne²⁶ found in dealing with stellar atmospheres. We may state without giving the calculations that light pressure and scattering effects calculated from the Rayleigh scattering formula are entirely negligible compared to the absorption and fluorescence processes which we have assumed.

Atomic absorption coefficients of order 10^{-11} or 10^{-12} as assumed in sections 6 and 7 may be too high, although one can not be very sure about it. Various theories²⁷ indicate values of β of order 10^{-15} to 10^{-17} near the heads of the principal series of hydrogenic atoms. Observations²⁸ on the lines and continuous spectrum near the heads of the principal series of the alkali metals give β of the order of 10^{-19} . In the ozone molecular band²⁹ β is 10^{-17} at about 2500\AA , and in the oxygen molecular band β is greater than 10^{-17} at 1500\AA ,

as judged from Lyman's³⁰ spectrograms of the oxygen band. One can not be very certain that these values of β give a correct idea of the order of magnitude of β in the far ultra-violet for the atmospheric atoms, which are probably helium, nitrogen and oxygen. However, in the present case we are not restricted to a definite assumption about β ; we require that the product βI_0 have certain specified values. If β should be less than 10^{-12} we can increase the assumed value of I_0 , which is of course permissible within limits.

9. *The ion ring on the side of the earth near the sun is compressed toward the earth and on the side away from the sun is stretched out to a great distance.* It has been shown⁷ that long free path ions, no matter what their velocities are, under the combined action of gravity and the earth's magnetic field move at right angles to these two vectors with a velocity w given approximately by

$$w = mg \sin \phi / He, \quad (6)$$

the positive ions going eastward and the negative ions and electrons westward. ϕ is the angle between g and H ; w is a maximum at the equator and decreases rapidly at high latitudes. The drift of the ions and electrons constitutes an electric current flowing eastward around the earth if the circuit is complete. If the circuit is not complete electric fields are built up which react on the motion of the ions. At the surface of the earth $w = 4.6 \text{ cm} \cdot \text{sec}^{-1}$ for a singly charged nitrogen atomic ion at the equator, and is $1/26,000$ of this or practically zero, for the electron. The eastward current i , due to the drift velocity w , is $i = y_1 ew$ where y_1 is the total number of ions in a cross-section of the ring 1 cm thick in a plane passing through the earth's axis. Since g and H are proportional to z^{-2} and z^{-3} , respectively, z being the distance to the center of the earth, $w = 4.6z/z_0$, where $z_0 = 6400 \text{ km}$ is the radius of the earth, and $i = 4.6ey_1/z_0$. With $e = 1.59 \times 10^{-20}$

$$i = 1.14 \times 10^{-28} z y_1. \quad (7)$$

We note in passing that this current causes a negligibly small magnetic field at the earth. With $y_1 = 2 \times 10^{20}$ and $z = 50,000 \text{ km}$, i from (7) is 10^3 amperes. The current causes a magnetic field at the earth less than 10^{-5} gauss, which is probably inappreciable.

In order that the zodiacal ion ring be in a steady state the drift current i must be a constant through all cross-sections of the ring. Therefore from (7) zy_1 should be a constant. The values of y_1 are given by (4) and hence

$$z = A/(1 + \cos \theta), \quad (8)$$

where A is a constant. The z, θ curve from (8) is the curve for the steady state and is shown by $c'ba'ed'$, Fig. 3. The branches bc' and ed' meet at infinity. This is wrong; actually they join at a finite distance. The error arises from the fact that (8) is derived through (4) from (2) which gives no ions at $\theta = 180^\circ$. As explained in section 6 there are ions at all values of θ , and hence z in (8) is always finite. Therefore, the branches of the steady state

³⁰ Lyman, *Astrophys. Jr.* 27, 87 (1908).

curve will be something like bc'' and ed'' . The curve is quite different from the circular ring $abcde$ in which the ions are produced. Therefore the ions immediately and continually flow from the circle to distribute themselves in the curve $c''ba'ed''$ although because of radiation pressure they probably never attain this distribution. The process is similar to that worked out³¹ for the ions in the lower atmospheric levels from 100 to 200 km and is as follows:

Suppose that the ring were circular as $abcde$, Fig. 3, and that y_1 were given by (4). i would not be constant around the ring. Due to the drift w positive ions accumulate on the side b of the ring leaving a negative accumulation on side e . This gives rise to an electric field E' from the b to the e side of the ring. E' is in such a direction that, combined with H , it causes the charged particles of both signs to move at right angles to E' and H with a velocity $v' = E'\sin\phi/H$, where ϕ is the angle between E' and H . The movement together with the wobble of the earth's magnetic field (section 7) causes ions in or near the equatorial plane to move away from the sun roughly parallel to the equatorial plane. Thus ions and electrons formed in the region bae , Fig. 3, flow toward $ba'e$. If the ring has an angular width of 20° at $\theta = 90^\circ$ then at a' , i.e. at $\theta = 0$, because of its greater proximity to the earth and its greater supply and less loss of ions than $\theta = 90^\circ$, the ring may have an angular width of as much as 70° , in agreement with the observations of Barnard³ and Newcomb.⁴ Likewise ions and electrons formed at $bcd e$, Fig. 3, stream toward $c''GFd''$ maintaining their concentration in the equatorial plane, the motion being modified by radiation pressure after they get beyond 100,000 km (section 10). The flow or streaming of the ions away from the sun is a maximum at the equator and falls off rapidly at the higher latitudes. Therefore the details of the ion movements brought out here do not disturb the aurora theory⁷ but offer helpful additions to the theory which will be considered in a future paper.

To work out E' and v' exactly throughout the region $BGFD$, Fig. 3, is intricate. Approximate calculations show that the ions and electrons stream away from $BcdD$ about as rapidly as they are produced and that v' becomes less as z increases; beyond $z = 100,000$ km v' is negligible compared with the effects of radiation pressure. An average v' of order 1 km sec^{-1} from $z = 50,000$ km to $100,000$ km is indicated.

10. *Radiation pressure causes the zodiacal ions and electrons to stream away in or near to the plane of the ecliptic.* The accelerations due to the pressure of solar radiation at the earth were estimated in section 9 to be 1.5, 5.2 and $20.8 \text{ cm} \cdot \text{sec}^{-2}$, respectively, for a nitrogen, helium and hydrogen atomic ion; these are also the values of the earth's gravitational accelerations at about 210,000, 96,000 and 45,000 km, respectively. The solar gravitational attraction is just cancelled, or nearly so, by the centrifugal force due to the velocity of the earth in its orbit around the sun and may be neglected. Thus ions and electrons which are formed in the region $bcd e$, Fig. 3, and which move out in

³¹ Hulburt, Phys. Rev. 34, 1167 (1929).

the equatorial plane with velocity v' find themselves subjected to a radiation pressure parallel to the ecliptic plane which beyond, say, $z=100,000$ km is equal to or greater than the earth's gravitational attraction.

In order to find out what happens to these particles we must examine the motion of a neutral ion cloud of finite size in a magnetic field H acted on by a constant force F , F being normal to H . Take H along the X -axis and F along the Y -axis. Then the ions drift along the Z -axis with a velocity F/He , the positive and negative ions going in opposite directions. As a result of the drift a separation of charge occurs which causes an electric field E along Z in such a direction that, combined with H , it causes the ions of both signs to move in the direction of F with a velocity v . The energy acquired from F goes into the kinetic energy η of the ions and the energy ξ of the electric field. At all times $v=E/H$. $\eta=mv^2y/2$ and $\xi=E^2/8\pi c^2$. Therefore $\xi/\eta=2H^2/8\pi c^2my=2.85H^2/y$. With H two or three orders of magnitude less than y , as in the present problem, ξ/η is less than 10^{-4} . Thus the energy taken by the field E is small compared to that of the moving ions. Therefore the ion cloud moves across the magnetic field under the action of the force approximately as it would if there were no magnetic field. This of course can not keep up indefinitely. For, as they recede from the earth the ions reach a region where the magnetic field is so small that the simple formulas used in the foregoing sentences become invalid. Actually the ion progresses along a cycloidal path and $v=E/H$ is approximately the average velocity of progression. The approximation breaks down when the radii ρ , equation 3, of the loops of the cycloid become comparable with the size of the ion cloud. This occurs at about $z=500,000$ km for a radiation pressure acceleration $p=5 \text{ cm}\cdot\text{sec}^{-2}$ and an ion cloud 50,000 km across. At this distance the ions commence to progress away from the sun more slowly than they would if their acceleration were constantly $5 \text{ cm}\cdot\text{sec}^{-2}$, their motion being in large cycloidal loops. At greater distances, beyond 10^6 km, the earth's magnetic field becomes inappreciable, the ion paths straighten out and the ions move away under light pressure.

We now make use of what has been said about the motion of the zodiacal ions and electrons and give some numerical calculations. Ions formed on the day side of the earth for the most part do not drift to the night side. For an ion at a or a' , Fig. 3, hardly stays there more than 10^6 sec (section 7) before falling back to the earth; its drift velocity w is of the order $10^2 \text{ cm}\cdot\text{sec}^{-1}$, and in 10^6 sec it drifts eastward only 1000 km, which does not take it very far around the ion ring. Therefore the ions on the night side of the earth practically all come from those formed in the region bcd , Fig. 3. Consider ions and electrons at b , Fig. 3, at winter solstice; these are at the intersection of the planes of the equator and the ecliptic. Due to the combined effects of a light pressure acceleration $p=5 \text{ cm}\cdot\text{sec}^{-2}$ in the ecliptic plane and an average velocity $v=1 \text{ cm}\cdot\text{sec}^{-1}$ in the equatorial plane out to $z=100,000$ km, and zero beyond this (v' being due to E' which arises from the gravitational magnetic drift w , section 9) the ions move in 3×10^4 sec or 8.3 hr away from the sun to a position about 49,500 km from and 12,000 km south of the ecliptic. After

this v' becomes negligible and the accelerations which act on the ions are p and g , g being the acceleration of the earth's gravitational attraction. In the next 4×10^4 sec or 11.2 hr the ions move away from the sun to z about 400,000 km, at this distance having a velocity around 3 or 4 km·sec⁻¹. The component of the vector $p+g$ toward the line AK , Fig. 3, is about 0.5 cm·sec⁻², and thus the ions progress about 4000 km toward AK . The ions then continue to progress away from the sun with a lessened acceleration until z is perhaps 10^6 km, at the same time they bear in slightly closer to AK . After this the effect of the earth's magnetic field becomes inappreciable and the ions stream away with the full light pressure acceleration p . The earth's shadow has practically no effect on the motion, the ions in the shadow moving along with those in full sunlight. This is because the ions in the shadow are few compared with those in the sunlight, since the cross-section of the shadow is small compared with that of the ion cloud, and because the ions in the

Fig. 5. The zodiacal ion ring at various seasons of the year.

sunlight move by setting up the electric field E , which acts equally on the sunlit and the dark ions.

11. *Comparison of the atmospheric theory of the zodiacal light with observation.* The results of the theory of the zodiacal ions worked out in sections 5 to 10 are represented in Fig. 5. The figure is not drawn to scale. On the daylight side of the earth the zodiacal ion ring is wide and follows the plane of the earth's equator. On the night side the ring is narrow, is warped off the equatorial plane roughly on to the ecliptic plane and trails off to a great distance. Referring to the portions of the zodiacal band at roughly $\theta = 90^\circ$ to 130° from the sun it is seen from Fig. 5 that both the morning and evening zodiacal cones should appear somewhat to the south of the ecliptic near winter solstice and to the north of the ecliptic near summer solstice. Around spring equinox the evening cone should be to the south and the morning cone to the north of the ecliptic, with a reversed position of the cones at autumn equinox. Fig. 6 gives a plot obtained from Jones' observations.⁸ The ordinates are the positions in degrees to the north or south of the ecliptic of

the center of the zodiacal cone for $\theta = 90^\circ$ to 130° at solstice and 70° to 130° at equinox, approximately; the dots and crosses refer to the evening and morning cones, respectively. The course of the dots and crosses is in accord with the theoretical deductions. The dots and crosses are together at the solstices, those at winter solstice being below those at summer solstice; the crosses are above the dots at spring equinox and below the dots at winter equinox. The observations of Cassini⁸ made in 1685 to 1687 are plotted in Fig. 6, the circles being the evening observations and the triangles the morning observations. They agree well with those of Jones, as Jones himself remarked. The magnetic storms, shown by the vertical lines in Fig. 6, are discussed in section 13.

Although the march of the crosses and dots of Fig. 6 is in qualitative agreement with the present theory, there is a quantitative discrepancy. At equinox the morning and evening cones are separated in latitude by

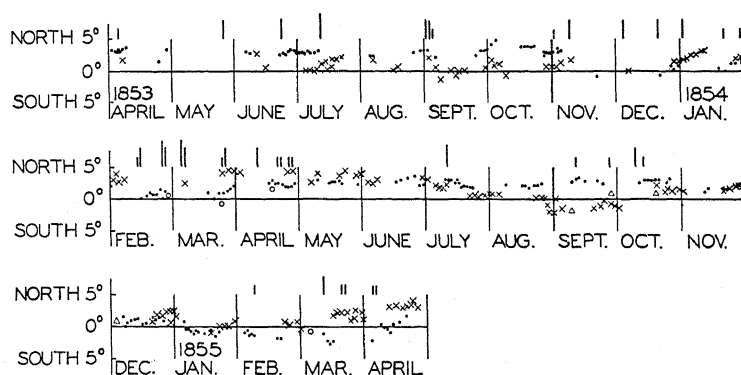

Fig. 6. Positions in degrees to the north or south of the ecliptic of the evening and morning zodiacal cones, shown by dots and crosses, respectively, from the observations of Jones. The observations of Cassini are shown by circles, evening, and triangles, morning.

about 5° , whereas if the cones lie partly along the earth's equatorial plane the separation should perhaps be greater than 5° , but not more than 46° . Whether the discrepancy is serious or whether it will disappear upon further attention to theory or observation can not be said at the present time. On the other hand the north and south shift of the cones of about 5° from winter to summer solstice agrees with the theory. If one plots from Jones' drawings the positions of the apexes of the zodiacal cones to the north or south of the ecliptic the points show the same general trend as those of Fig. 6, but much less pronounced and with many irregularities due no doubt to observational errors. The average deviation of the apexes from the ecliptic is less than 2° . This would be expected on the present view for the apexes of the cones are light from zodiacal ions which are probably more than 100,000 km away.

The dots and crosses of Fig. 6 are on the average about 2° to the north of the ecliptic, whereas one would expect the average over a year to be on the ecliptic. In explanation we follow a suggestion of others⁹ and make use of

the fact that the atmospheric transmission due to haze, etc., decreases toward the horizon. Thus if the ecliptic and the zodiacal cones had a slant, say, to the south of the vertical with the horizon, an observer would place the zodiacal cones too far to the north. Any traces of twilight would accentuate the error, although Jones avoided errors from twilight by making most of his observations after the sun was 18° below the horizon. The correction due to the slant of the cones shifts the points of Fig. 6 generally southward and therefore is qualitatively in the right direction to bring their average close to the ecliptic, without however disturbing the equinox and solstice relations brought out in the last paragraph. In more detail, from April to December, 1854, the zodiacal cones slanted in general to the south; the points of Fig. 6 in this period should therefore all be shifted a degree or so southward. In January, 1855, the ecliptic was nearly vertical and the points need no correction. In February the correction is northward on both dots and crosses, in March is zero for the crosses and slightly northward for the dots, and in the latter part of April is southward again for all the points. Thus we find a simple explanation of the curious fact^{1,2,9} that in general observers in northern and southern latitudes have recorded the zodiacal cones to the north and the south of the ecliptic, respectively. From the foregoing analysis of Jones' observations it seems that it is not the latitude of the observer but the slant of the cones with the horizon that is important.

From Fig. 5 one can see how Jones and other observers sometimes got an apparent negative parallax of the zodiacal cones. At equinox the observer found himself south of the ecliptic in, say, the evening. He recorded the position of the evening cone against the stars. By the rotation of the earth on its axis he was carried to the north of the ecliptic in the morning and recorded the position of the morning cone. Upon comparing the two results he found to his surprise that the zodiacal cone had apparently moved with him from the south to the north of the ecliptic. Thus the parallax came out zero or negative, which is to be expected on the present view because the evening and morning cones are two different portions of a warped zodiacal band.

From the observations of Serpieri, Heis, Weber and others (see reference 9) as well as from those of Jones it seems to be an accepted fact that the zodiacal cones are longer at solstice than at equinox. The present theory does not provide an explanation of this. Qualitatively, at any rate, it does not point with any clearness to marked seasonal variations in the shape of the cones. The theoretical calculations of the motions of the zodiacal ions have been pretty rough and it is possible that many details, and perhaps important ones, have escaped us.

12. *Moon zodiacal light.* Here we have to deal with conclusions so incomprehensible on any theory that we think they are in error. Nor are we the first to think this, for Newcomb¹ commented on Bayldon's¹ observations as follows, "He (Bayldon) also describes the moon as adding to the zodiacal light in her first and last quarters, a result so difficult to explain that it needs confirmation." To give a typical experiment; the observer an hour or two after sunset could see as usual the western zodiacal cone but ordinarily he

could not see the zodiacal band extending across the sky down to the eastern horizon. The moon was about to rise in the east and he thought that he could see the zodiacal band near the eastern horizon. He concluded that this was due to an illumination of the zodiacal particles by the moonlight. However, the intensity of moonlight at the earth is 10^{-6} of that of sunlight and the conclusion would be that the brilliance of the zodiacal cone or band which is barely discernable when illuminated by sunlight is perceptibly increased by light 1,000,000 times weaker. The moon zodiacal light observations were made when the moon was less than 10° , and usually less than 5° , below the horizon. Therefore moon twilight would certainly have interfered with the observations and perhaps moon twilight was all that the observer saw. Jones recorded 13 moon zodiacal light observations and by chance 8 of these were during magnetic storms when the zodiacal light might have been unusually brilliant, because of the solar activity and not because of the moon.

On the present theory the moon, being about 380,000 km from the earth, moves through the zodiacal ions in the region *K*, Fig. 3. At 10,000 km from the center of the moon the acceleration of the moon's gravitation is 5 cm sec^{-2} , which is comparable with the light pressure acceleration. Therefore the moon might sweep a hole through the zodiacal ions probably less than 20,000 km in diameter. The magnetic moment of the moon may be estimated³² to be considerably less than 10^{-2} of that of the earth and the effect of the moon's magnetic field on the ions is probably inappreciable beyond 1000 km from the moon compared to that of light pressure. The hole in the zodiacal ions caused by the moon would be difficult to observe, being wrongly oriented to the terrestrial observer, and being healed quickly by the ion flow would not be expected to give rise to zodiacal or gegenschein variations which could be detected.

13. *Zodiacal light variations and solar outbursts.* The effects of sunlight in producing the zodiacal ions and in stimulating them to emit light, which have been described for a quiet sun, are accentuated during solar outbursts. According to the ultra-violet light theory⁷ of aurorae and magnetic storms the solar outburst is a flare of ultra-violet light. The ultra-violet flare would in general be expected to increase the number of the zodiacal ions and the intensity of their fluorescence. We make no attempt here to enter into a complete discussion of the complicated effects which the flare might produce, but a few simple cases are of interest. The zodiacal ion ring on the day side of the earth might be compressed toward the earth because I_0 is increased and t is decreased during the flare (section 6). Therefore the portion of the ring from $\theta = 0$ to 90° might be widened during a magnetic disturbance. Apparently this is what happened during the latter part of June 1853 according to Jones' observations. The position and shape of the ring on the night side of the earth would not be expected to be greatly changed by the flare. In keeping with this idea the magnetic storms are shown by vertical lines in Fig. 6, and it is seen that the course of the dots and crosses is on the whole undisturbed during the magnetic storms.

³² From equation (12), Gunn, Phys. Rev. 34, 335 (1929).

A flickering of the intensity of the ultra-violet wave-lengths of the flare which cause the fluorescence of the zodiacal ions would cause pulsations in the entire body of the zodiacal light, as are observed. Various types of flares would be expected to occur (see the discussion of an earlier paper³³), in particular, the ionizing wave-lengths might be feeble compared to the fluorescent wave-lengths. This might occur at any time or when the flare was warming up to storm intensity. In the first case there might be zodiacal light changes with no accompanying magnetic storm, and in the second case the zodiacal light variation would be followed by the magnetic storm. Instances of both these possibilities are found in the data of section 2. For example, the zodiacal light fluctuations of November 3, 1929, (section 2) were seen at about 3 A.M. and the magnetic storm began 4 hours later. Similarly, auroral displays and vagaries in the propagation of wireless waves are known³³ to occur before a magnetic storm at times. The Radio Division of this Laboratory has noticed on a few occasions that wireless communication was very unusual several days before a magnetic storm; the storm was actually predicted in advance, the feeling at the time being that the prediction was about as certain as a weather prediction.

14. *The gegenschein.* The ions which stream away from the region *bcde*, Fig. 3, form a sheet mainly in the ecliptic plane extending throughout the region *BGKFD*, which seen edge-on is the zodiacal band. The ion densities are somewhat greater near the boundaries *bc''* and *ed''* of the sheet than in the interior regions. As shown in section 10 the boundaries swing into some extent toward the line *AK*, and at about $z = 0.5 \times 10^6$ km the ions progress more slowly away from the earth until $z = 10^6$ km is reached, whereupon they stream away with the full light pressure acceleration like the particles of a comet's tail. Thus looking end-on at the ion stream the terrestrial observer sees it as a patch of greater luminosity on the zodiacal band. This is the gegenschein. If the cross-section of the stream were 100,000 km in width along the ecliptic and 40,000 km high and if the equivalent optical distance were 10^6 km, the patch would be 6° wide along the ecliptic and 3° high, as seen from the earth, and its parallax as determined by two observers 20,000 km apart would be 1° . These values agree with observation^{5,6}; Barnard⁵ stated that the brighter portion of the gegenschein is about 7° in diameter fading insensibly into the night, the luminosity sometimes being perceptible to a diameter of more than 30° . The present theory of the gegenschein is of course quite different from the meteorite theory of Gylden and of Moulton.³⁴

That the gegenschein may be a comet tail appendage of the terrestrial atmosphere was mentioned long ago by Arrhenius, Evershed and others.¹ Barnard⁵ suggested that the atmosphere surrounding the earth acts as a lens to give a concentration of light somewhere along the line *AK*, Fig. 3. This would make a spot of illumination if there were particles there to be illuminated. Exact calculations are difficult but approximate ones show that the con-

³³ Hulburt, Phys. Rev. 34, 344 (1929).

³⁴ Moulton, "Celestial Mechanics," page 305 (1914).

centration of the light due to the lens, or refraction, effects probably occurs beyond $z = 0.5 \times 10^6$ km and that the concentration is not very great, perhaps about the same as the effects of diffraction. The apex of the cone of the earth's geometrical shadow is at $z = 1.37 \times 10^6$ km.

The present theory gives no clear indication of marked seasonal variations in the appearance of the gegenschein, but Barnard⁵ found that the gegenschein "undergoes singular changes in form and that these changes are periodic with the seasons." To explain Barnard's observations we turn to the magnetic storms. In a time of solar quiescence the gegenschein would be a small spot elongated into the zodiacal band along the ecliptic. During a magnetic storm the spot would be larger for the number of gegenschein ions and their fluorescent light would be increased. From 73 observations extending over 15 years Barnard concluded that the gegenschein was large and round in February, March (especially in the latter part of the month), April, August, September, the first part of October, and November. It was small and elongated along the ecliptic in January, July and the latter part of October. The milky way interfered with observations in June and December, and there were few observations in May. These facts are pictured in Fig. 7.

Fig. 7. Average magnetic character curve and Barnard's observations of the gegenschein for the years from October 1882 to February 1899.

Barnard made the 73 observations of the gegenschein from October 1883 to February 1899. We have added together all the magnetic storms for the first and last halves of each month throughout this period and have plotted the results in the broken curve of Fig. 7. In the addition storms of intensity 1, 2, 3 and 4 counted as 1, 2, 3 and 4, respectively. The curve is a magnetic character curve for the 15 years. It is seen that very roughly the gegenschein was large during epochs of magnetic storms and small during magnetic calm. The magnetic character curve has an ill defined maximum near equinox and a minimum near solstice, and thus has a sort of seasonal period. Fig. 7 can not be regarded as offering convincing evidence of a connection between magnetic storms and changes in the gegenschein. Further evidence would be desirable. It suggests, however, that the seasonal variations in the gegenschein were perhaps due to solar disturbances rather than to the tilt of the earth's axis.

15. *The rate of escape of the earth's atmosphere.* Zodiacal ions and electrons in the region *BDFG*, Fig. 3, which get beyond roughly 100,000 km move away under the solar radiation pressure. They do not come back to the earth. The zodiacal light and the gegenschein are the last fleeting evidences of particles which are leaving the earth never to return. If 1/10 of the high flying atoms

and molecules pass into space *via* the zodiacal band and the gegenschein, there is a loss of 10^6 particles $\cdot \text{cm}^{-2} \cdot \text{sec}^{-1}$ from the atmosphere, or 10^{-6} of the entire atmosphere in 10^6 years. This is, if anything, an under-estimate, but a rate of escape of this amount, or even two or three orders of magnitude greater, seems small and open to no objection on general cosmogonical grounds.

We may go a step farther. Geophysicists³⁵ have found a difficulty in explaining the smallness of the amount of helium, 10^{13} atoms in a 1 cm^2 column, present in the earth's atmosphere. They estimate that the average acid rock sets free helium at the rate of 10^7 atoms of helium per year per gram of rock, and therefore that, say, 100 grams of acid rock per cm^2 would in 10,000 years produce the 10^{13} helium atoms. Thus in the long periods of geological time much more helium would be produced than is found to exist, especially so since no processes are recognized which would remove the helium by absorption back into the crust of the earth. The present theory points a way out of the difficulty in that it suggests that helium may escape from the atmosphere more rapidly than the other gases. For helium atoms, being lighter, will be sprayed away from the earth with greater velocities than the heavier nitrogen or oxygen molecules and atoms. More energy is required to ionize helium than the other gases and hence the helium particles reach much greater distances from the earth before being ionized and swept away by radiation pressure. Therefore, compared with oxygen or nitrogen ions, few of the fast flying helium ions return to the earth, and the rate of escape of the helium into space may be of the same order of magnitude as the rate of supply from the earth.

POLAR MOLECULES, THEIR CONTRIBUTION
TO ENERGY LOSS IN DIELECTRICS

BY F. HAMBURGER, JR.

SCHOOL OF ENGINEERING, JOHNS HOPKINS UNIVERSITY

(Received March 8, 1930)

ABSTRACT

Recently suggestion has been made that even at frequencies as low as those of commercial power circuits the theory of molecular orientation may serve as an explanation of at least a portion of the dielectric energy loss. This paper is an attempt to examine this suggestion on the basis of the Debye theory and the available experimental data. It reaches the following conclusions:

(a) The contribution of molecular orientation to the energy loss at frequencies below ten thousand cycles per second is negligible at the temperatures of zero and ten degrees Centigrade, for glycerine.

(b) For temperatures higher than ten degrees the contribution becomes still smaller and in all probability vanishes.

(c) The probability that any substantial portion of the normal dielectric loss found in the usual insulating oils, at commercial frequencies, may be accounted for on the basis of the Debye theory, is remote.

(d) In order to determine the effect of the dipoles in their contribution to dielectric loss, very accurate determinations of the dielectric constant must be made, especially for those substances that show small changes in dielectric constant with temperature and frequency.

INTRODUCTION

THE principle interest in Debye's theory of polar molecules has centered in its explanation of hitherto anomalous behavior of dielectric constant as related to temperature and frequency, and in the light it has thrown on the groupings within the molecules of compounds and mixtures. Little attention has been given to the necessary energy dissipation associated with the oscillation of polar molecules in an electric field. These losses, in absolute energy values, are relatively unimportant within the luminous range of frequencies although their close interrelation with absorption and anomalous dispersion is well understood. Under certain conditions, however, it is to be expected that an energy maximum will be encountered at some lower frequency. In general these maxima should occur at frequencies which are still relatively high, as related to those pertaining to the electric systems of practice, with the possible exception of those of radio transmission. There is in fact an increasing tendency in the literature of dielectric loss to invoke the frictional oscillation of the Debye polar molecule in explanation of the loss phenomenon. There is some evidence that this may be true, in part at least, within the upper range of radio frequencies. Some authors^{1,2} however

¹ D. W. Kitchin, *Trans. A. I. E. E.* **48**, April (1929).

² D. W. Kitchin, and Hans Müller, *Phys. Rev.* **32**, 979 (1928).

have attempted to extend the application of the theory, in the matter of energy loss, even to the low alternating frequencies of commercial power circuits. This paper is an effort to examine this last proposal from the standpoint of the theory and the available experimental data. It reaches the conclusion that there is little probability that in any of the materials as commonly used for insulation, any appreciable part of the observed dielectric loss is to be accounted for by the oscillation of polar molecules.

In his discussion of anomalous dispersion and absorption Debye³ considers the effects of dipole oscillation in periodic electric fields. He develops the distribution function of the moments and shows that the mean moment of the molecules is a complex number. The meaning of the complex moment is that there is a difference in phase between the moment and the external force. This difference in phase between the field intensity and polarization is accompanied by energy absorption. Since the moment is complex the molar polarization and hence the dielectric constant are complex. The dielectric constant must therefore be of the form

$$\epsilon = \epsilon' - j\epsilon''.$$

This means that in a dielectric under alternating stress, instead of having a current that is 90 degrees ahead of the voltage in phase, we also have a component of current which is in phase with the electromotive force and therefore causes an energy loss. The constant ϵ' is the 90 degree component and is the value that is usually determined by ordinary bridge methods. Considering a condenser in an electric circuit, Debye shows that $\epsilon' = C/C_0$, where C_0 is the capacity of an empty condenser and C is the capacity of the same condenser with a dielectric. The in-phase or loss component is ϵ'' where $\epsilon'' = 1/\omega WC_0$ and we consider the condenser in question as having no losses and having a capacity C shunted by a resistance W . The energy loss may therefore be expressed in terms of the phase defect angle Φ so that $\tan \Phi = \epsilon''/\epsilon'$.

It is natural to expect that under the influence of a periodic electric field the polarized molecules will tend to oscillate following the direction of the field. In a liquid dielectric this rotational motion would take place in a more or less viscous medium and the motion of the dipoles through this medium would be opposed by friction and so lag in phase behind that of the field. Heat would be generated which we observe as energy loss. This energy loss is that which would contribute the phase defect angle mentioned above.

Bearing in mind that the polar oscillation takes place during the period of free motion of kinetic agitation, we must conclude that the variations and losses in question would generally be associated only with frequencies relatively high. The theory however has recently been invoked by Kitchin and Müller to explain the phenomena observed in low frequency fields. Kitchin suggests in fact that the orientation of the molecules in a field of frequency as low as 60 cycles per second may account for at least a portion of the observed energy loss. From the relation of the time interval of molecular orientation with the kinetic activity it would appear that the orientation in a low fre-

³ P. Debye, *Polar Molecules*, The Chemical Catalog Company, 1929.

quency field would be such that there would be no phase difference between the field intensity and the polarization and hence no energy absorption.

METHOD OF ATTACK

As mentioned above the energy loss can be expressed in terms of the phase defect angle, that is,

$$\tan \Phi = \epsilon''/\epsilon'$$

Debye derives the following expressions for ϵ' and ϵ'' ;

$$\epsilon' = \epsilon_0 + \frac{\epsilon_1 - \epsilon_0}{1 + [(\epsilon_1 + 2)/(\epsilon_0 + 2)]\omega^2\tau^2}$$

$$\epsilon'' = (\epsilon_1 - \epsilon_0) \frac{[(\epsilon_1 + 2)/(\epsilon_0 + 2)]\omega\tau}{1 + [(\epsilon_1 + 2)/(\epsilon_0 + 2)]\omega^2\tau^2}$$

In these equations the values ϵ_0 , ϵ_1 and τ are constants for a given material at a given temperature, the value of ω is 2π times the frequency. The quantity τ is known as the relaxation time of the liquid and is the time required for all the molecules to revert to a random state after the removal of the impressed field. The dielectric constant ϵ_0 is the dielectric constant at very high frequency and the constant ϵ_1 is the dielectric constant for zero frequency. It is readily seen that if the constants ϵ_0 , ϵ_1 and τ are known it is possible to calculate from the above two equations the values of ϵ' and ϵ'' , and hence the phase defect angle, for any frequency.

It should be possible to determine these three constants by measuring ϵ' for three different values of ω and solving three simultaneous equations. Therefore from data taken at three frequencies it is possible to calculate, for any frequency, the contribution of molecular orientation to the energy loss in a dielectric. We can therefore show the importance or lack of importance of such a contribution at low frequency.

A search of the literature in an effort to find data that would permit such calculations to be carried out revealed only a meagre amount of suitable material. The data from which the calculations, given below, were made were taken from the work of Mizushima.⁴ On the basis of his observations on glycerine the calculations shown in Table I were made. The table gives the energy loss in terms of power factor.

RESULTS OF CALCULATIONS

The column headed "normal power factor" was calculated as a basis for comparison. This is the power factor due to dielectric constant and resistivity and is approximately the value that would be obtained by the usual bridge measurements at low frequency. The calculation was made on the basis of the following formula,

$$\tan \theta = (18 \times 10^{11}) / (f \epsilon' \rho)$$

In this formula θ is the phase angle, f is the frequency in cycles per second, ϵ' is the dielectric constant and ρ is the resistivity in ohms per cm³.

The results show that for glycerine the dipole contribution to the energy absorption is negligible for frequencies below ten thousand cycles, both for zero and ten degrees Centigrade. Furthermore, at the low frequency of 60 cycles per second their contribution is only three thousandths of one percent, a quantity entirely out of the range of accuracy of ordinary loss measurements. These results are strikingly brought out in Figure 1 where the value of power factor, for glycerine, is plotted against frequency. From Mizushima's data it is immediately apparent that for temperatures above ten degrees Centigrade the effect of the orientation becomes still smaller and certainly vanishes for low frequency.

Table I also gives some results on n-propyl alcohol and shows the small value of the power factor for 60 cycles compared to the high frequency value. The data are for -60°C and no resistivity values being available for this temperature, it was not possible to calculate the "normal power factor." However, it would appear that for temperatures near that of room, where the viscosity of the alcohol would be considerably less than at -60°C , the loss would be considerably less and would probably disappear for 60 cycles.

The paper by Kitchin¹ gives curves of dielectric constant and power factor against temperature for wood resin. The curves given are for 10^7 , 10^6 and 60 cycles per second and the suggestion was made on the basis of these curves and the curves of viscosity and dielectric loss for the same material. It would appear that these three measurements should permit calculation of the dipole

⁴ San-ichiro Mizushima, *Bull. Chem. Soc. Japan* 1, 47, 83, 115, 143, 163 (1928).

contribution. Such a calculation was attempted but was not satisfactory, since the observed changes in dielectric constant were too small. The calculations depend on differences in the value of the dielectric constant and it is thus evident that accurate determinations of that quantity are essential. Furthermore, it was necessary to take the data from the published curves which are not reproduced with sufficient fidelity. This was apparent from the fact that the same curves published in two different papers^{1,2} were not in entire agreement.

Fig. 1. Power factor due to molecular orientation. Glycerine at 0°C and 10° C. (Calculated curve.)

The "normal power factor" calculated as indicated above is probably somewhat smaller than that which would actually be measured since the calculation made on this basis takes no account of energy loss due to the "absorption" that is observed in short time studies of dielectrics. A recent paper by Whitehead⁵ shows beyond doubt that dielectric absorption in certain cases accounts for at least 95 percent of the dielectric loss. Taking this property into account, the dipole contribution would be even smaller than indicated in the last column of Table I, where the dipole contribution is given in percent of the "normal power factor."

EFFECTS IN INSULATING OILS

The suggestion of Kitchin, that the phenomenon of molecular orientation might account for energy absorption at 60 cycles was made with the idea of applying the theory to dielectrics used in commercial insulation. No other data in connection with such insulation are available from which calculations, similar to those made for glycerine, could be made.

So far as the commercial insulating oils are concerned there are certain general facts that enable us to estimate the possible effects of dipole orientation. It is obvious that in order to apply the theory to any liquid dielectric

⁵ J. B. Whitehead, Jour. Frank. Inst. 208, No. 4, October (1929).

the liquid must first of all be polar, that is, possess an electric moment. Probably the most used insulating oil is the well-known "transil" or transformer oil. This oil is a straight chain hydrocarbon and certainly possesses very small polarity, if it has any at all. It is certain that for this particular material dipole orientation plays no part in the energy loss.

As for the other insulating oils, particularly those used in high voltage impregnated paper cables, the lack of fundamental knowledge as to their molecular structure makes it impossible to estimate with any degree of precision the possible effects of orientation. The fact that the dielectric constant of this type of oil is always small, in the range of from say 2 to 3, and the dielectric constant of materials of the nature of glycerine is from ten to twenty times as large indicates that the effect of molecular orientation must necessarily be considerably smaller in such oils than in glycerine. And as we have shown the energy loss due to molecular orientation, at low frequency, is negligible for glycerine; it would seem safe to assume therefore that it should certainly be negligible for the insulating oils.

The author wishes to express his appreciation to Dr. J. B. Whitehead and to Dr. K. F. Herzfeld for their helpful suggestions during the preparation of this paper.

LETTERS TO THE EDITOR

Prompt publication of brief reports of important discoveries in physics may be secured by addressing them to this department. Closing dates for this department are, for the first issue of the month, the twenty-eighth of the preceding month; for the second issue, the thirteenth of the month. The Board of Editors does not hold itself responsible for the opinions expressed by the correspondents.

Possibility of Determining the Energy of the Cosmic β -Particles by Magnetic Deflection

In a recent letter to this section, Tuve¹ has pointed out how the scope of the Bothe and Kolhörster² coincidence method of investigating high-velocity β -particles can be greatly enlarged by making use of multiple coincidences in three or more electron-counting-tubes instead of the usual method of counting coincidences in only two counters. As Tuve has shown, there are two important advantages in this method: (1) a pair of counters can be used to define a beam of β -particles which is subsequently picked up by a third counter after being scattered, deflected by a magnetic field or otherwise experimented upon, and (2) the number of multiple coincidences occurring by chance can be reduced to a much smaller fraction of the true coincidences, making it possible to work with a beam of much smaller angle than can be used with only two counters.

When Tuve's note appeared, the writer had begun an experiment based on exactly these considerations in an attempt to obtain further information on the nature of the cosmic β -particles discovered by Skobelzyn³ and investigated by Bothe and Kolhörster.² It is planned to attempt a magnetic deflection of these particles, for such an experiment would test the possibility that they may be protons as well as give a direct measure of their energy. Definite knowledge of their energy distribution would be of assistance in deciding whether these particles are the actual cosmic rays or are of a secondary nature.

It may be of interest to describe an experimental arrangement, (at present under construction), by means of which it appears feasible to measure the energy of β -particles (or protons) having energy up to the value of 10^9 electron-volts which these particles are estimated to have. A pair of Geiger-Müller⁴

tube-counters will be used to "collimate" a beam of the particles, which are then passed through a region of strong magnetic field and are finally detected by a third counter placed at a suitable distance. By counting the number of particles which produce a triple coincidence in passing through all three counters, and by arranging the third counter to be suitably movable with respect to the axis of the apparatus, it will be possible to measure the deflection of the beam if sufficient deflection can be obtained. Calculation shows that with counting tubes of sufficient area and subtending a large enough solid angle to keep the intensity high enough to be measurable, a very strong magnetic field is necessary. Furthermore, on account of the necessity of using large counters, (our present "collimating" tubes are 4.4 cm in diameter and 27 cm long), this field must be produced over a considerable volume. These difficulties may be overcome by a device suggested by Skobelzyn,³ who points out that magnetic deflection of particles of such enormous penetrating power can be produced by passing them directly through a magnetized iron bar. By this method it will be possible to produce a magnetic induction of about 20,000 over a sufficient volume. The loss of energy of the rays in passing through the 15 cm of iron which will be used is not serious since particles of 10^9 e-volts energy can be expected to experience a loss of only about 12 percent.

² W. Bothe and W. Kolhörster, Zeits. f. Physik 56, 751, (1929).

³ D. Skobelzyn, Zeits. f. Physik 54, 686, (1929).

⁴ H. Geiger and W. Müller, Phys. Zeits. 29, 839, (1928).

A widening of the beam due to straggling in the iron is estimated to be negligible for particles of such high energy. Calculation shows that by choice of suitable geometrical conditions and under the assumption of a magnetic induction of 20,000 over a 15 cm path a deflection equal to the width of the beam (about 8 cm) can be obtained for β -particles with the assumed energy of 10^9 e-volts. A somewhat smaller but still detectable deflection can be expected for protons of the same

energy. Intensity considerations indicate that under these conditions the number of true triple coincidences will be sufficient to be measurable by a few hours of registration and that the number of such coincidences occurring by chance can be reduced to a small fraction of the true ones.

Magnetic Moment of the Sulfur Molecule

It is perhaps an open question as to whether the oxygen molecule is singly or doubly bound. According to Heitler and London the $^3\Sigma$ state indicates a singly bound molecule but Heitler and Herzberg have suggested that the second valence may reside in the exchange degeneracy of the electron orbits without involving the spins.

In the case of the sulfur molecule S_2 the evidence is more definite. Sulfur does not often form double bonds, and the fact that sulfur is a solid at ordinary temperatures and even in the vapor state is largely polymerized, indicates that the S_2 molecule is highly unsaturated. A $^3\Sigma$ state is to be expected.

The magnetic moment of the S_2 molecule has been determined in this laboratory and the prediction is confirmed. Since most of the S_2 molecules are in states of high rotational energy it would not be expected that the field would break the coupling between

the spins and the rotational axis. Under these circumstances only a widening of the molecular beam in the inhomogeneous field would occur and this result has been obtained in the experiments. In some cases however a faint satellite line on the side of the broadened central image has been observed. This line is on the side next the knife edge where the field is strongest. It seems probable that the field is strong enough here to uncouple the spins from the rotational axis in those molecules in the lower rotational states. If this is the case then the line is one of the three to be expected from a $^3\Sigma$ molecule with strong field quantization.

Raman Spectra from Sulfur Dioxide

In view of the increasing interest which is being shown in the spectra of polyatomic molecules, we desire to report the results of some Raman effect measurements on sulfur dioxide. The material used was taken from a commercial tank; it was passed over phosphorus pentoxide to dry it and then condensed in a heavy walled Pyrex glass tube 2 cm in diameter and 20 cm long. During the condensation care was taken to exclude moisture; but no further purification than drying was considered necessary since the commercial product is ordinarily much better than 99 percent pure. When this glass tube was nearly filled with liquid, it was sealed off and subsequently used for the light-scattering experiments.

The Raman spectra were obtained with a mercury arc and the plates calibrated with

* These two lines overlapped on the plates; separate measurement was attempted since one line was much sharper than the other.

an iron arc. The apparatus and method of measurements were substantially the same as previously used in the case of liquid ammonia (Dickinson, Dillon and Rasetti, *Phys. Rev.* **34**, 582 (1929)). The results of the measurements are given in Table I. The frequencies of modified lines in cm^{-1} , given in the first column, are averages obtained from several plates. Reduction of the calibrating wave-lengths to vacuo has been made.

These modified lines show the existence of three shifts with the following average values; 524.3 cm^{-1} , weak (diffuse); 1145.9 cm^{-1} , strong; 1340.1 cm^{-1} , medium (diffuse). The last two of these shifts agree, within the limits of error, with the frequencies of the two

strongest absorptions by gaseous sulfur dioxide found by Coblenz (Carnegie Institute Publication, No. 35, p. 177) in the infrared. The smallest shift lies outside of the range of Coblenz's measurements. It is of interest to recall that such direct agreement between Raman shift and infrared absorption frequency has not been found in the cases of carbon dioxide and carbon disulfide whose molecules have points of similarity with those of sulfur dioxide.

On the Reason for Pauli's Exclusion Principle

It is generally recognized nowadays that physics deals primarily with one aspect of human experience; thus has the philosophical contention of Berkeley and Kant become after a century one of the presuppositions of our science. It was substantially this principle that led Heisenberg, first to his quantum mechanics, and then to the Indetermination Principle.

An interesting attempt has been made by Condon and Mack (*Phys. Rev.* **35**, 579, 1930) to find in the same principle the ground for Pauli's exclusion rule. It is suggested that human beings are themselves in an antisymmetric quantum state and that for this reason we can perceive only those material structures which are likewise in an antisymmetric state; hence, for us, the apparent validity of the exclusion rule. By implication there may exist all round us another set of physical systems in non-antisymmetric states without our being able to perceive them at all; presumably (if I understand correctly) there may also exist another race of humans who are experimenting upon those other systems but who, not being quantum-mechanically antisymmetric, can no more perceive us than we can perceive them.

An adequate proof seems to be lacking, however, that such possibilities are actually contained in quantum mechanics; certainly they are not among the familiar results of the theory. If, for example, an "antisymmetric" atom were to encounter a "symmetric" one under a law of interaction that is symmetrical in the electrons of each, then it follows from "resonance" theory that the

first atom could never bump the second one into an antisymmetric state, nor could the second bump the first into a symmetric state; each atom would retain its initial character. There is, however, no indication that each would simply pass by as if the other were not there at all. The photons emitted by symmetric atoms would also, on current theory, be indistinguishable from photons of the same size emitted by other atoms and so should be observable. Since the same considerations hold for systems of any size, no reason is apparent why an antisymmetric physicist should be unable to perceive at all a symmetric world, or, perceiving it, to form an antisymmetric (?) concept of its symmetry.

The same consideration seems applicable at first sight to Condon and Mack's alternative suggestion that the non-antisymmetric electrons may all have vanished from our ken into Dirac states of negative energy, which for such electrons form a set having no "bottom." It remains to be shown that the endless dropping of these electrons into ever greater depths of the abyss would have no effect upon our instruments. Perhaps they are physically imperceptible just as an electron or photon with infinite positive energy has a zero coefficient of absorption and so is physically non-existent. I hope the authors of the paper will give us an exact mathematical analysis of this point.

Influence of Accelerating Fields on the Photoelectric and Thermionic Work Function of Composite Surfaces.

With an accelerating potential of 22.5 volts, Ives and Olpin (Phys. Rev. **34**, 117, (1929)) found that the long wave-length limit of an alkali metal film on platinum progressed toward the red as the film thickness increased, reached a maximum and then receded when the film was made very thick. Experiments by the writer with a twenty volt accelerating potential confirm this result with the exception that the long wave-length limits observed were more than 1000 Angstrom units farther into the infra-red than those reported by Ives and Olpin. Although there is an optimum film thickness, as pointed out above, when an accelerating field is applied, such is not the case at *zero field*. Lowering the accelerating field causes the optimum thickness to increase until at zero field the long wave-length limit has been observed to change progressively from that of the background metal to that of the alkali metal *without a maximum excursion* and regression.

This investigation has also been carried over into the field of thermionics using a type T thoriated tungsten filament with a small carbon content. With an activation temperature of 1920°K, a test temperature of 1230°K and a test accelerating potential of 20 volts, the thermionic current increased to a maximum of 98×10^{-6} amp. per cm^2 at the end of 90 minutes activation. This time of activation had produced the optimum thickness. With continued activation the thermionic current decreased until at 280 minutes an equilibrium condition was produced with a current of 59.3×10^{-6} amp. per cm^2 . This observation is thus exactly analogous to that reported for the photo-electric effect. Judging by abstract 62 of the forthcoming meeting at Washington this phenomenon has also been

observed by W. H. Brattain who deposited the thorium on tungsten from an external source but made no mention of the importance of the accelerating field. In order to prove that an excess film thickness had caused the decrease in emission described above, the activation temperature was raised and the emission was observed to *increase* with time of activation reaching new equilibrium values for each temperature. At a temperature of 2085°K the rates of evaporation and diffusion were so balanced as to keep the surface covered to just the optimum thickness for maximum thermionic emission which was 98×10^{-6} amp. per cm^2 . Further increase in temperature reduced the thermionic emission indicating that the equilibrium condition of the surface corresponded to a film thickness less than the optimum. Tests with *lower* accelerating potentials showed that the optimum thickness depended on the test potential and moved toward thicker films as the potential was decreased until at practically zero field the maximum emission of 40.5×10^{-6} amp. per cm^2 was attained after 200 minutes of activation at 1920°K and practically no decrease in emission was produced by continued activation. These experiments, showing such close relationships between the thermionic and photoelectric behaviour of thin films, lend support to the theory that the "thermionic" and "photo-electric" electrons in these experiments come from the same family, presumably the "free" electrons.

Capture of Electrons by Alpha-Particles

The important experiments of A. H. Barnes on the above subject reported in the Phys. Rev. for Feb. 1, 1930, render rather interesting the theory of x-ray emission independent of temporary excitation suggested in a recent letter of the writer's in the Phys. Rev., since the latter gives a very simple explanation of the dependence of electron capture on the relative velocity; the result of those experiments.

According to the theory, if the relative velocity is such that relative kinetic energy is $E = h\nu_n$ corresponding to a natural frequency of the alpha-particle, then there is a probability that the electron will penetrate to the n -level, radiate the energy $h\nu_n$ and emerge from the field of the nucleus with a zero relative velocity; the probability of capture is thus equal to that when the initial relative velocity is zero. On the other hand if the

initial relative velocity is not one of the critical values the electron will penetrate to a level n such that $h\nu_n$ is less than the relative kinetic energy, and finally emerge with a finite relative velocity, thus reducing the probability of capture.

On this theory therefore we should expect the energy to be radiated in two separate and independent frequencies, one being governed by the relative velocity of the electron and the alpha-particle, and the other by the probability laws pertaining to the capture of stray electrons.

Further, if this suggestion is true, we should

X-Ray Emission Independent of Temporary Excitation

The usual explanation of Kramer's rule is that only when an incident electron has an incident minimum energy $eV = h\nu_x$ is it able to remove an electron from the X level of an atom; in the subsequent refilling of the level the X -radiation is emitted. Kramers in particular has studied the results of this assumption, and has explained to some extent the intensity distribution of the continuous spectrum by means of the statistics of collision between free electrons and temporarily ionized atoms.

But may we point out that an electron is given, over and above any initial energy, sufficient extra kinetic energy due to the attraction of the nucleus, to remove the X electron at a head-on collision. If the electron impacts are perfectly elastic, then their masses being equal they merely interchange velocity, and the ejected electron eventually emerges with an energy equal to the initial energy of the incident electron. No radiation is emitted. If the impact is not perfectly elastic, then the ejected electron emerges with less energy, and the incident electron, instead of remaining in the X orbit, may be carried out to a level n where $eV > h\nu_n$, and radiation of frequency $\nu_x - \nu_n$ will be emitted when it drops back into the vacant X level. Both these processes can occur even when the

expect that when the relative energy was not a critical value, then there should appear a finite percentage of electrons with a velocity nearly, but not quite, equal to the velocity of the alpha-particles, and independent of the initial velocity of the electron beam, or nearly so. This point could be tested by the first experimental tube of A. H. Barnes, using a magnetic separation of the various particles in the beam emerging from the collision region.

WILLIAM BAND

Yenching University, Peking,
March 15, 1930.

energy $eV < h\nu_x$, contrary to experimental data.

To avoid this dilemma I would propose the following hypothesis. That an incident electron cannot penetrate to the n level of an atom unless (a) that level is vacant, or failing this, (b) the electron has sufficient initial energy $eV = h\nu_n$ to carry it out again into free space after radiating the energy $h\nu_n$ appropriate to the n level. That this energy is automatically emitted whenever an electron penetrates to that level, but that it may be emitted either in the fundamental frequency ν_n or else as a spectrum of frequencies $(\nu_n - \nu_{n+k})$, $(\nu_{n+k} - \nu_{n+k+i})$, etc.

The initial energy of the incident electrons is thus itself directly changed into radiation, and no temporary excitation of the atom is required.

It seems that the experimental facts force us to this position, but although it is an interesting move back towards the classical theory, it is nevertheless obvious that the wave mechanics will be required to give it a satisfactory theoretical basis.

Motion of Positive Ions through Gases

In a previous paper¹ the writer published the results of some experiments on slow moving heavy alkali ions passing through light gases at low pressures. The method used is that of Dempster.² The ions pass through a slit into the space 3 mm wide between the pole pieces of a magnet. The ions move in the

magnetic field in a semi-circular path, passing out through a second slit into a faraday chamber, where they give up their charge to an

¹ R. B. Kennard, Phys. Rev. 31, 423 (1928).

² A. J. Dempster, Phys. Rev. 11, 316 (1918) et seq.

electrometer. From the curves showing the change in electrometer current with changing gas pressure and magnetic field, conclusions were drawn concerning the mean free path, neutralization, scattering, and loss of velocity of the ions in passing through the gas in the system.

Cox³ using the same method with lithium ions passing through mercury gas, questions the possibility of distinguishing between scattering and neutralization. He assumes that the number of ions scattered along the slot between the pole pieces would be negligible compared to the number scattered into the pole pieces and so lost. Scattering would therefore have the same effect as neutralization; that is, at the higher gas pressures there would be a decrease in the peaks of the curves obtained, without a broadening of the base of the curves to both sides. This assumption is valid in the case of light ions in a heavy gas, but it is not necessarily valid for a heavy ion passing through a light gas. In fact a study, based on the kinetic theory, of the space distribution of the once-scattered ions, shows that scattering should have been observed in three of the four cases investigated by the writer.

Cox assumes that in a collision between an ion and a gas atom, the ion rebounds from the atom as from an immovable sphere. This is a legitimate approximation in the case of lithium ions making impacts with mercury atoms, since the mass of the atom is twenty-nine times the mass of the ion. It is however not valid when the mass of the ion is of the same order or greater than the mass of the atom. If M_1 is the mass of the ion and M_2 the mass of the gas atom or molecule, conservation of energy and momenta give for the scattering angle ϕ as a function of the angle of impact θ ,

$$\phi = \cot^{-1} \left[\frac{M_1}{M_2} \csc 2\theta - \cot 2\theta \right], \quad (1)$$

and for the fractional loss of velocity of the ion,

$$\frac{\bar{c}-c}{\bar{c}} = 1 - 1/(\cos \theta + \sin \phi \cot \theta). \quad (2)$$

From Eq. (1) and its derivative, the maximum scattering angle can be found, namely:

³ I. W. Cox, Phys. Rev. 34, 1426 (1929).

$$\phi_{(\max)} = \cot^{-1} \left(\left(\frac{M_1}{M_2} \right)^2 - 1 \right)^{1/2}. \quad (3)$$

The maximum scattering angle for caesium in hydrogen is 51'-46"; for caesium in helium 1°-31'; for sodium in hydrogen 5°; for caesium in argon 17°-10'.

In the apparatus used by the writer the slits were 3×1 mm and the semicircular path from the first to the second slit was 112 mm. The maximum displacement of the once-scattered ions in the plane of the second slit is therefore: for caesium in hydrogen 1.71 mm; caesium in helium 3.4 mm; sodium in hydrogen 9.9 mm, and caesium in argon 35.6 mm.

The statistical distribution of the once-scattered ions in the plane of the second slit is determined by:

- (1) the equation between ϕ and θ ;
- (2) the fact that collisions are equally probable at all points in the path;
- (3) the probability of a collision occurring between θ and $\theta+\Delta\theta$ is given by $p = \sin 2\theta\Delta\theta$;
- (4) In a constant magnetic field, the proportional decrease in the radius of curvature of the path is equal to the proportional decrease in velocity.

When the range of scattering angle is small, due to the large ratio of M_1/M_2 , the pattern produced by the scattered ions cannot be calculated on the assumption that the ions are all scattered on the center line of the stream. By dividing the ion stream into elementary streams and the normal plane at the second slit into elementary areas, the distribution of the ions over the plane of the second slit is given by the summation of the contribution of each of the stream elements to each area element.

A single distribution function involving all the above factors has not as yet been found. However, a close approximation of the distribution of the scattered ions can be obtained by graphic methods. In this manner the proportion of once-scattered ions that will fall on an area 3×1 mm adjacent to the second slit has been determined. It is for caesium in hydrogen 14%; caesium in helium 11%; sodium in hydrogen 6.5%, and caesium in argon 1.6%. When the magnetic field is increased so that the undeviated ions just fail to pass the second slit, the above proportion of once-scattered ions will pass through the

slit and register as current to the electrometer. In all cases but that of caesium in argon this proportion is sufficient to give a measurable current. No current was however observed. The slight evidence for sodium in hydrogen occurs for ions that have had, on an average, many more than one collision.

The failure to find small angle scattering by the method used would indicate that the collisions between the ions and the gas molecules or atoms are not governed by the simple assumption of the kinetic theory. (1) The force between the ion and the molecule may be a function of the distance, as indicated by Cox. This would increase the proportion of ions scattered at very small angles but would not affect the maximum scattering angle. (2) The collisions may not be perfectly elastic, part of the energy being converted into radia-

tion. (3) The collision may involve something analogous to friction, resulting in a spin of either the molecule, the ion, or both.

Further experiments are needed which will determine the distribution in angle of the scattered ions and the loss of velocity for different angles of scattering. From the results of such experiments one may expect more definite information as to what happens when a moving ion comes close enough to a relatively stationary atom or molecule to suffer a change in the direction and magnitude of its velocity.

Certain Effects Accompanying Electron Diffraction

Results on electron diffraction by a copper crystal, for normal incidence on a (100) face, have previously been reported by the writer.¹ With two exceptions, all of the expected diffraction beams which are the x-ray analogues in the two principal azimuths, and in the range below 250 volts were found. In addition, 20 sets of beams were found, 12 of which satisfy the conditions required by a wave of one-half the length given by $\lambda = h/mv$, or by a double grating spacing. It was pointed out that these beams must be due to the structure of the crystal since most of them appear in the (111) azimuth. These beams appeared not to be due to gas. Hendricks² has suggested that these "additional" beams are best accounted for by assuming a simple-cubic surface structure with the dimensions of the face-centered structure, and that those "additional" beams not accounted for by this arrangement may be some which have their maximum development in some minor azimuth closely adjacent to the ones in which observations were made. The structure suggested by Hendricks had previously been considered, but did not appear feasible at that time, since the azimuths of the beams not accounted for by this arrangement had been checked and found to be the same as the azimuths in which observations were made. However, there is still the possibility that the "additional" beams may consist of more than one type and that more

than one hypothesis will be necessary to account for all of them. As Hendricks pointed out, if the simple-cubic structure is present, then reflection from other possible crystal planes, such as (521) should occur. A search for such beams should then be of value in deciding this question.

During the past several months the measurements above described have been repeated for a new crystal made of exceptionally pure copper. The crystal was made by slowly lowering the molten copper, contained in a pure graphite mold, through a temperature gradient in an atmosphere of hydrogen. The results obtained with the second crystal are in accord with those previously obtained with the first crystal. These results were obtained after outgassing the crystal in a high vacuum for many hours at such red-heat temperatures that considerable copper evaporated from the surface of the crystal. Wolf³ has recently obtained results which confirm the above observations. For the second crystal *all* of the expected diffraction beams in the two principal azimuths and in the region below 325 volts have been observed. A search for the

¹ H. E. Farnsworth, *Phys. Rev.* **34**, 679 (1929).

² S. B. Hendricks, *Phys. Rev.* **34**, 1287 (1929).

³ Karl Wolf, Private communication.

(521) beam above referred to showed it to be present, and hence confirms the hypothesis of a simple-cubic structure.

After obtaining the above observations, the second crystal was then heated at temperatures considerably higher than those previously used, in fact, so near the melting point that in about 10 minutes sufficient copper evaporated from the crystal to make the surrounding glass tube practically opaque to visible light. After 30 minutes of heating at this temperature, with one exception, the "additional" beams occupying the positions required by the simple-cubic structure had decreased in intensity to about 10 to 20 percent of their former values so that only the stronger beams were observable. However, further heating for periods of several hours at the higher temperature failed to further decrease the intensity of these stronger beams. (The crystal has been outgassed at various red-heat temperatures for about 35 hours.) It is thus obvious that these "additional" beams are due to a surface structure. Exposing the crystal while red hot to pressures of hydrogen up to 2 mm Hg failed further to decrease the intensity of these "additional" beams. Hence if this surface structure consists of gas, the last traces of it are much more difficult to remove than in the case of a nickel surface, as found by Davisson and Germer.⁴ There is still the possibility that this surface layer is composed of copper atoms, the thickness of which is a function of heat treatment. Very recently the crystal has been exposed to the atmosphere for several days. Then, subsequent to moderate heating at red heat in a vacuum for only a few minutes, it was found to give the same diffraction pattern as originally. With further heating the surface appears to be quickly brought back to its final state, although complete observations on this point have not yet been obtained. This result substantiates the possibility of a gas or oxide layer.

During the course of the above observations certain beams have been found which require a refractive index of unity. A search for other weak beams of this nature reveals a whole series of such beams which accompany the intense diffraction beams as satellites. In many cases these satellites are so close to the main beams that they are not completely resolved, and hence are not observed by the usual method of taking colatitude curves for

various primary voltages. In these cases their presence is detected by varying the primary voltage in small steps, and measuring the current to the Faraday collector, whose angular position is adjusted for the maximum of the beam at each reading, while the total primary current is held constant for the entire set of observations.

In the (100) azimuth the satellites which accompany the 4 first-order beams below 325 volts all occur within 2 volts of the theoretical values for unit refractive index; that of one second-order beam occurs within 11.9 volts; that of the other second-order beam is missing. In the (111) azimuth, the satellites of 3 first-order beams are within 2.7 volts of theoretical values; that of the other first-order beams below 325 volts is within 7.3 volts; those of 2 second-order beams are within 5 volts; that of the other second-order beam is within 19.5 volts; that of 1 third-order beam is within 5 volts. The intensities of the satellites are between 10 and 20 percent of those of the main diffraction beams at the lowest voltages, and decrease to an unmeasurable amount at about 325 volts.

It is significant that with but one exception all of the first-order beams fall well within the observational error of the required value for unit refractive index. For the exceptional case in which the voltage difference is 7.3, it should be pointed out that the voltage of the main beam which the satellite accompanies is also several volts from the expected position, indicating an error of the same sign as that of the satellite, and it is the corresponding beam in the second-order whose satellite differs by 19.5 volts from the theoretical value. The voltage of this second-order main beam is also several volts from the expected position, indicating an error of the same sign as that of the satellite. Satellites of the higher-order beams are less certain, but since the higher-order beams are relatively weak and occur only at the higher voltages, this may perhaps be expected. Although the satellites are not present until after a certain amount of red-heat treatment of the crystal, they were observed previous to the final rigorous heating at temperatures very near the melting point. In fact, at least two of the beams obtained with the first crystal are of this type.

⁴ Davisson and Germer, *Phys. Rev.* 30, 705 (1927).

The satellites are as sharp in voltage and colatitude angle as the main diffraction beams, and are not confined to large colatitude angles. Hence, they are not due to a two-dimensional surface grating. Two possibilities suggest themselves. First: a surface contraction of the crystal lattice. Lennard-Jones and Dent⁵ have computed the contraction of the lattice at the (100) boundary of crystals of the NaCl type. They found that the contraction is confined almost entirely to the top layer, and is only of the order of 5 percent. Further, they obtain a decrease in the interatomic spacing in the surface layer of the order of 5 percent. Thus, on the basis of these computations, the depth contraction would be insufficient to account for the shift of some of the beams, and the decrease in the interatomic spacing in the surface layer would produce a marked displacement of the beams from the plane grating lines on which they are found. In addition, the contraction necessary varies from 17.5 percent for the lowest voltage beams to less than 5 percent for the higher voltage beams, and there is no evident reason why a contraction should be such as to make the apparent refractive index exactly unity. Second: a penetration of the incident electron through several layers of the crystal before its velocity is appreciably altered under the action of the inner potential of the crystal. This view is, of course, contrary to the present conception, and, while it would account for observations similar to the above for a single lattice, there is some uncertainty in explaining on this basis the presence of the above satellites previous to the removal of most of the surface lattice.

Additional observations which, however, appear in accord with this view are the following. Simultaneously with the weakening of the "additional" beams requiring a simple-cubic structure, there appeared a new set of beams on the $\frac{1}{2}$ -order lines in both the (100) and (111) azimuths indicating that the surface layer on the crystal was changing in structure from a single-spaced simple cubic to a double-spaced face-centered cubic. Further, the positions of these latter beams are such as to require a refractive index of approximately

unity while those due to the simple-cubic structure require a refractive index *greater than unity*. There is also a shift in the voltage of the beams due to the simple-cubic structure as their intensity decreases, such as to decrease the refractive index. Observations on the structure formed by the condensation of hydrogen on the crystal show that hydrogen forms in two different lattices depending on the pressure of the hydrogen while the lattice is formed. At small pressures (less than 0.5 mm Hg) a relatively thin double-spaced face-centered structure is formed; at larger pressures (2 mm Hg) a thicker single-spaced simple-cubic structure takes its place. The beams for the first structure require a refractive index of approximately unity while those of the second structure require one *greater than unity*. This second structure is extremely unstable and reverts to the first structure in the course of a few minutes under the bombardment of the low-velocity primary electrons. The presence of hydrogen on the surface does not decrease the intensity of the main diffraction beams as is the case for air.

A careful examination of the observations on the "additional" beams requiring a simple-cubic structure shows in some cases the presence of satellites of these beams requiring a refractive index close to unity.

Taking into account the various types of diffraction beams outlined above, there are still a few very weak beams observed with the first copper crystal which cannot be classified. It was found, however, that during the course of the heat treatment of the second crystal, most of these weak beams disappeared before the decrease in intensity of the "additional" beams requiring a single-spaced simple-cubic structure occurred. They may, therefore, be attributed to a slight trace of some other form of surface structure which was not identified.

Absorption and Emission Spectra in the Region $\lambda 600-1100$.

Lyman discovered the resonance series of helium several years ago. I have repeated his work and in addition have studied the

ultraviolet light emitted by helium, and by helium mixed with other gases. The following is a preliminary report of many new

phenomena observed.

A region, $\lambda 600\text{--}\lambda 1000$, of very strong continuous light has been discovered in helium. This is best observed in a condensed discharge. The short wave-length limit of the continuous source found by Lyman and Schumann is about $\lambda 900$. The new continuous spectrum is the only one known in the region $\lambda 600\text{--}900$. This continuous spectrum is an isolated one, and on this account its second order is also very useful. With this light as a background, absorption bands have been observed in this region. Among these is a new system of bands in hydrogen. The 0-0 band of this system is $\lambda 842$, and the electronic levels concerned in its production are the normal level and a new one 14.7 volts above it. A progression of eight bands have been observed. These new bands are much stronger than the *A-B* and the *A-C* absorption bands previously found by Dieke and Hopfield.

Strong absorption bands in this region have been obtained also in nitrogen and oxygen. I have not yet examined any of these in great detail. There are several scores of them forming perhaps many systems. They are especially interesting for in this region of high frequency one expects to find bands with high electronic quantum numbers, bands concerned with double electronic transitions and possibly even bands of ionized molecules.

An examination of a small part of these spectra shows clearly six bands in a region unmixing with others. They are $\lambda\lambda 722$, 694, 682, 675, 671 and 669. These bands form approximately a Rydberg series. Since they occur in absorption they are probably due to electronic transitions from the normal level, and their limit of convergence, 18.58 volts, is the ionizing potential of the molecule. The form of the series, the spacing of the bands and the experimental conditions all point to helium (He_2) as the source of these bands. From the above measurements the

effective quantum number of the lowest level is 0.853. This is one unit less than the value of the number for the $2S^1\Sigma$ term of helium found by Curtis and others.

The resonance series of the helium atom discovered by Lyman has been extended to nine members which is two more than were observed by him. I have observed the first line self-reversed and lying in what appears to be a strong band several angstroms wide. This resonance line was obtained in five orders and the fourth and fifth orders have been photographed against iron standards. Its wave-length measured in the fifth order is $\lambda 584.358$ I.A. reduced to vacuum. This value is about 0.04A lower than that given by Lyman. The band at $\lambda 600$ was observed under certain conditions, and there have been found also some new emission bands in this region probably due to helium.

In a mixture of helium and hydrogen thirteen members of the Lyman series have been observed. This more than doubles the known length of the series. Two very interesting things are evident from the spectrograms. One is that the Lyman series shows a much smaller intensity gradient when produced in an excess of helium than when produced with only atomic hydrogen present in the discharge tube. The other is that in an excess of helium an anomalous intensity occurs in the line $\lambda 972$ of hydrogen. This line, the third member of the series, is much weaker than the lines near it. It is in fact only as strong as the sixth line. If this anomaly has its source in the four-quantum state of the atom one would expect a similar weakening of H_β of the Balmer series. This phenomenon is now being investigated. If this found to be true in the visible series it would be a parallel to the case of the spectra of *M*-type stars in which H_γ is weaker than H_β .

BOOK REVIEWS

Technische Mechanik. L. FÖPPL, Pp. 189+x, figs. 117. Akademische Verlagsgesellschaft, Leipzig, 1929. Price bound, RM 19.75.

This book constitutes part 2 of mechanics in the "Handbuch der Experimentalphysik," many references being made to A. Hass' "Mechanik der Massenpunkte und der starren Körper" which appeared as part 1.

The text contains an elementary presentation of the simpler problems of applied mechanics, the author's endeavor being to impart to the reader a clear understanding of the principles underlying the subject rather than to furnish him with information alone. Although the treatment is quite elementary, the author uses the calculus freely and introduces scalar and vector products without much explanation of their meaning. The topics treated are statics, kinematics, dynamics of particles, dynamics of groups of particles, dynamics of rigid bodies, impulse, friction, in the order given. The book is exceptionally well illustrated by line drawings and halftones.

LEIGH PAGE

Intermediate Dynamics and Properties of Matter. R. A. HOUSTOUN. Pp. 138, figs. 139. Longmans Green and Co., London, 1929. Price \$1.25.

This text constitutes the first part of a series on Intermediate Physics of which the sections on Heat, Light and Electricity and Magnetism have already been published. Elementary algebra and trigonometry are used, but no calculus. The topics are well selected and clearly treated, although one may object to the time-honored but meaningless definition: "The mass of a body is the quantity of matter in it." A number of simple problems are placed at the end of each of the twelve chapters, and a list of Oxford and Cambridge Schools examination questions together with answers to problems at the end of the book.

LEIGH PAGE

Foundations of Potential Theory. O. D. KELLOGG. Pp. 384+ix. Julius Springer, Berlin, 1929. Price bound RM 21.40.

This excellent treatise on potential theory is based on two courses, one elementary and the other advanced, which the author has given at Harvard. In the first quarter of the book the subject is treated in a fairly elementary manner, with applications to gravitational theory, electrostatics, magnetostatics and the flow of heat. It is, perhaps, unfortunate that the author feels constrained to follow the convention of defining the potential in a gravitational field as the negative of the potential energy per unit mass, as this procedure necessitates a revision of the definition when elements which repel as well as attract are taken into consideration, causing needless confusion on the part of the student as to the proper sign to be used. The author avoids the use of vector notation, writing (X, Y, Z) for the vector whose rectangular components are represented by the three capitals, and employs the notation, grad, div, curl in preference to Gibbs' significant symbols.

The last three-quarters of the book is more mathematical in character. The restrictions on the validity of Gauss' and Stokes' theorems are carefully examined and these theorems are proved under broad conditions, a study is made of Laplace's equation with applications to electrostatics, and the development of functions in series of spherical harmonics and in Fourier series is investigated. The last part of the book is concerned with the establishment of existence theorems, particular attention being paid to the Dirichlet problem and its investigation by the use of integral equations.

Exercises in the form of problems are interspersed through the text, and an index and a brief bibliography are appended. The book should prove very valuable, particularly to those who are interested in the rigorous development of the subject of potential theory.

LEIGH PAGE

Atoms, Molecules, and Quanta. ARTHUR E. RUARK AND HAROLD C. UREY. First edition, 1930. Pp. xvii+765+25 (indices), 6×9 in. McGraw-Hill Book Co., New York, Price \$7.00.

This is the second book of the International Series in Physics, F. K. Richtmeyer, Consulting Editor, which was inaugurated last fall by the "Quantum Mechanics" of Condon and Morse. It bids fair to become the long needed prototype of Sommerfeld's *Atombau* for the English language. Written with a double purpose, the first part (Chap. I–XIV) is intended to satisfy the needs of those who are approaching the study of atomic and molecular structure for the first time, while the latter part attempts to furnish the initiated with an up-to-date account of the theoretical and experimental aspects of quantum mechanics.

The chemical influence of one of the authors is strongly suspected (and approved) by the reviewer in reading the significant statement in the preface, "On the other hand, a very large number of physicists and chemists do not wish to eliminate models from their modes of thought, nor to rely entirely on mathematical connections between their observations. In the past these models have consisted of particles, moving on selected orbits. . . . It is only human nature to construct a new picture of a hidden mechanism as soon as an old one is discarded." It is with this view point that the authors devote the first eleven chapters to a complete discussion of the orbital theory of the atom. After a historical development of the fundamentals of atomic theory, with a careful description of experimental details, a very good chapter entitled "Review of Dynamical Principles" is inserted. This is distinguished by many clarifying illustrative examples. Then follows a consideration of hydrogenic atoms and their spectra. It is to be regretted that the authors have not seen fit to adhere to the Gibbs system of vector notation and have preferred the German. Chapter VI on general theorems of the older quantum theory (such as the correspondence principles, the adiabatic principle and a justification of the Bohr quantum conditions) is a parenthesis interrupting the continuity of the treatment of spectra and would have been better placed in the appendix along with relations between average kinetic and potential energies, quantum integral evaluation, phase and group velocities, mathematical manipulation of functions arising in the wave mechanics, Maxwell's equations, Larmor's theorem, radiation from a moving charge and the relativity transformation. The subsequent chapters then develop spectroscopic theory, the climax occurring in chapter X where the general theory is illustrated by an actual typical multiplet spectrum (Cr). The theory of molecular spectra is expounded in Chapter XII, which comprises some eighty pages. The discussion of this subject is divided into three parts, the first dealing with infrared spectra (18 pages), the second with electronic bands (50 pages) and the last with spectra from polyatomic molecules. The discussion of the spectra of diatomic molecules is quite satisfactory. A paragraph is devoted to the relation between the different systems of nomenclature (five in addition to that of the authors) now in use. The inclusion of polyatomic spectra is especially welcome, as this is the first serious attempt at a critical treatment in any treatise beyond the statement that they are too complicated and that too little is known concerning them. The first or elementary part of this book winds up with a presentation of the present status of critical potential measurements and experiments involving collisions of the second kind.

The second part of the book starts off with a chapter on wave mechanics, followed by its application to hydrogenic atoms. An intelligible chapter is then devoted to an exposition of matrix mechanics, which it seems we must understand in spite of the almost insurmountable difficulties experienced in obtaining important results (without the aid of Schrödinger's method), because of the persistence of theoretical physicists in interjecting surreptitiously into their discussions the phrase, "The matrix components of such and such." A couple of paragraphs are also given of Dirac's formulation of quantum dynamics and his theory of q numbers. The general theory of quantum dynamics is next developed in its relation to Heisenberg's uncertainty principle. The transformation theory of Dirac is also given. Chapter XIX takes up the conditions occasioned by equivalence degeneracy and discusses He, H_2 and H_2^+ and the symmetry properties of diatomic molecules consisting of equivalent nuclei. As most of the material in chapter XX on spectral intensities is derived from classical theory, that involving quantum mechanics being merely quoted without proof, it seems that this chapter is out of place and should have been presented earlier in the first part along with spectroscopy,

perhaps immediately following the chapter on band spectra. The book ends with a presentation of the Davisson and Germer effect, and allied matters.

The authors have not discussed the quantum mechanical aspects of radioactivity, statistics, valence, nor group theory. The book is well illustrated, but tables of data for the use of the experimental worker are rather scarce. This, however, is probably beyond the scope of such a treatise. Although the arrangement in places is not ideal, the wealth of material seems to be well indexed and the book is therefore highly recommended for reference use in clearing up knotty theoretical points.

D. S. VILLARS

Lehrbuch der Chemischen Physik. A. EUCKEN. Pp. xvi and 1037, 250 figures. Akademische Verlagsgesellschaft, m.b.H., Leipzig 1930. Price bound RM 56.

Eucken's book which appeared in its first edition in 1922 with 492 pages, has grown with this third edition into a volume of double the size and has changed its name from a text-book in physical chemistry to a text-book in chemical physics, making the emphasis on the physical side even stronger than it had been in the first edition. A number of features which were characteristic of the first edition have survived. Among them is the general plan which consists in dividing the book into two parts, the first presenting the phenomena from the standpoint of the theory of heat and occupying about 600 pages. The second, under the title "Structure of Matter," occupies the rest.

The first part is divided according to subjects. Each chapter falls then into usually four parts: presentation of the experimental facts, treatment with the method of thermodynamics, explanation with the help of kinetic theory and practical applications. In the whole treatment of the first part it is characteristic that the modern views are introduced rather early. But as a concession to the reader the somewhat crisp statements of the first edition have been elaborated and perhaps from the standpoint of the theoretical physicist lose something of their original precision.

The first chapter is an introduction presenting the first and second law, the general ideas of the kinetic theory, Maxwell's distribution law and even the statistical interpretation of entropy. The Reviewer thinks it a pity that Eucken has relinquished the name of "free energy at constant pressure" for $U - TS + pv$ which he had adopted in his first edition in agreement with Lewis and Randall and has gone back to the historical name introduced by Gibbs.

The following chapters treat ideal gases, then solid bodies. In this latter chapter a rather full treatment of the specific heat of solids is given and accordingly the quantum theory of specific heats is introduced already here. The next chapter on real gases gives more concerning the corrections for the reduction to the ideal gas state than is usual. Chapters on liquids and on the laws concerning the change of state follow in which the empirical relations, the new thermodynamics, kinetic theory and general statistics are discussed very completely. The next chapters deal with the more chemical equilibria, first for ideal gases then for condensed solutions of all types. It is in these chapters and the following where the growth compared with the first edition is largest. Formerly Eucken had referred the reader for these more conventional subjects to other books but since this time even these old-fashioned questions have advanced so much that an extended treatment seems necessary. This applies especially to the theory of strong electrolytes which was almost completely missing in the first German edition, but had been added to the English translation by Jette and La Mer. An almost completely new chapter follows on surface phenomena, dealing with adsorption and the highly important question of surface potentials.

The next three chapters treat of irreversible processes, namely diffusion, electrical phenomena, among which are to be mentioned a treatment of electrokinetics which play such an important part in biology, and finally on chemical kinetics. It is in this last subject that the American reader will feel some gaps. Especially he will be astonished that the name of H. S. Taylor does not occur.

The whole treatment in this first part is admirably suited to teach the subject in its many sides. There are a number of small points where the opinion of the Reviewer differs with that of the author in this as well as in the second part.

The subject of the second part makes the task of the writer particularly difficult, because the more intricate problems of theoretical physics, the theory of line and especially band spectra have gained a large importance for the chemists as the only method of gaining a knowledge of some molecules which can not be prepared in large amounts. Accordingly one must make available to the physico-chemist the methods to analyze spectra without forcing him to go through all the difficult calculations of the theory. In this Eucken has been highly successful.

After an introduction giving the general properties of electrons and nuclei and radioactivity, he treats first the general quantum principles for emission and absorption of energy and then he goes on to describe the characterization of optical and x-ray spectra, including the new quantum theory but without giving too many mathematical details. The Pauli principle leads to the periodic system and a description of the possible spectral terms.

The next chapter deals with the properties of molecules, their spectra, the application to specific heats—the hydrogen problem is included. The calculation of the heat of dissociation concludes this subject. There is then a chapter on optical refraction and polarization in which field the measurement of dipole-moments has given considerable insight into the structure of organic molecules. Finally the nature of the chemical valence is discussed, the unipolar bond is explained according to the new quantum theory (Heitler and London), while for the polar compound the older theory of Kossel is given. The properties of crystals, determination of their structure and the question of the forces holding them together are treated next with mention of the theory of metals at the end.

Summing up, the book is a treatment of the most interesting chapters of physics, written for chemists who have the necessary endurance to master the difficulties which can not be avoided.

KARL F. HERZFELD

Inorganic Chemistry for Colleges. WILLIAM FOSTER. Pp. viii+837. Figs. 212. D. Van Nostrand Company, New York, 1929. Price \$3.90.

Since the author has written this book for students of second year chemistry, the treatment is much more complete and comprehensive than most of the text-books for college chemistry. The author follows a different yet worthwhile arrangement of subject matter, and divides the book into four parts: I. Introduction, II. Non-metals, III. Metals, IV. Supplementary—carbon compounds.

It is in Part I that the greatest departure from standard practice occurs. Following an excellent historical introduction the author considers such fundamentals as the laws of chemical combination, the atomic theory, the gas laws, the kinetic theory, and the internal structure of crystals. These are well presented and very nicely illustrated. Radioactivity and the radioactive elements are then studied in some detail so that an experimental foundation is laid for the study of atomic structure and the classification of the elements. This concludes the first section of the book.

The second part of the book covers in a fairly complete way the chemistry of the non-metallic elements. In addition the subject of solutions follows the chapter on the chemistry of water. Ionization, ionic theory, the properties of acids, bases, and salts as well as oxidation and reduction are also considered in this section which is concluded by a chapter on colloid chemistry. In the work on colloids, the author makes the mistake of using $\mu\mu$ for $m\mu$. This is one of the very few errors in the book. The third section deals with the chemistry of the metallic elements together with a chapter on electrochemistry. As stated by the author, part four is supplementary and may be used or not as the teacher sees fit. It is an introduction to the study of organic chemistry. Ten pages of well chosen problems appear at the end of the book as well as a useful appendix of tables.

The book as a whole is very well written and should prove valuable as a text for second year students. The presentation of radioactivity and atomic structure before consideration of the chemistry of the elements is being advocated more and more by teachers of college chemistry. The author places his book in the forefront of those adopting this style of presentation. The format of the book is good and it is excellently illustrated.

L. H. REYERSON

THE PHYSICAL REVIEW

SPACE-DISTRIBUTION OF X-RAY PHOTOELECTRONS EJECTED FROM THE *K* AND *L* ATOMIC ENERGY-LEVELS

BY CARL D. ANDERSON

CALIFORNIA INSTITUTE OF TECHNOLOGY, PASADENA, CALIFORNIA

(Received April 2, 1930)

ABSTRACT

A C.T.R. Wilson expansion-chamber was used to study the space-distribution of photoelectrons ejected from a gas by monochromatic x-rays. In agreement with Auger, and Watson and Van den Akker a more isotropic space-distribution was found for electrons ejected from the *L* energy-levels than for those ejected from the *K* energy-level. The distribution of the electrons from the *L* energy-levels became less isotropic with an increase in frequency of the incident radiation. For a given radiation, the average forward momentum of the electrons from the *K* energy-level was found to decrease with an increase in the binding energy of the parent atom. Within experimental error, however, for electrons from the *K* energy level, even for different binding energies, the average forward momentum remained the same for a given velocity of ejection of the electron. The average forward momentum of electrons from the *L* energy-level was greater than that for electrons from the *K* energy-level for a given velocity of ejection. The space-distribution of electrons from the *K* energy-level was in fair accord with the recent results of quantum mechanics.

THE longitudinal space-distribution of photoelectrons ejected from a gas by x-rays has been extensively studied by means of the C. T. R. Wilson expansion-chamber by several investigators.^{1,2} The general shape of the distribution curve for electrons ejected from the *K* energy-level and the dependence on the frequency of the incident radiation has been determined, and are in approximate agreement with the recent quantum mechanical expressions.^{3,4,5,6} Results so far published for the space-distribution of electrons ejected from the *L* energy-levels are rather meager. Auger⁷ and Watson and Van den Akker⁸ have shown, however, that a more isotropic

⁸ E. C. Watson and J. A. Van den Akker, Proc. Roy. Soc. A126, 138 (1929).

space-distribution exists in this case. In the present work, the distribution of electrons ejected from the L energy-levels is found to become less isotropic as the frequency of the incident radiation is increased.

The C. T. R. Wilson expansion-chamber employed in this investigation was essentially that described by Simon and Loughridge.^{9,10} Only minor refinements were effected to insure greater accuracy in the data obtained.

Simple filtering of the general radiation obtained from an x-ray tube was found to produce radiation not sufficiently monochromatic so other means of monochromatizing the x-rays were employed. Monochromatism

Fig. 1. Fluorescence radiator as source of monochromatic x-rays.

was insured, in one instance, by the selection of the $K\alpha$ line of molybdenum by means of a calcite crystal spectrometer. For the other frequencies, the secondary fluorescence radiation from a metal plate, irradiated by primary x-rays from a tungsten-target Coolidge type tube, was collimated to a narrow beam and passed into the expansion chamber (Fig. 1). A. H. Compton¹¹ has shown the fluorescence radiation obtained in this manner to be very homogeneous, having 99 percent of its energy in the characteristic K line-radiation of the metal radiator.

The wave-lengths of the x-rays used in this investigation are given in Table I together with the metal radiator employed in three cases.

TABLE I.

Source	Monochromatizer	λ
M ₀ target tube	Calcite spectrometer	0.71 Å
W " "	Silver radiator	0.56 Å
W " "	Palladium radiator	0.59 Å
W " "	Tin radiator	0.49 Å

The relatively faint $K\beta$ lines of palladium were filtered out by means of a ruthenium filter. The presence of the $K\beta$ lines in the other cases was not objectionable.

The longitudinal space-distribution curves, representing the density of emission per unit angle of the photoelectrons as a function of the angle between the direction of ejection and the forward direction of the x-ray beam, were plotted in a number of cases to show the effect of the energy level from

which the electron is taken, and also the effect of a change in the frequency of the incident radiation.

In Figs. 2 and 3 are plotted the results obtained respectively from measurements on 272 tracks in air produced by radiation of 0.71A and on 200 tracks in air produced by radiation of 0.56A. Each small circle represents the number of electrons ejected in a 15° interval the point being plotted at an angle corresponding to the center of the interval. Points are plotted every 5° and therefore represent overlapping intervals.

In order to study the distribution where the binding energy was of appreciable magnitude, C_2H_5Br was introduced into the expansion-chamber in an atmosphere of hydrogen. The photoelectrons were produced by radiation of 0.59A, most of them being ejected from the *K* shell of the bromine

Figs. 2 and 3. Space distribution of photoelectrons ejected from air.

atom. About 64 percent of the energy of the incident radiation was required to remove the electron from the atom, the remaining 36 percent appearing as kinetic energy. The secondary and tertiary photoelectrons could easily be distinguished from one another due to the difference in path length.* Photoelectrons ejected from levels other than the *K* level of bromine or from light atoms could be distinguished by their long path length and hence omitted in the measurements. Thus, only the photoelectrons having their origin in the *K* shell of bromine were included. Fig. 4 represents the distribution curve plotted as before for 233 tracks of electrons ejected from the *K* level of bromine by radiation of 0.59A.¹²

For the study of the distribution of electrons ejected from the *L* energy levels, CH_3I was introduced into the chamber in an atmosphere of hydrogen and photoelectrons produced by radiation of 0.71A and 0.49A emission, being from the *L* levels of iodine. The results of measurements on 200 tracks formed by radiation of 0.71A are shown in Fig. 5. In agreement with the work of Auger the curve is broader than that found for the *K* electrons indicating a

* The ratio of the number of secondary to tertiary photoelectrons was found to be 2.5 in agreement with Auger [Ann. de Physique 6, 229 (1926)] and Wentzel [Zeits. f. Physik 43, 524 (1927)].

¹² C. D. Anderson, Phys. Rev. 34, 547 (1929).

more isotropic distribution. The small circles as before represent the experimental points. Fig. 6 represents the distribution of 264 photoelectrons ejected from the L levels of iodine by radiation of 0.49A. The curve here is narrower

Fig. 4. Space distribution of photoelectrons ejected from K energy-level of bromine.

than in Fig. 5, indicating a decrease in the isotropy of the distribution with an increase in the frequency of the incident radiation. Watson and Van den Akker⁸ have shown that photoelectrons ejected from the L_{11} and L_{111} energy levels have a space-distribution more isotropic than those from the K and L_1 energy levels, and Robinson and Cassie¹³ have found the relative number of

Figs. 5 and 6. Space distribution of photoelectrons ejected from L energy-levels of iodine.

L_1 electrons ejected to increase with an increase in the frequency of the incident radiation. The narrower distribution curve of Fig. 6 may then be explained by the presence of a greater proportion of L_1 electrons than is the case for the curve of Fig. 6.

A theoretical expression derived recently by Wentzel¹⁴ on the basis of quantum mechanics,

$$P(\theta) \propto \frac{\sin^3 \theta}{\left[1 - \frac{v}{c} \cos \theta + \frac{h\nu}{2mc^2}\right]^4} \quad (1)$$

¹³ H. R. Robinson and A. M. Cassie, Proc. Roy. Soc. A113, 296 (1926-27).

¹⁴ G. Wentzel, reference 4.

gives the probability of ejection per unit angle of a photoelectron from the K energy level as a function of the angle, θ , between the direction of ejection and the forward direction of the x-ray beam, where v represents the velocity of ejection, ν the frequency of the incident radiation, and h , m , and c are the customary physical constants.

The solid-line curves of Figs. 2, 3 and 4 represent $P(\theta)$ with the proper values of ν and v inserted, the curves being plotted on a scale to conform to the experimental points. No analogous theoretical expression has as yet been published for the probability of ejection of a photoelectron from the L levels.

The observed asymmetry of the distribution about a plane normal to the x-ray beam may be compared with the theory in several ways.¹⁵ The value of $\cos \theta$ averaged over all the photoelectron tracks, a quantity proportional to the average forward momentum of the photoelectrons may be computed as follows

$$\overline{\cos \theta} = \frac{\int_0^\pi P(\theta) \cos \theta d\theta}{\int_0^\pi P(\theta) d\theta} = \frac{4}{5} \frac{v}{c} + \dots \quad (2)$$

if only first order terms in v/c are retained. The observed and calculated values of the mean of $\cos \theta$ are listed in Table II.

TABLE II.

Energy Level	Gas	λ	$\overline{\cos \theta}$ (obs.)	$\overline{\cos \theta}$ (calc.)
K	Air	0.71 A	0.182	0.210
K	Air	0.56 A	0.210	0.235
K	C_2H_5Br	0.59 A	0.133	0.138
L	CH_3I	0.71 A	0.230	
L	CH_3I	0.49 A	0.255	

The average forward momentum of the K electrons for a given radiation decreases with an increase of the binding energy of the parent atom. Within experimental error, however, K electrons of the same initial velocity have the same average forward momentum. It is to be noted, moreover, that in accord with the results of Auger and Watson and Van den Akker for a given velocity of ejection, the L electrons have an average forward momentum greater than that of the K electrons. The difference in behavior of the K and L electrons is more marked for the lower frequencies of incident radiation. The asymmetry to be expected on theoretical grounds for the L electrons has not as yet been brought to light.

The bi-partition angle, θ_b , the half-angle at the apex of a cone which divides the photoelectrons into two groups of equal numbers, is defined by Eq. (3). Calculation of $\cos \theta_b$ shows it to be equal to v/c to a first approximation. The experimental and calculated values of $\cos \theta_b$ are given in Table III.

¹⁵ Williams, Nuttall and Barlow, reference 1.

$$\int_0^{\theta_b} P(\theta) d\theta = \int_{\theta_b}^{\pi} P(\theta) d\theta. \quad (3)$$

TABLE III.

Energy Level	Gas	λ	$\cos \theta_b$ (obs.)	$\cos \theta_b$ (calc.)
<i>K</i>	Air	0.71 A	0.242	0.262
<i>K</i>	Air	0.56 A	0.292	0.294
<i>K</i>	C ₂ H ₅ Br	0.59 A	0.191	0.173
<i>L</i>	CH ₃ I	0.71 A	0.174	
<i>L</i>	CH ₃ I	0.49 A	0.242	

For a given value of v/c the bi-partition angle for electrons ejected from the *L* energy-levels seems to occur nearer 90° than for those from the *K* energy-level, in agreement with the conclusions of Auger.^{2,7}

The ratio, of the number of electrons ejected forward of the plane normal to the x-ray beam, to the number ejected backward, ρ , is given by Eq. (4):

$$\rho = \frac{\int_0^{\pi/2} P(\theta) d\theta}{\int_{\pi/2}^{\pi} P(\theta) d\theta} = \frac{2 + 3 \frac{v}{c}}{2 - 3 \frac{v}{c}} + \dots \quad (4)$$

The observed and calculated values of ρ are given in Table IV.

It is to be noted that no marked difference was found in the behavior of ρ for the *K* and *L* electrons.

TABLE IV.

Energy Level	Gas	λ	ρ (obs.)	ρ (calc.)
<i>K</i>	Air	0.71 A	2.17	2.30
<i>K</i>	Air	0.56 A	2.39	2.58
<i>K</i>	C ₂ H ₅ Br	0.59 A	1.74	1.70
<i>L</i>	CH ₃ I	0.71 A	2.00	
<i>L</i>	CH ₃ I	0.49 A	2.30	

In conclusion I wish to express my gratitude to Professor R. A. Millikan and Professor E. C. Watson for their interest in this work.

Note added in proof:

Since this article was written, G. Schur [Ann. d. Physik, 4, 441, (1930)] has published a theoretical expression for the space-distribution of photo-electrons ejected from the *L* energy-levels of an atom. For the longitudinal space-distribution he finds,

$$P(\theta) \propto \sin^3 \theta + \frac{4\nu}{c} \sin^3 \theta \cos \theta \left(1 - \frac{I_L}{h\nu} \right) + \frac{I_L \sin \theta}{h\nu + 3I_L} \left\{ 1 + \frac{8I_L}{h\nu} \sin^2 \theta + \frac{2\nu}{c} \cos \theta \left(1 + 2 \sin^2 \theta \left(1 + \frac{11I_L}{h\nu} \right) \right) \right\} \quad (5)$$

where I_L represents the mean value of the binding energy of the L energy-levels, and the other quantities remain as defined above.

Calculation of the average value of $\cos \theta$ for L electrons, in the manner carried out above for K electrons, leads to the following results:

TABLE V.

Energy level	Gas	λ	$\overline{\cos \theta}$ (obs.)	$\overline{\cos \theta}$ (calc.)
L	CH_3I	0.71 A	.23	.17
L	CH_3I	0.49 A	.25	.22

The agreement here is not satisfactory, the observations seeming to indicate a greater average forward momentum of the photoelectrons than the theory.

Calculation of ρ , defined as above, leads to the following results:

TABLE VI.

Energy level	Gas	λ	ρ (obs.)	ρ (calc.)
L	CH_3I	0.71 A	2.0	1.9
L	CH_3I	0.49 A	2.3	2.4

With regard to ρ , experiment and theory are in fair accord.

A decrease in the isotropy of the space-distribution curve for L electrons, with an increase in the frequency of the incident radiation, as was found above, is also to be expected from the theory. The ratio of the number of L_{II} and L_{III} electrons to the L_I electrons is given by

$$\frac{L_{II} + L_{III}}{L_I} = \frac{I_L}{h\nu + 3I_L} \left(3 + 8 \frac{I_L}{h\nu} \right) \quad (6)$$

which for this case, leads to:

TABLE VII.

Energy level	Gas	λ	Relative proportion of	
			L_I Electrons	L_{II} and L_{III} Electrons
L	CH_3I	0.71 A	67%	33%
L	CH_3I	0.49 A	72%	28%

For the harder radiation then, due to the greater proportion of L_I electrons ejected, a slightly less isotropic distribution is to be expected.

HYPERFINE STRUCTURE IN NEUTRAL MANGANESE, $Mn I$.

By H. E. WHITE* AND R. RITSCHL

PHYSIKALISCH-TECHNISCHE REICHSANSTALT, BERLIN

(Received March 5, 1930)

ABSTRACT

Observations. The hyperfine structure patterns of some 30 or 40 lines in the spectrum of $Mn I$ have been photographed by means of a prism spectrograph and silvered Fabry-Perot etalons. A tube, designed by Schüler, and operated at liquid air temperatures, has been used as a light source for most of the lines and a king vacuum furnace for the others. Patterns of from 2 to 6 components are found, some degrading in intensity and intervals toward low frequencies and others toward higher frequencies.

Interpretation. The strictly LS coupling in the well-known multiplet structure of $Mn I$, and Ji coupling in the hyperfine structure enable vector diagrams to be drawn for the space quantization of each valence electron with respect to the nucleus. Some of the hyperfine structure terms are computed directly from observed term differences while others are computed from the observed diagonal components. The normal state ${}^6S_{5/2}(3d^5 4s^2)$ is found to be quite narrow, whereas the metastable ${}^6D(3d^5 4s)$ terms show the widest separations. While the hyperfine structure intervals for any given term are proportional to $\cos(Ji)$, the total separations are approximately determined by $\cos(Si)$, the l values of the electrons contributing but very little.

Theoretical computations. A study of the vector diagrams for the different multiplet terms shows quite definitely that while the hyperfine structure is determined primarily by the coupling between the $4s$ electron and the nucleus, the remaining valence electrons must also be taken into account. The hyperfine structure formula given by Goudsmit and Bacher for the interaction between an s electron spin and the nuclear spin is extended so as to include not only the spins of all of the valence electrons but their l values as well. From the derived general formula and the observed hyperfine structure term separations, coupling constants to be associated with each electron have been computed. While the energy of interaction between electron spin s and nuclear spin i is given by $ais \cos(is)$ the energy of interaction between electron l value and nuclear spin i is given by $a'il \cos(il)$.

THE hyperfine structure in the spectral lines of neutral manganese was investigated in this laboratory by Janicki¹ some twenty years ago and later verified by Wali-Mohammed.² An analysis of the gross or multiplet structure of $Mn I$ was first given by Catalan,³ some of the terms being later assigned to definite electron configurations by Hund.⁴ A more complete analysis of the gross structure has been given by Russell⁵ and by McLennan,

⁵ Russell, Astrophys. J. 66, 184 (1927).

McLay and Crawford.⁶ Since the *hfs*⁷ of many of the lines is observed to have the same general appearance as that found in a number of other elements (for example, praseodymium, lanthanum, iodine, and bromine) it was hoped that an analysis of the *hfs*, at the expense of the well-known *gs*, would not only verify the interpretation of *hfs* given previously by one of the authors,⁸ but at the same time to lead to some conclusions concerning *hfs* in general.

APPARATUS AND MEASUREMENTS

A Zeiss three-prism constant deviation spectrograph, with a large glass optical system specially constructed for fine-structure work, was used in conjunction with quartz Fabry-Perot etalons for photographing the *hfs*. In order to eliminate self-reversal of resonance lines and at the same time to

Fig. 1. Term scheme of neutral manganese, Mn I.

produce very sharp lines, a metal discharge tube, operated at liquid air temperatures, has been used. Prior to publication, the design and operation of this tube was very kindly submitted to the authors by Dr. Schüler.⁹ The manganese lines were excited in a discharge of argon by placing small pieces

of manganese metal in the tube, the discharge itself taking place in a small cylinder, 2 cm long and 1 cm in diameter, working as a Paschen hollow cathode, in the bottom of the tube. The light from the discharge was reflected into a horizontal position by a plane mirror and then brought to focus on the slit of the spectrograph. With a current of 100 to 200 m.a. at about 2500 volts d.c., exposure times at 4000Å ranged from 1 to 5 minutes. In the absence of hydrogen, and at the right pressure, the manganese lines were stronger than those of argon. With silvered quartz mirrors, separated by invar rings 5, 7.5, 10, 12, and 15 mm in thickness, placed between the collimating lens and the prisms, a resolving power of nearly one million at 4000Å has been obtained. The mirrors were silvered in vacuum by evaporation from electrically heated silver filaments, a method developed previously by one of the authors.¹⁰ While the lines photographed have the same appearance as those found in praseodymium,¹¹ they are in general about one-fifth to one tenth as wide and vary in number from one to six components.

An energy level diagram of Mn I is given in Fig. 1. Each *gs*-multiplet, for which the *hfs* has been studied, is shown by a transition arrow and assigned a number for reference in Tables I and II. All of the lines except those in multiplets numbered six and seven, have been photographed with the light source at liquid air temperatures, thus enabling the *hfs* $\Delta\lambda$'s in Tables I and II to be given to four decimal places. The last two multiplets, numbers six and

seven, were photographed using as a light source a King vacuum furnace operated at about 2000°C. Fortunately these two multiplets show the widest *hfs* in Mn I, thus making it possible to resolve some of the patterns at this temperature. The manganese lines were brought out much stronger than is usually obtained from such a furnace by applying a potential of 120 volts d.c. between a small anode and the heating element of the furnace.¹² The anode is

¹⁰ Ritschl, Verhand. d. Deutsch. Phys. Ges. (3), 10, 33 (1929).

¹² Schüller, Zeits. f. Physik 37, 728 (1926).

here placed coaxial with and extends half way through the heated graphite tube of the furnace.¹⁰ Since the relative intensities of the components in each pattern are always found to decrease regularly toward longer or shorter wave-lengths, the wave-length and frequency number of only the strongest component in each pattern is given in column three. The wave-lengths and frequency numbers of the other components may be obtained by adding or subtracting, as the case may be, the $\Delta\lambda$'s and $\Delta\nu$'s given in columns four, five, six, seven and eight. Where only the first two, three, or four components of a group are resolved, the end of the group has been measured. The total

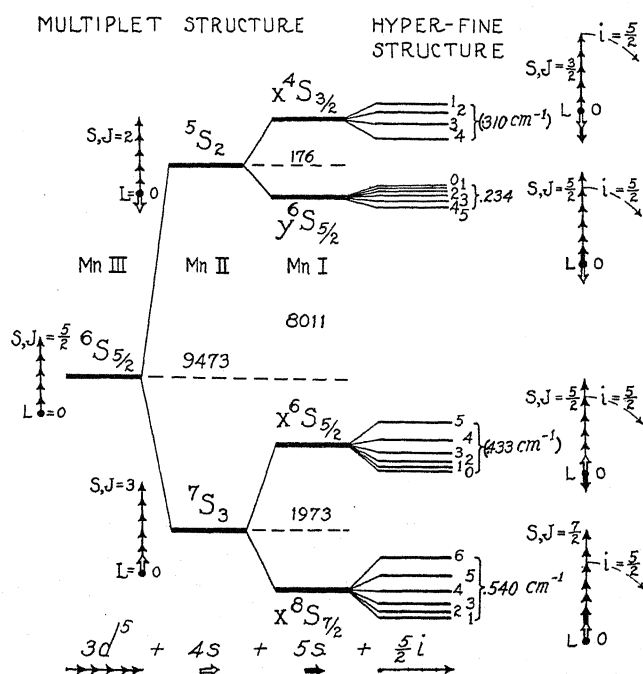

Fig. 2. Hyperfine structure terms and space quantization vectors for the electron configuration $3d^5 4s 5s$.

width of each pattern is given in the last column. In general the measurements given by Janicki¹ are in good agreement with those in Tables I and II. The additional component which Janicki found on the short wave-length side of $\lambda\lambda 4030, 4033$ and 4034 is very probably a self-reversal effect of each hfs -component, and, is not found on any of our plates. At liquid air temperatures very sharp and well-resolved patterns of these three lines have been photographed. As reported by Janicki, $\lambda\lambda 6021, 6016$, and 6013 appear sharp. Although these lines are quite strongly excited at liquid air temperatures and are visually seen to be quite narrow, they have not been photographed due to the extremely long exposures necessary at this wave-length.

Owing to an early mistake in the width of an etalon ring, the computations reported in a brief note, "Letters to the Editor" in the Physical Review,¹³ are

¹³ White and Ritschl, Phys. Rev. 35, 208 (1930).

in error. The $\Delta\lambda$'s and $\Delta\nu$'s for the two lines there given may be corrected by multiplying by a factor of 1.25.

THE COMPUTATION AND INTERPRETATION OF THE *HFS*-TERM SEPARATIONS

There are two distinct and characteristic systems of multiplet terms in the arc spectrum of manganese, as may be seen from Fig. 1; (a) a system of *normal* multiplet terms built upon the 5S and 7S ($3d^54s$) terms of Mn II, which in turn are built upon the 6S ($3d^6$) term of Mn III, and (b) a system of inverted multiplet terms built upon the inverted 5D ($3d^6$) term of Mn II. It has been indicated previously⁸ that the *hfs* of manganese is in good agreement with the

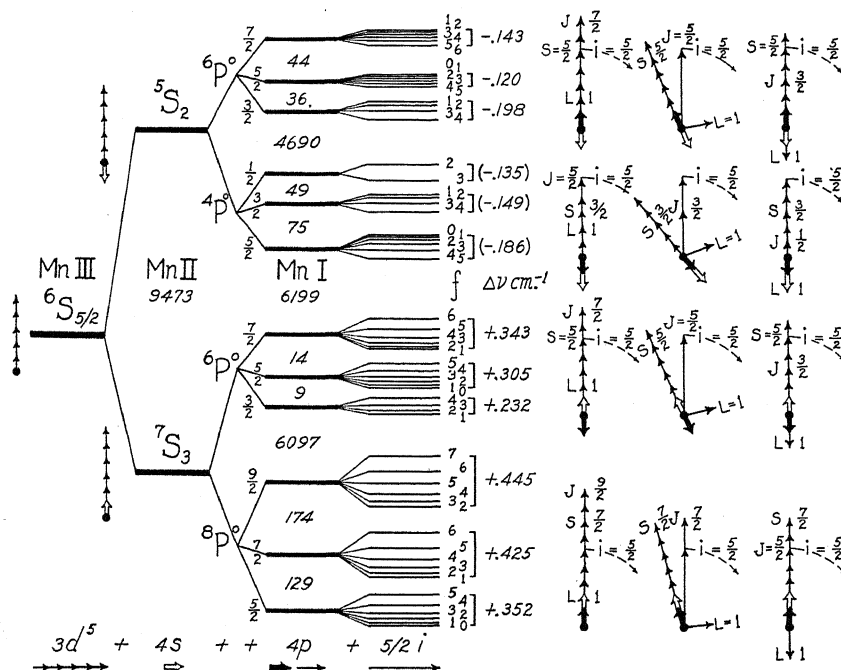

Fig. 3. Multiplet structure terms, *hfs*-terms, and space quantization vectors for the electron configuration $3d^5 4s 4p$.

interpretation of *hfs* in other elements. Here in manganese, as in many other elements, the deep penetrating and tightly bound *s* electron is found to play an important role. The coupling of a *4s* electron with the resultant of six other valence electrons is observed to give the widest *gs*-separations while its strong coupling with the nucleus gives rise to the widest *hfs*-separations. Fortunately, *LS* coupling in the *gs* and *Ji* coupling in the *hfs* is quite rigidly held to, thus enabling vector diagrams for the space quantization of the *s* and *l* values for each valence electron to be quite accurately drawn. It has also been previously shown⁸ that the total *hfs*-separation of a *gs*-term should be approximately proportional to $\cos(is)$, where *s* is the spin of the deeply penetrating and tightly bound *s* electron, and *i* is the nuclear spin momentum. Since this proportionality is taken for the vector position $\cos(Ji) = 1$, where

$\cos(is) = \cos(Js)$, it may be stated that for each gs -term where $\cos(Js)$ is *positive*, the hfs -terms are *normal*, and where $\cos(Js)$ is *negative* the hfs -terms are *inverted*.

At the left in Fig. 2 the building up of the x^4S , x^6S , y^6S , and x^8S ($3d^54s5s$) terms of Mn I is shown starting with the parent term 6S ($3d^5$) of Mn III. This is done in order to show the direction taken on by the spins of the $4s$ and $5s$ electrons in each gs -term and to show the shift in energy due to the inversion (with respect to the electron resultant J) of either the $4s$ or $5s$ electron. At the right in Fig. 2, it may be seen that when the $4s$ electron spin is parallel with J , $\cos(Js_{4s})$ positive, the hfs -terms are *normal*, and when oppositely directed, $\cos(Js_{4s})$ negative, the hfs -terms are *inverted*. Space quantization of i with J and s is only shown for the position of largest f value.

Fig. 4. Hyperfine structure terms and space quantization vectors for the electron configuration $3d^5 4s$.

The building up of the a^4P^0 , a^6P^0 , b^6P^0 , and a^8P^0 ($3d^5 4s 4p$) terms in Fig. 3 is quite similar to that of the x^4S , x^6S , y^6S and x^8S terms in Fig. 2. The addition of a $4p$ electron, with quantum number $s = \frac{1}{2}$ and $l = 1$, in place of a $5s$ electron, with $s = \frac{1}{2}$ and $l = 0$, however, splits both 5S and 7S ($3d^5 4s$) of Mn II into six levels in place of two. The vector diagrams for each level are given at the right in Fig. 3. For each gs -level of a^4P^0 and b^6P^0 , $\cos(Js_{4s})$ negative, the hfs -terms are *inverted*, whereas, for a^6P^0 and a^8P^0 , $\cos(Js_{4s})$ positive, the hfs -terms are *normal*.

Starting with the inverted 5D ($3d^5$) term of Mn II at the left in Fig. 4, the addition of a $4s$ electron splits each level into two levels resulting in the *inverted* multiplet terms a^4D and a^6D ($3d^5 4s$). Here again for $\cos(Js_{4s})$ negative, the hfs -terms are *inverted*, while for $\cos(Js_{4s})$ positive they are *normal*.

The stepwise inversion of the *hfs* in the four terms of a^4D follows directly from the stepwise change from positive $\cos(Js_{4s})$ in $a^4D_{3/2}$ to negative $\cos(Js_{4s})$ in $a^4D_{5/2}$.

Each spectral line in manganese is in reality a tiny multiplet. Several characteristic types of these *hfs*-multiplets are shown in Figs. 5 and 6. A new Zeiss microphotometer, having variable magnification, has been used to obtain density curves from the best plates, copies of which are shown at the bottom of the figures. From the total width of lines of the type shown in Fig. 5, it is obvious why only the *diagonal* lines have been resolved and measured. The intervals between the *diagonal* lines give only the difference between the

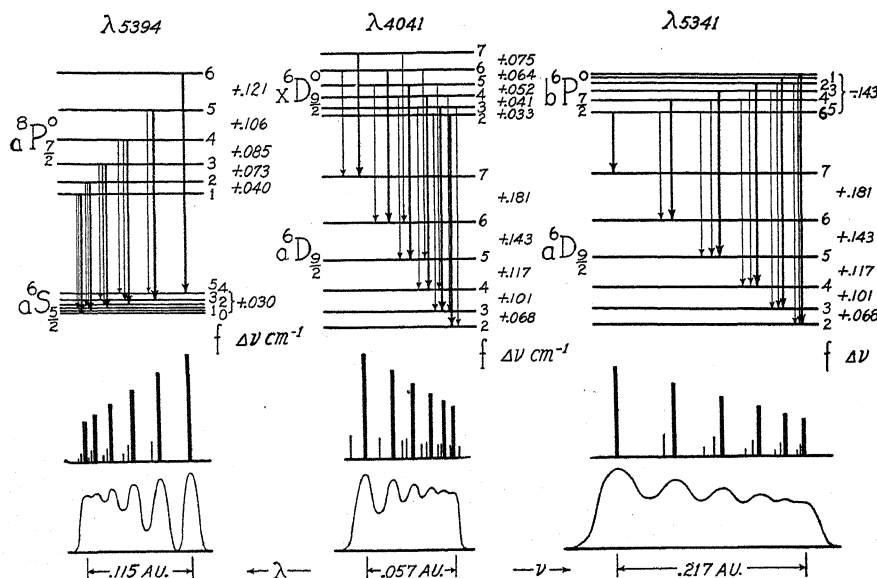

Fig. 5. Hyperfine structure patterns in neutral manganese. $\lambda\lambda 5394$ and 4041 taken at liquid air temperatures and $\lambda 5341$ taken from a vacuum furnace.

set of levels above and the set below. It should here be pointed out that the total width of $\lambda 4041$ is only 0.057\AA . It was hoped, therefore, in a wide pattern of lines like $\lambda 5341$, Fig. 5, that the *off diagonal*, or faint lines, could be observed. Since the *gs*-multiplet to which this line belongs was so weakly excited in the Schüller tube, and at the same time lies in a region of the spectrum where photographic plates are rather insensitive, the vacuum furnace was resorted to. The only trace of the *off diagonal*, or faint lines, in any of the *hfs*-multiplets has been found in the lines $a^8P^0_{4\frac{1}{2}, 3\frac{1}{2}, 2\frac{1}{2}}, -x^8S_{3\frac{1}{2}}$. All three lines of this *gs*-multiplet, $\lambda\lambda 4823, 4783$, and 4754 , are shown in Fig. 6. Even though the extremely narrow patterns of these lines have not been completely resolved, their interpretation is quite unambiguous since their general appearance verifies the order and magnitude of the *hfs*-term separations of a^8P^0 and x^8S arrived at from other considerations. What has actually been measured is indicated at the bottom of the figure. The five *off diagonal* lines on the low frequency side of $\lambda 4783$ fortunately fall almost together and can be

measured as a single strong component. With the measured separations between this component and the first two diagonal components and, making the valid assumption that the Landé interval rule is in operation, the x^8S , and in turn the a^8P^0 , hfs -term separations can be approximately computed. With this as a start, the total separation of the normal state $^6S_{5/2}$ ($3d^54s^2$) is determined from the two resonance lines $\lambda\lambda 5394$ and 5432 to be about 0.030 cm^{-1} . The separations for $a^6P^0_{3/2, 2/2, 1/2}$ are then determined from $\lambda\lambda 4030$, 4033 , and 4034 . While the hfs -patterns of $^6D-^6D^0$ and $^4D-^4D^0$ ($3d^64s-3d^64p$)

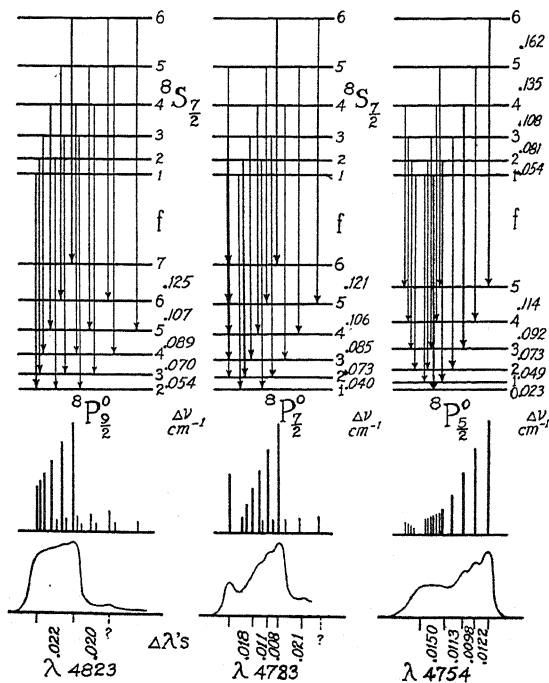

Fig. 6. Very narrow hyperfine structure patterns in the octet system of manganese taken at liquid air temperatures.

have been obtained at liquid air temperatures, none of them resolve the *off diagonal* components that must certainly be there. From the measured differences between the different patterns of a multiplet, however, a clue to the hfs -separations is obtained. The successive differences, for example, between the $\Delta\nu$'s of $\lambda\lambda 4018$, 4055 and 4083 as compared with the successive differences between the $\Delta\nu$'s of $\lambda\lambda 4079$, 4055 and 4035 show that the a^6D ($3d^64s$) separations are about two and one-half times as wide as those of x^6D^0 ($3d^64p$). Even though relations of this kind can only give, at best, an approximation to the true separations, it has been necessary to use such relations to compute the separations for a^6D , b^6P^0 , a^4D , x^6D^0 and x^4D^0 . The gs -terms and hfs -term intervals are given in Table III.

THEORETICAL INTERPRETATION

It has quite generally been observed that the widest hfs -separations are due to the strong coupling between the spin of a single s electron and the nu-

clear spin i , and also that the observed intervals follow the Landé interval rule. Since the classical quantum mechanics have yielded interval rules which agree so well with observations in *gs*-multiplets, Goudsmit and Bacher¹⁴ have extended them to some of the simpler cases in *hfs*. The Landé interval rule for separations between two states f and $(f+1)$ is, as in *gs*, given by $\Delta\nu = A(f+1)$, where f is the resultant of i and J , and A is an observed proportionality constant. The total separation of a multiplet term is given by

$$\Delta\nu = mA \quad (1)$$

where $m = \sum f$'s minus the smallest f .

Assuming the cosine law for the interaction energy of any two electronic angular momentum vectors, the energy of interaction between an s electron spin and the nuclear spin, i , as shown by Goudsmit and Bacher and others, may be written

$$a i s \cos(is). \quad (2)$$

Since i and s are constants, a is a constant to be associated with the electron, its value depending upon how strongly the electron spin is coupled with the nucleus spin.

¹⁴ Goudsmit and Bacher, Phys. Rev. 34, 1501 (1929).

In the case of an s electron and an arbitrary other electron, in LS coupling,

$$a_1 i s \overline{\cos(i s_1)} = a_1 i s_1 \cos(i j) \cos(j s) \cos(s s_1) = A i j \cos(i j) \quad (3)$$

where in terms of the quantum mechanics cosines

$$A = a_1 \frac{s(s+1) + s_1(s_1+1) - s_2(s_2+1)}{2s(s+1)} \cdot \frac{j(j+1) + s(s+1) - l_2(l_2+1)}{2j(j+1)} \quad (4)$$

and is the A of Eq. (1). The subscripts denote the s and arbitrary electron respectively. As pointed out by Goudsmit and Bacher, this expression for A , which is also applicable in the case where an s electron is added to a more general electron configuration, takes into account only the interaction between the s electron and the nucleus and neglects the interaction of the other valence electrons. A study of the vector diagrams and hfs shown in Figs. 2, 3, and 4 shows quite definitely that while the total hfs -separations depend primarily upon the $4s$ electron, the remaining valence electrons also make some contribution, and in some cases almost equal the contribution of the $4s$ electron. We may extend Eq. (4) in such a way that it is applicable to p , d , and f electrons as well as to s electrons. This is done by assuming that the electron has only a spin s and that its l vector is associated with the remaining valence electrons. This total *remainder* is then thought of as a parent term R_1 to which an electron spin S_1 alone is added to give the resultant multiplet term under consideration. Eq. (4) is then written

$$A = a_1 \frac{S(S+1) + S_1(S_1+1) - S_{R_1}(S_{R_1}+1)}{2S(S+1)} \cdot \frac{J(J+1) + S(S+1) - L_{R_1}(L_{R_1}+1)}{2J(J+1)} \quad (5)$$

Here S_1 may represent the spin of one or more electrons and a_1 the coupling constant associated with S_1 . Making the valid assumption that the energy of interaction between an l vector and the nuclear spin i is given by

$$a i l \cos(i l) \quad (6)$$

the l vectors of each valence electron may be taken into account by replacing each S and L of Eq. (5) by L and S respectively. Taking into account all of the electrons we get the general expression

$$A = \sum_n a_n \frac{S(S+1) + S_n(S_n+1) - S_{R_n}(S_{R_n}+1)}{2S(S+1)} \cdot \frac{J(J+1) + S(S+1) - L_{R_n}(L_{R_n}+1)}{2J(J+1)} + \sum_n a_n \frac{L(L+1) + L_n(L_n+1) - L_{R_n}(L_{R_n}+1)}{2L(L+1)} \cdot \frac{J(J+1) + L(L+1) - S_{R_n}(S_{R_n}+1)}{2J(J+1)} \quad (7)$$

For n valence electrons this gives A in terms of $2n$ constants. With seven valence electrons in manganese the fourteen constants are readily reduced to

three or four since five $3d$ electrons may be treated as a unit. The electron configuration $3d^5 4s 4p$, for the terms shown in Fig. 3, will here be used as an example. For the $4s$ electron with l value 0, only one constant, a_1 of Table IV, is to be determined. The contribution of a $4p$ electron with s value $\frac{1}{2}$ and l value 1 is represented by two constants, a_2 and a_3 respectively. The five $3d$ electrons, considered as a unit, have a spin value $2\frac{1}{2}$ and an l value 0 and may therefore be treated as a single s electron with spin $2\frac{1}{2}$ and represented by one constant, a_4 , Table IV.

The values of the a 's in the last four columns of Table IV may be computed from the $\Delta\nu$'s of Table III in the following manner. From Eqs. (1) and (7) and the total $\Delta\nu$'s we get for

$$a^6S_{21}, + 0.030 = 15(\quad + a_4) \quad (8)$$

$$a^8P_{43}^0, + 0.445 = 25(a_1 1/9 + a_2 1/9 + a_3 2/9 + a_4 5/9) \quad (9)$$

$$a^8P_{23}^0, + 0.352 = 15(a_1 9/49 + a_2 9/49 - a_3 2/7 + a_4 45/49) \quad (10)$$

$$a^6P_{31}^0, + 0.343 = 20(a_1 1/7 - a_2 5/49 + a_3 2/7 + a_4 5/7). \quad (11)$$

From the four simultaneous equations the four constants a_1 , a_2 , a_3 , and a_4 can be determined. Since a_3 and a_4 are small as compared with a_1 and a_2 they are assumed the same for all of the terms in Table IV and are set in italics. The constant a_3 for $^8P_{43}^0$ for example, is the mean of six values, taking each time Eq. (9) and one of the six equations from the $^6P^0$ terms. The a_1 's for the $4s$ electron are then computed independently for each term, so that the four constants following each term give the total $\Delta\nu$ in column two. Since the $\Delta\nu$'s for the a^4P^0 terms have not been observed they have been computed from the mean values of the a 's of the other nine P^0 terms. A method similar to that used for the P^0 terms has been used to determine the a 's for the D and S terms of the electron configurations $3d^5 4s 5s$ and $3d^5 4s$ respectively. The results are shown in Tables V and VI.

It is to be expected that the value of a_1 for the $4s$ electron obtained from each term of each electron configuration would be nearly the same. It is likewise to be expected that a_4 of Table IV and a_3 of Table VI would have nearly the same value. Attempts to alter any one set of a 's or $\Delta\nu$'s is found to alter other sets of a 's or $\Delta\nu$'s in such a way as to make conditions worse. Just how much, from the theoretical standpoint, a_1 ($4s$) should be changed by a change in the electron configuration, for example from $3d^5 4s 4p$ to $3d^5 4s$, is difficult to determine. The agreement between the a_1 's within each of the electron configurations is as good as can be expected.

The narrow hfs -separations in the 4D terms of Fig. 4 and the wide separations in the 6D terms show that the coupling of the six $3d$ electrons with the nucleus almost neutralizes that of the $4s$ electron. This same effect is also found in the b^6P^0 terms of Fig. 3. It should here be stated that preliminary calculations of a_1 , a_2 , and a_4 for the first nine terms of Table IV, omitting the l value of the $4p$ electron a_3 , indicated that the inclusion of the l value would give more constant values of a_1 and a_2 .

A study of Figs. 2, 3, and 4 and a comparison of these figures with Tables IV, V, and VI shows that only a few of the interesting relations to be found between the hfs and the gs of manganese have been pointed out above. This investigation has been carried on at Professor Paschen's laboratory at the Physikalisch-Technische Reichsanstalt, Berlin.

MEAN LIVES OF LINES OF MERCURY TRIPLET $2^3P_{012} - 2^3S_1$

BY ROBERT H. RANDALL

PHYSICS LABORATORIES, COLUMBIA UNIVERSITY

(Received April 4, 1930)

ABSTRACT

The mean life of each of three lines coming from the same upper level in the mercury atom has been measured. The triplet $2^3P_{012} - 2^3S_1$ was excited by electron impact under conditions involving negligible ionization and concentration of excited atoms. The method was that previously described by Webb, in which high frequency voltages are applied in phase to the excitation and detecting systems. The lines were excited in a sealed-off tube with mercury pressures between 0.004 and 0.03 mm. The exciting voltage was less than ten volts. The excitation was such that there was no appreciable concentration in the $2P$ states. A specially designed potassium-hydride photoelectric cell was used as the detecting system. Optical filters were used to isolate the line measured. The results agree with the assumption that the radiation decays exponentially after impact. For the lines $\lambda 4047$ and $\lambda 4358$ the lives were found to be the same within the experimental error (0.75 percent) viz. $\tau = 5.75 \times 10^{-8}$ secs. The value for $\lambda 5461$ was four times greater, $\tau = 2.37 \times 10^{-7}$ secs. The agreement between the lives of $\lambda 4047$ and $\lambda 4358$ supports the quantum assumption that lines coming from the same level in the atom have the same life. Collins has found that under certain exciting conditions the fine-structure of $\lambda 5461$ is anomalous as compared to $\lambda 4047$ and 4358 . It is suggested that the longer life found for $\lambda 5461$ may be explained by considering the fine structure of the 2^3S_1 level. The results are then consistent with the above assumption.

INTRODUCTION

FROM the relation between the mean life, τ_n , of an excited atomic state and the Einstein probabilities for transitions to all possible lower states,

$$\tau_n = \left(\sum_m A_m^n \right)^{-1}$$

it is generally assumed that all spectral lines originating in the same upper level in the atom have the same life.¹ Direct experimental evidence on this point is scarce.

While Kerschbaum² has measured τ for a number of spectral lines, using Wien's canal-ray method, and has found equal lives for lines originating in the same upper level, in agreement with the Einstein assumptions, he also found, in general, equal lives for *all* the arc lines of any one element. This last is hardly to be expected, as Maxwell³ has pointed out, since the sum of the transition probabilities, upon which the lives depend, is not necessarily the same for every level in the atom.

The present investigation was undertaken to test further the validity of the Einstein assumptions by measuring the mean lives of each of several

lines coming from the same upper level, but under simpler excitation conditions than obtained in Kerschbaum's measurements. The lines were excited by simple electron impact at voltages below ionization. The mercury $2^3P_{012} - 2^3S_1$ triplet, $\lambda\lambda 5461, 4358$ and 4047 , was chosen because the intensity of the lines and their wide wave-length separation favored the application of the particular method of measurement used. Since levels higher than the 2^3S_1 were not excited to any appreciable extent, the conditions were less complicated than where high voltage excitation is used, as in Wien's canal-ray method. Voltage and pressure conditions were such as to make it unlikely that absorption and re-emission played any part in the persistence of the radiation.

METHOD

The method of measurement employed was a modification of that previously used in this laboratory.⁴ The excitation was produced by electron impact excited by alternating voltages in such a way that there was excitation during only the positive half cycle. A voltage of the same frequency and phase was applied to a photoelectric detecting system, so that only radiation reaching the photoelectric surface in the positive half cycle was effective; during the negative half cycle the photoelectrons were held in the surface. As the frequency was increased, the total excitation being held constant, the photoelectric current decreased, owing to the persistence of the radiation, some of which then reached the photoelectric surface in the negative half cycle. From the form of the curve, the value of the mean life τ of the radiation was calculated, assuming that radiation excited at the time $t=0$ falls off according to the law e^{-kt} .

APPARATUS

The details of the apparatus are shown in Fig. 1. The excitation was produced in an evacuated vessel of Pyrex, containing electrodes C, G, G' and O . The hot cathode C , for which we are indebted to Dr. A. W. Hull of the General Electric Company, was equipotential, consisting of an oxide-coated nickel cylinder with an internal tungsten heater. Electrodes G and G' , comprising the accelerating system, were in the form of two concentric cylinders of 1.6 mm mesh nickel gauze, with a difference in radius of 2.0 mm. For most of the measurements grids G and G' were connected together just outside the cell and used as a single electrode which we shall call GG' . The outer cylindrical electrode O , of sheet nickel, had a window covered with gauze to allow the passage of the radiation.

All metal parts were pre-outgassed. Before sealing off, the excitation cell was baked for several hours at 450°C , the filament sensitized and a strong arc operated for an hour. Later tests indicated that accumulated gas did not exceed 10^{-4} mm of mercury.

The mercury vapor pressure in the excitation cell was controlled by a mercury well at the bottom, kept in a water-bath whose temperature was

⁴ H. W. Webb, Phys. Rev. **24**, 113 (1924); F. G. Slack, Phys. Rev. **28**, 1, (1926); H. W. Webb and H. A. Messenger, Phys. Rev. **33**, 319 (1929).

held constant to 0.1°C . The body of the tube was superheated to about 80°C .

The detecting system, containing electrodes P , H and W , was a specially constructed photoelectric cell placed at a distance of 8 cm from the excitation cell. The potassium-covered electrode P was a nickel cylinder, supported on a long re-entrant glass tube to increase the electrical leakage path. Surrounding P was a cylindrical nickel gauze electrode H . Against the walls was a third cylindrical grid, which in addition to removing the photoelectrons quickly, served as a flashing electrode in forming the sensitive potassium-hydride surface. During the flashing process electrode H was slid to one end of the cell, allowing a more uniform discharge between W and P and preventing the formation of a light sensitive surface on H .

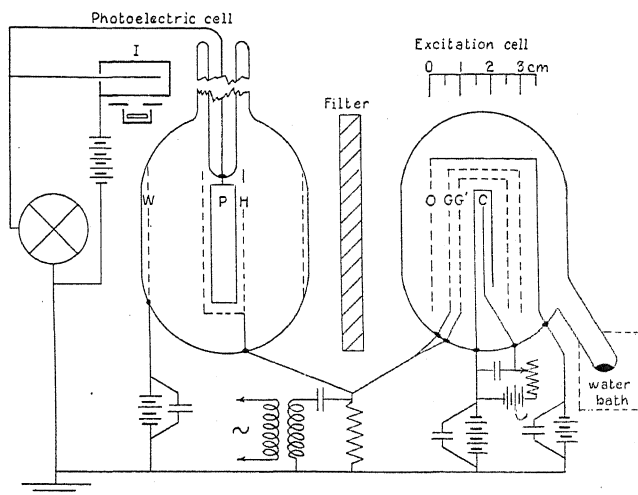

Fig. 1. Schematic diagram of apparatus and electrical circuits.

The metal parts were pre-outgassed and the cell which was of Pyrex, was baked out before distilling in the potassium. The hydrogen necessary for the flashing process was thoroughly pumped out before sealing off. The gas pressure in the cell after sealing off was below 10^{-4} mm mercury.

An electric heater on the electrometer lead prevented internal electrical leakage due to the formation of a film of potassium. Occasionally, after standing, a strong reverse photoelectric current from the grid H was found, due probably to a thin potassium film. This effect soon disappeared, however, after exposure to the heat of the excitation cell.

Corning glass filters were used between the excitation cell and the photoelectric cell to isolate each of the three lines; filters nos. G 555-Q and G 34-Y for $\lambda 5461$; nos. G 585-L and G-38 for $\lambda 4358$; and nos. G 586-A and G 38-L for $\lambda 4047$.

Photographs of a mercury arc taken through the filter for $\lambda 5461$ and for $\lambda 4358$, made certain that under the conditions of excitation of this experiment, the transmission of one filter for either of the other two lines, or for any other line likely to be excited, was less than 1 percent of the transmission

for the desired line. The radiation transmitted by the filter for $\lambda 4047$ also included the line $\lambda 4078$, but was otherwise monochromatic. White⁵ and Crozier⁶ have found that under excitation conditions similar to those of this experiment, $\lambda 4078$ was considerably weaker than $\lambda 4047$. A study of the results of the present investigation showed that the presence of the small quantity of $\lambda 4078$ did not affect the measurement of the life of $\lambda 4047$.

There was always a considerable steady photoelectric current, due to the light from the hot cathode of the excitation cell. This was balanced out by means of a radio-active leak, I , Fig. 1, controlled by a variable lead shutter over the opening of the metal box containing the active material.

The filament was heated by an 8 volt storage battery while all other d.c. voltages were furnished by small dry cells. The alternating voltages were supplied by air-core transformers coupled to the 60 cycle lighting circuit

Fig. 2. Curve A, a typical excitation curve ($\lambda 4358$). Curve B, photoelectric characteristics.

or to a vacuum-tube oscillator of variable frequency. The voltages were applied to the experimental cells across a nearly non-inductive resistance of about 45 ohms, one end of which was connected directly to the grids H and GG' . In the case of the high frequencies supplied by the oscillator this resistance formed part of a tuned circuit which helped to insure a pure impressed sine wave. The alternating voltages were measured with a vacuum-tube voltmeter. The frequencies were measured with a wave-meter.

A Compton quadrant electrometer with a sensitivity of about 3000 mm per volt was used to measure the photoelectric current.

EXPERIMENTAL AND RESULTS

Fig. 2 shows the steady current characteristics of the exciting and of the detecting systems which it was necessary to know in calculating the lives of the radiations. The excitation curve (A) was taken with the filter for $\lambda 4358$ in place, and shows how the photoelectric current varied with the accelerating voltage between GG' and C , the voltage between H and P being held constant. The voltage conditions were $P=0.0$, $H=2.0$, $W=6.0$, $GG'=0.0$, $O=-3.0$, and C variable between 0.0 and -10.5 volts.

⁵ D. R. White, Phys. Rev. 28, 1125 (1926).

⁶ W. D. Crozier, Phys. Rev. 31, 800 (1928).

The curve for $\lambda 4358$ shows that this radiation appeared at about the theoretical voltage 7.7 and that the variation of the photoelectric current was roughly linear for higher voltages up to 10.5 volts. Excitation curves taken with each of the other two filters were found to have exactly the same shape as that shown for $\lambda 4358$, agreeing with the results of White⁵ and Crozier.⁶ The line $\lambda 4078$ should theoretically come in at 7.9 volts. There was, however, no evidence of complexity in the excitation curve found for $\lambda 4047$, indicating that $\lambda 4078$ was considerably weaker than $\lambda 4047$.

The photoelectric characteristics Fig. 2 (B) were taken with each of the three filters separately, maintaining a constant voltage between GG' and C

Fig. 3. R -frequency curves.

and varying the voltage between H and P . The ordinates are proportional to the photoelectric currents in each case and have been reduced to the same saturation current for comparison. The voltage conditions for the curves shown were $GG' = 0.0$, $C = -9.0$, $O = -3.0$, $P = 0.0$, and H variable between -3.0 and 3.0 volts. The three curves show that for these wave-lengths the cell was practically unidirectional and that a change of only a volt in the potential on H was sufficient to produce saturation. The shift in the stopping voltage is the only marked variation of the photoelectric characteristic with wave-length.

The curves from which the lives of the radiations were determined were obtained by applying alternating voltages, of the same peak value and phase, to GG' and H simultaneously and measuring the photoelectric current at different frequencies. The curves in Fig. 3 are typical of those obtained.

The abscissas are the frequencies. The ordinates are proportional to the photoelectric currents and represent in each case the ratio R of the current obtained with a high frequency to that obtained with a low frequency, 60 cycles, for which the effect of the persistence of the radiation was negligible. The ratio R was used instead of the actual photoelectric current to avoid error due to changes in the sensitivity of the photoelectric cell.

The d.c. voltage conditions for the curves shown were $GG'=0.0$, $C=-7.5$, $O=-3.0$, $P=0.0$, $H=0.0$ and $W=6.0$. The peak value of the alternating voltage applied to GG' and H was 2.5, so that the accelerating voltage varied between 5 and 10 volts. Measurements were taken at several different pressures, varying between 0.004 and 0.03 mm of mercury, as indicated in the figure. In the case of $\lambda 4047$ the different pressures are not specified on the graph, for the sake of clearness, but the points for this line were taken over the same pressure range as for $\lambda 4358$. Pressures below 0.004 mm in the case of $\lambda 4047$ and 4358, and below 0.007 mm in the case of $\lambda 5461$, could not be used since there was then insufficient energy to give a measurable photoelectric current, while with pressures much above 0.03 mm trouble was experienced with the arc striking.

It is important for this method of measurement that the impressed alternating voltages be of approximately sine form. The tests for wave-form described in earlier papers, were made for each frequency and indicated that up to the highest frequency it was possible to use, 1.2×10^7 cycles, no error was introduced due to faulty wave-form.

The solid lines shown with the experimental points in Fig. 3 were calculated in a manner similar to that discussed in earlier papers. It was assumed that the radiation excited at any time $t=0$ falls off according to the exponential law e^{-kt} . Since the excitation was approximately linear with the voltage, the excitation during the positive half cycle approximated the form of the positive half of a sine curve. Also the photoelectric cell was nearly unidirectional and saturated quickly with a reversal of the voltage. It was therefore possible to find a simple approximate analytic expression for R as a function of the frequency f

$$R = \frac{K^2 + 2\pi^2 f^2}{K^2 + 4\pi^2 f^2}.$$

To this approximate expression certain correction terms, amounting to about 10 percent had to be added to take care of the fact that the photoelectric cell did not saturate instantaneously with a reversal of the voltage, and also the fact that excitation did not begin immediately with positive values of the alternating voltage. Since these correction terms were complicated and involved quantities determined empirically from the excitation and photoelectric characteristics, they are of no special interest here. With very high frequencies R approached a limiting value determined by the photoelectric characteristics and the amplitude of the applied alternating voltages. This is shown in Fig. 3 (a) and (b) by a horizontal dotted line.

By trial, a value of K was found such that the calculated curve best fitted the experimental points. The agreement was such as to justify the assumption of an exponential decay. For $\lambda 5461$, K was found to be $4.23 \times 10^6 \text{ secs.}^{-1}$; the mean life of the radiation, τ , was then $1/K$ or $2.37 \times 10^{-7} \text{ secs.}$ The same K was found for $\lambda 4358$ and for $\lambda 4047$, viz. $1.74 \times 10^7 \text{ secs.}^{-1}$, giving a mean life for each of these lines of $5.75 \times 10^{-8} \text{ secs.}$ The life of $\lambda 5461$ was therefore closely four times that of $\lambda 4358$ and 4047 .

The precision of measurement for τ was about 4 percent. In order to see how closely the lives of $\lambda 4358$ and $\lambda 4047$ agreed, a fixed frequency of 3×10^6 cycles was used and a large number of alternate measurements of R were taken by simply interchanging the filters, the electrical conditions remaining the same. The same value of R was found for both lines to within the experimental error 0.75 percent, indicating the same value of K for the two lines to within that precision.

Measurements were taken using a peak value for the alternating voltage of 1.1 instead of 2.5. This resulted in a slightly different form for the calculated R -frequency curve. The experimental points lay on the calculated curve, however, and the values of K which best fitted the data agreed in every case with those found using a peak voltage of 2.5, to within the experimental error.

Using Corning glass filter no. G-586-AW, measurements were made on the mean life of another group of lines, which included the singlet $2^3P_1 - 3^1D_2$, $\lambda 3663$, and the triplet $2^3P_1 - 3^3D_{1,2,3}$, $\lambda \lambda 3650, 3654$ and 3662 . These lines could not be separated optically and the life measured was for the composite radiation. It was found impossible to obtain a complete R -frequency curve, since the radiation was apparently short-lived and it was necessary to go to very high frequencies before the photoelectric current began to decrease. Enough of the curve was obtained from which to estimate a value for the mean life of the radiation of $2.4 \times 10^{-8} \text{ secs.}$, certain to within 10 percent. The curve was too incomplete, however, to be able to determine whether there were different lives for the different components of the radiation.

DISCUSSION

There was some question as to the purity of the radiation reaching the photoelectric cell when using the filter for $\lambda 4047$. The theoretical voltages at which $\lambda 4047$ and $\lambda 4078$ come in are 7.7 and 7.9 respectively. Both White⁵ and Crozier,⁶ however, found no appreciable intensity for $\lambda 4078$ under 8.4 volts. From a study of their voltage-intensity curves for these lines, the change in the peak value of the alternating voltage from 1.1 to 2.5 volts which changed the peak of the excitation voltage from 8.6 to 10.0 volts, would be expected to increase the average intensity of $\lambda 4078$, as compared to that of $\lambda 4047$, several times. If the intensity of $\lambda 4078$ were comparable to that of $\lambda 4047$, a change in the peak voltage should result in different R -frequency curves, providing the life of $\lambda 4078$ were appreciably different from that of $\lambda 4047$. No such change was noted, indicating either that the intensity of $\lambda 4078$ was too low to give a measurable photoelectric current; or that if $\lambda 4078$ were present to any considerable extent, its life was very

nearly that of $\lambda 4047$. In either case the measured life must be approximately the true life of $\lambda 4047$.

A study of the results for all three lines, $\lambda\lambda 5461, 4358$ and 4047 , leads to the conclusion that the results were not affected by absorption and re-emission of the radiation, but that the lives measured are actually those of the single atomic processes. It has been shown that for $\lambda 2537$ these absorption and re-emission processes play an important part in the persistence of the radiation emitted by excited mercury vapor, even down to pressures of 0.0002 mm of mercury.⁷ It is also known that under certain conditions large concentrations of excited atoms in the 2^3P_1 and the metastable 2^3P_0 state exist in the vapor and considerable absorption of $\lambda 4358$ and $\lambda 4047$ results.⁸ The subsequent re-emission of all three lines, $\lambda\lambda 4047, 4358$ and 5461 by atoms so excited to the 2^3S_1 level would cause persistence of the radiation in the vapor, beyond the mean life of the single atomic processes.

That such absorption processes did not occur to any measurable extent in the present experiment is evident from the fact that no change in the mean life resulted from varying the pressure and the exciting alternating voltages. Increasing the pressure should increase the concentration of atoms excited to the 2^3P_1 and 2^3P_0 states and as a consequence there should be greater persistence of the lines under study, if absorption processes were playing a part. The concentration of atoms in the 2^3P_1 and 2^3P_0 states would also be greater when the peak voltage of 2.5 was used than with the peak voltage of 1.1 , since in the former case the population in these states would be augmented by the return of electrons from upper states excited by the higher accelerating voltages.

A further test for effects due to absorption was made by varying the voltage on the outer electrode O in the excitation cell between the limits -8.0 and 0.0 volts. This had the result of increasing the total number of excited atoms produced in the positive half cycle, as O was made less negative, and this change should have increased the probability of any quantum of radiation being absorbed by an excited atom before escaping from the vapor. Again, some of the curves were taken with the two accelerating grids, G and G' connected together; for other curves only the inner grid served as an accelerating grid, the outer of the pair being connected to the electrode O . This change also affected the total concentration of excited atoms and should therefore have affected any persistence due to absorption.

The lives measured were, however, found to be independent of any of these pressure or voltage changes, indicating that they are the true mean lives of the corresponding single atomic processes.

The results show identical lives for $\lambda\lambda 4047$ and 4358 . This is strong evidence in support of the assumption that lines coming from the same upper level in the atom have the same life. While the fact that $\lambda 5461$ was found to have quite a different life than the other two lines may be interpreted as evidence that the Einstein relation is not valid, it is believed that a much more reasonable explanation will be found in the fine-structure of the lines.

⁷ H. W. Webb and H. A. Messenger, *Phys. Rev.* **33**, 319 (1929).

⁸ C. Fuchtbauer, *Phys. Zeits.* **21**, 635 (1920); R. W. Wood, *Proc. Roy. Soc. A* **106**, 679, (1924), *Phil. Mag.* **50**, 774 (1925), *Phil. Mag.* **4**, 406 (1927).

These fine-structure components have been carefully studied. Under the conditions obtaining in a strong arc $\lambda 5461$ has at least twelve distinct components; $\lambda 4358$ at least twenty; and $\lambda 4047$ at least nine. Ruark⁹ has proposed a fine-structure energy level scheme which supposes a triple fine structure for the 2^3S_1 level as well as a triple fine structure for each of the $2P$ levels, and which accounts for about $\frac{2}{3}$ of the components found in the arc. Some experiments of Collins,¹⁰ however, have shown that the fine structure of these lines is much simpler when the lines are optically excited than in the strong arc. He excited the lines in a resonance tube placed next to a mercury arc. Atoms were excited to the 2^3S_1 level by the successive absorption of $\lambda 2537$ and $\lambda 4358$. About half the components found in a strong arc appeared in the case of $\lambda \lambda 4358$ and 4047 , while only *one* of the many arc components of $\lambda 5461$ appeared. When nitrogen was introduced into the resonance tube little change was noted in the fine structures of $\lambda \lambda 4358$ and 4047 , but to the single component of $\lambda 5461$ was added one other equally strong component.

These results indicate a certain anomalous character for $\lambda 5461$ as compared to the other two lines. It suggests that under certain excitation conditions, quite different upper fine-structure levels may be involved in the case of $\lambda 5461$ than in the case of $\lambda \lambda 4047$ and 4358 , and that the lives measured in the present investigation may therefore be the lives characteristic of these different sub-levels. It is, however, not possible to say whether a single one of these sub-levels is involved in the case of each of the lines or whether the result, in each case, is the average life of lines coming from a group of sub-levels. The precision of the method is such that if a radiation were made up of two components of about equal intensity, the complexity could be detected if their lives differed by more than 30 percent. Again, if there were two components of widely different lives, the complexity could be detected as long as the intensity of one component was not less than 10 percent that of the other. Since there was no evidence of complexity from the curves, it was concluded either that one fine-structure component predominated in the case of each of the three lines, or that if several strong components were excited in each case, they had about equal lives.

A study of the fine structure of these lines under conditions of excitation somewhat similar to those of this investigation is being undertaken in this laboratory.

It is interesting to note that Wien,¹¹ using his canal-ray method, found a value for the mean life of $\lambda 4358$ of 1.82×10^{-8} secs. No explanation can be offered for the difference between the value of the mean life found here and Wien's result. It should be pointed out, however, that the type of excitation was quite different for the two experiments, Wien using high voltages, while here the exciting voltage was always below ionization.

The author wishes to express his thanks to Professor H. W. Webb, who suggested this problem, for his continued help and advice throughout the experiment.

THE HYDROGEN ATOM IN THE STARK EFFECT

BY FRANCIS G. SLACK

DEPARTMENT OF PHYSICS, VANDERBILT UNIVERSITY

(Received April 4, 1930)

ABSTRACT

Characteristics of the hydrogen atom wave function, which show the statistical distribution of electronic charge with respect to the nucleus and electric field, are computed for the first five quantum states. The results are tabulated and are represented graphically for one state as an example. The average coordinates of the electronic charge are also computed and included in the tabulation.

EXPERIMENTS¹ with hydrogen canal rays in an electric field show phenomena apparently dependent upon the statistical distribution of the electronic charge with respect to the nucleus and to the electric field.² This statistical "distribution of charge" or "electronic configuration" is dependent on the wave functions of the various states of the hydrogen atom, as indicated by Schrödinger.³

In the following paper we compute and present in tabular and graphical form certain characteristics of the electronic configuration of the hydrogen atom wave function, namely, the statistical total charge in certain regions between which this charge reduces to zero, and the average coordinates of the total electronic charge with respect to the nucleus. These are computed from Schrödinger's³ expressions for the Stark effect, using unperturbed wave functions in the case of a vanishingly small field.⁴ No attempt is made to place any special significance or meaning on the computed values further than has been done⁵ and it is unnecessary to choose from among the several points of view already expressed by various authors.⁶

We start with the Schrödinger wave equation for the hydrogen atom in an electric field of strength F :

$$\Delta\psi + \frac{8\pi^2m}{h^2} \left(E + \frac{e^2}{r} - eFz \right) \psi = 0$$

and insert the parabolic coordinates $\lambda_1, \lambda_2, \phi$ where: $x = (\lambda_1 \lambda_2)^{1/2} \cos \phi$, $y = (\lambda_1 \lambda_2)^{1/2} \sin \phi$, and $z = 1/2(\lambda_1 - \lambda_2)$. The field has the direction of $+z$,

i.e. the direction of the axis of the λ_2 parabolas. The wave function (ψ) satisfying this equation under these conditions is given by Schrödinger as:

$$\psi_{k_1 k_2 m} = \lambda_1^{m/2} \lambda_2^{m/2} e^{-(\lambda_1 + \lambda_2)/2na_0} L_{m+k_1}^m \left(\frac{\lambda_1}{na_0} \right) L_{m+k_2}^m \left(\frac{\lambda_2}{na_0} \right) e^{\pm im\phi}$$

where $n = (k_1 + k_2 + m + 1)$ is the total quantum number, k_1 and k_2 are parabolic quantum numbers and $(m+1)$ is the equatorial quantum number. L_{m+k}^m is the m th derivative of the $(m+k)$ th Laguerre polynomial. $a_0 = \hbar^2/4\pi^2 me^2$ the radius of the first Bohr orbit of the hydrogen atom. Forming the product of the wave function (ψ) with its conjugate ($\bar{\psi}$) we obtain the "electronic charge density" or "electronic probability"

$$\rho = \psi\bar{\psi} = \lambda_1^m \lambda_2^m e^{-(\lambda_1 + \lambda_2)/na_0} \left[L_{m+k_1}^m \left(\frac{\lambda_1}{na_0} \right) \right]^2 \left[L_{m+k_2}^m \left(\frac{\lambda_2}{na_0} \right) \right]^2.$$

For normalization² we introduce the factor C so that $\int_{\phi=0}^{2\pi} \int_{\lambda_1=0}^{\infty} \int_{\lambda_2=0}^{\infty} C \rho dv = e$ where $dv = 1/4(\lambda_1 + \lambda_2) d\lambda_1 d\lambda_2 d\phi$ is the volume element and e is the total extra-nuclear or electronic charge. We determine

$$C = \frac{k_1! k_2! e}{\pi (na_0)^{2m+3} [(m+k_1)!]^3 [(m+k_2)!]^3 n}.$$

Thus we obtain a final normalized expression for the integral of ρdv where we may evaluate over any set of limits to determine $e_{\text{limits}} = \iiint C \rho dv$ within their boundary. This being the integral of "charge density" multiplied by volume element we designate it by e_{limits} and have:

$$e_{\text{limits}} = \iiint \frac{C}{4} (\lambda_1 + \lambda_2) \lambda_1^m \lambda_2^m e^{-(\lambda_1 + \lambda_2)/na_0} \left[L_{m+k_1}^m \left(\frac{\lambda_1}{na_0} \right) \right]^2 \left[L_{m+k_2}^m \left(\frac{\lambda_2}{na_0} \right) \right]^2 d\lambda_1 d\lambda_2 d\phi$$

where the limits $\int_{\phi=0}^{2\pi} \int_{\lambda_1=0}^{\infty} \int_{\lambda_2=0}^{\infty}$ will give a total electronic charge e . However on substituting concrete values of the quantum numbers and evaluating the Laguerre polynomials it is seen that for certain values of λ_1 and λ_2 the expression for ρ vanishes. Along these parabolas the "charge density" and hence the charge is zero. This gives us natural limits or boundaries within which we shall evaluate the integral. (The expression is degenerate in regard to the angular coordinate (ϕ) and thus has axial symmetry about an axis parallel to the impressed field. Integration over this coordinate then always introduces the factor 2π .)

As an example we introduce the quantum numbers for one substate and carry through the integration. Thus for the state $2-1-2$, $n=5$, $k_1=2$, $k_2=1$ and $m=1$ we have:

$$e_{2-1-2 \text{ limits}} = \int_{\lambda_1} \int_{\lambda_2} \frac{C\pi}{2} (\lambda_1 + \lambda_2) \lambda_1 \lambda_2 e^{-(\lambda_1 + \lambda_2)/5a_0} \left[L_3^1 \left(\frac{\lambda_1}{5a_0} \right) \right]^2 \left[L_2^1 \left(\frac{\lambda_2}{5a_0} \right) \right]^2 d\lambda_1 d\lambda_2$$

$$= \frac{C\pi}{2} \int_{\lambda_1} \int_{\lambda_2} (\lambda_1 + \lambda_2) \lambda_1 \lambda_2 e^{-(\lambda_1 + \lambda_2)/5a_0} \left[-3 \left(\frac{\lambda_1}{5a_0} \right)^2 + 18 \left(\frac{\lambda_1}{5a_0} \right) - 18 \right]^2 \left[2 \left(\frac{\lambda_2}{5a_0} \right) - 4 \right]^2 d\lambda_1 d\lambda_2.$$

The roots of $[-(\lambda_1/5a_0)^2 + 6(\lambda_1/5a_0) - 6]$ are $\lambda_1 = 6.34a_0$ and $\lambda_1 = 23.66a_0$, and the root of $[(\lambda_2/5a_0) - 2]$ is $\lambda_2 = 10a_0$ and thus the expression under the integral will vanish along the three parabolas fixed by these values of λ_1 and λ_2 as well as for $\lambda_1 = 0$ or $\lambda_2 = 0$ and for $\lambda_1 = \infty$ or $\lambda_2 = \infty$. These four λ_1 parabolas intersected by the three λ_2 parabolas will divide the region surrounding the nucleus into six regions⁷ bounded by the limits:

$$\begin{aligned} e_1 &= \int_{\lambda_1=0}^{6.34a_0} \int_{\lambda_2=0}^{10a_0} ; e_2 = \int_{\lambda_1=0}^{6.34a_0} \int_{\lambda_2=10a_0}^{\infty} ; e_3 = \int_{\lambda_1=6.34a_0}^{23.66a_0} \int_{\lambda_2=0}^{10a_0} ; \\ e_4 &= \int_{\lambda_1=6.34a_0}^{23.66a_0} \int_{\lambda_2=10a_0}^{\infty} ; e_5 = \int_{\lambda_1=23.66a_0}^{\infty} \int_{\lambda_2=0}^{10a_0} ; \\ e_6 &= \int_{\lambda_1=23.66a_0}^{\infty} \int_{\lambda_2=10a_0}^{\infty} . \end{aligned}$$

Substituting its values as given for C and integrating in this particular case we have:

$$\begin{aligned} e_{2-1-2 \text{ limits}} &= \frac{e}{2^3 \cdot 5^6 \cdot 6a_0^5} \left\{ \left[-\frac{\lambda_1^6}{125a_0^3} e^{-\lambda_1/5a_0} \right. \right. \\ &+ \frac{6}{25a_0} \lambda_1^5 e^{-\lambda_1/5a_0} - \frac{18}{5a_0} \lambda_1^4 e^{-\lambda_1/5a_0} - 180a_0 \lambda_1^2 e^{-\lambda_1/5a_0} \\ &- 1800a_0^2 \lambda_1 e^{-\lambda_1/5a_0} - 9000a_0^3 e^{-\lambda_1/5a_0} \left. \right] \text{limits} \left[-\frac{\lambda_2^3}{5a_0} e^{-\lambda_2/5a_0} + \lambda_2^2 e^{-\lambda_2/5a_0} \right. \\ &- 10a_0 \lambda_2 e^{-\lambda_2/5a_0} - 50a_0^2 e^{-\lambda_2/5a_0} \left. \right] \text{limits} + \left[-\frac{\lambda_1^5}{125a_0^3} e^{-\lambda_1/5a_0} + \frac{7}{25a_0^2} \lambda_1^4 e^{-\lambda_1/5a_0} \right. \\ &- \frac{20}{5a_0} \lambda_1^3 e^{-\lambda_1/5a_0} + 12\lambda_1^2 e^{-\lambda_1/5a_0} - 60a_0 \lambda_1 e^{-\lambda_1/5a_0} - 300a_0^2 e^{-\lambda_1/5a_0} \left. \right] \text{limits} \\ &\left. \left[-\frac{\lambda_2^4}{5a_0} e^{-\lambda_2/5a_0} - 20a_0 \lambda_2^2 e^{-\lambda_2/5a_0} - 200a_0^2 \lambda_2 e^{-\lambda_2/5a_0} - 1000a_0^3 e^{-\lambda_2/5a_0} \right] \text{limits} \right\} . \end{aligned}$$

and on substituting the above limits we have: $e_1 = 0.0055 e$; $e_2 = 0.0820 e$; $e_3 = 0.0187 e$; $e_4 = 0.0219 e$; $e_5 = 0.1907 e$; $e_6 = 0.6792 e$; as shown in Table I and in Fig. 1-g.

⁷ F. G. Slack, Ann. d. Physik 80, 582 (1927). The statement that there will always be $(n-m)$ regions given here is incorrect. This holds only for the special cases $k_1=0$ or $k_2=0$ where there are no intersecting parabolas for which ρ disappears. The number of regions in the general case is given by $(k_1+1)(k_2+1)$.

Similar evaluations⁸ have been made for all possible quantum combinations through $n=5$ and thus the configurations are given for the initial and final states resulting in several of the spectral lines of the Lyman, Balmer, and Paschen series for which the most reliable observations have been made. The results of the computations are given in Table I. In column 1 is given the total quantum number $n=(k_1+k_2+m+1)$. In the second column the values of k_1 , k_2 , and $(m+1)$ are given, in the third column the value of $[(k_1+1)(k_2+1)]$ or the number of regions into which the space about the nucleus is divided by the parabolas for which ρ disappears. Columns 4 and 5 give respectively the limits of the integrations over λ_1 and λ_2 in units of $a_0=0.528 \times 10^{-8}$ cm, while column 6 gives the results of the integration over these limits in terms of the total electronic charge e . Since the general expressions are symmetrical with respect to k_1 and k_2 results are given only for those combinations resulting in zero or positive values of (k_1-k_2) .

Also in order to convey pictorially the form of the configurations we show in Fig. 1 to scale ($a_0=0.528 \times 10^{-8}$ cm) the various possible configurations for the total quantum number $n=5$ with the exception of the substate $k_1=k_2=0$, $(m+1)=5$ which results in a toroidal charge in a single region about the nucleus. The solid line parabolas are those for which $\rho=\psi\bar{\psi}=0$ and they are plotted to the rectangular coordinates x and z where the $+z$ direction, the axis of the λ_2 parabolas, is the positive direction of the electric field. The nucleus is at the origin. The figures represent sections in the xz plane and the values of e_{limits} given are the average electronic charge contained in the total volume obtained when the areas shown are revolved about the z axis. The value of \bar{z} the average z coordinate⁹ of the electronic charge as shown in each figure is computed from the general expression $\bar{z}=3/2na_0(k_1-k_2)$. This is also given in column 8 of Table I. For the states with k_1 and k_2 interchanged that is for states $k_1=0$, $k_2=1$, $(m+1)=4$; $k_1=0$, $k_2=2$, $(m+1)=3$; etc. the configurations will be identical to those shown but with the direction of the electrical field reversed.

The values of \bar{x} or the average x coordinates of the charge in any plane are not so easily determined since the expression

$$\bar{x} = \iiint C \rho x dv = \int_0^\infty \int_0^\infty \int_0^{2\pi} C \rho (\lambda_1 \lambda_2)^{1/2} \cos \phi \frac{1}{4} (\lambda_1 + \lambda_2) d\lambda_1 d\lambda_2 d\phi$$

involves fractional exponents and the general integral may be expressed only as a series. For any individual quantum state however the expression may be reduced to a series with a finite number of terms of the form $\int_0^\infty \lambda^P e^{-\lambda/na_0} d\lambda$ which are readily evaluated. The integration results in the common gamma function. The angle ϕ is set equal to zero and \bar{x} thus is the distance from the z axis to the cylindrical shell, concentric with the z axis, which divides the

electronic charge in half. Or as shown in Fig. 2, drawn for the state 3-1-1 the values of \bar{x} and \bar{z} determine a ring which locates the average position of

Fig. 1. Electronic configuration for quantum state $n=5$.

the electronic charge with respect to the nucleus. The values of \bar{x} are given in column 7 of Table I and shown on the x axis in the figures of Fig. 1.

Attention is called to the point that for the quantum states 0-0-1, 0-0-2, etc. (i.e. for $k_1=k_2=0$, the circular orbits of the Bohr atom) the

values of \bar{x} are not $n^2 a_0$ as in the Bohr atom but for $n=1$, $\bar{x}=1.178a_0$, $n=2$, $\bar{x}=4.4178a_0$ and for $n=5$, $\bar{x}=26.16a_0$ etc. In general for $k_1=k_2=0$ we have

$$\bar{x}_n = \frac{(2n+1)!(2n-1)!\pi a_0}{2^{4n} n! [(n-1)!]^3}.$$

This arises from the degeneracy of the system in the case of the unperturbed atom.

Fig. 2. Location of average electronic charge for state 3-1-1.

As stated in the introductory paragraph calculations of this type have been used by the author to explain the intensity dissymmetry found between the long and short wave components of the hydrogen canal ray light in an electric field parallel to the motion of the beam. It appears to the author that it should be possible to explain the discrepancies between the intensity ratios found by Mark and Wierl¹¹ and those calculated on the Schrödinger theory on the basis of impact probability computed from the above given configurations. This problem and that of polarization in hydrogen canal-ray light due to impact are now under investigation from this point of view.

A POSSIBLE ORIGIN OF THE BAND AT 2540 IN THE SPECTRUM OF MERCURY VAPOR

BY R. ROLLEFSON

UNIVERSITY OF WISCONSIN, MADISON

(Received March 26, 1930)

ABSTRACT

It can be shown that the band at 2540A in the spectrum of mercury vapor can be accounted for on the basis of a molecule with low energy of dissociation, in agreement with the work of Koernicke who used this band to determine the heat of dissociation of Hg_2 . Certain possibilities are suggested for explaining the high value of the heat of dissociation obtained by Mrozowski.

MUCH of the recent work on the spectrum of mercury vapor has concerned itself with the fluted bands lying between 3000 and 1850A, especially those to the short wave-length side of the resonance line 2536A. By assuming these bands to be due to Hg_2 , and correlating the electronic levels involved with certain atomic levels, Mrozowski¹ has been able to obtain a value for the heat of dissociation of Hg_2 in the normal electronic state, using an extrapolation to obtain the band convergence point. The values obtained ranged between about 10 and 20 k cal/mol, depending on which band was used, but the indication was that the result should be nearer 20 than 10 since the lowest value was obtained by using a long extrapolation and hence was less reliable than the others. Using a different method, the study of the change in absorption by Hg vapor of three lines in the cadmium spark, 2144A, 2573A, and 2749A, as a function of the temperature, he obtained approximately 17 k cal/mol. These results are of a different order of magnitude from the ones obtained by Franck and Grottrian² (1 k cal/mol) and later by Koernicke³ (1.4 k cal/mol). The latter investigators, however, made use of the decrease in intensity of absorption in a definite band, that at 2540, with increasing temperature. It is the purpose of this note to show that this band at 2540, which was used by Koernicke in his determination of the heat of dissociation of Hg_2 , may be rather easily accounted for if we assume his small value for the energy of dissociation to be correct. We thus have two self consistent groups of phenomena which seem to contradict one another.

Considerations concerning the type of molecule one would expect to result from the union of two closed-shell atoms would seem to indicate that it should have a small energy of binding. If one considers a configuration consisting of two such atoms, attracting and repelling forces may each be expected to vary inversely as a high power of the distance between them,

¹ Mrozowski, *Zeits. f. Physik* 55, 338 (1929).

² Franck and Grottrian, *Zeits. f. techn. Physik* 3, 194 (1922).

³ Koernicke, *Zeits. f. Physik* 33, 219 (1925).

due to the high degree of symmetry of the atoms. If, then, we should plot the potential energy of the configuration as a function of the nuclear separation (following Franck) we should obtain a curve similar to I, Fig. 1. Such a sharp curvature of the potential energy curve indicates that the frequency of vibration in the zeroth vibrational state would be comparatively large, hence the energy of this lowest level might well be nearly that necessary for dissociation. In fact this ground state might be the only existing vibrational state connected with the lowest electronic level of Hg_2 . A case similar to this has already been treated according to the new quantum mechanics by Peierls,⁴ who also suggested the possibility of the application of his results to homopolar molecules with polarization binding. The latter is very probably what is dealt with in the case being considered, that of a molecule formed

Fig. 1

by the union of two unexcited mercury atoms. Thus curve I, with only one vibrational level may be taken to represent the ground level of such a molecule.

With one atom excited, however, conditions would be somewhat changed. The polarizability and hence the binding force would be greater, and consequently the internuclear distance corresponding to equilibrium would be diminished, resulting in a potential energy curve similar to II and a smaller moment of inertia for the molecule. Applying the Franck-Condon principle for determination of the intensity of bands, we may represent the most probable transitions by the shaded area in the diagram. The number of intense bands would then be determined by the number of vibrational levels between C and D. Then, since a decrease in the moment of inertia is involved in the transition, these bands would be shaded toward shorter wave-lengths. If, for

⁴ Peierls, *Zeits. f. Physik* 58, 59 (1929).

instance, there were two vibrational levels f and g between C and D , we should have two bands, sharp on the long wave-length side and shaded toward the resonance line 2536, and if the energy difference between f and g were small, the two bands would be partially superposed. This is in complete agreement with what has been observed by Wood and Voss.⁵ Thus the band at 2540 can be accounted for by assuming a low heat of dissociation for unexcited Hg_2 , and this same band, when studied by Koernicke's method indicates that neutral Hg_2 has that low heat of dissociation.

In the light of the above it may be well to consider again the results of Mrozowski. Although the consistency of the results he obtained argues in favor of his interpretation, still it seems reasonable to assume that agencies other than Hg_2 contribute to the absorption by mercury vapor in the regions he used for determining the heat of dissociation. In the case of the line 2573 for instance, it is possible that Hg_2 is responsible for none of the absorption, but that what occurred was an interaction of radiation and impact, that is, absorption during collision, such as has already been discussed by Oldenberg,⁶ or absorption by quasi-molecules as discussed by Born and Franck.⁸ A possible explanation of the fact that the fluted bands indicate a large energy of dissociation may be that the bands do not involve a transition to or from the lowest electronic level of a molecule composed of two unexcited mercury atoms. For example Walter and Barratt⁷ have been able to obtain the fluted band between 3000 and 2600 only when oxygen was present in the absorption tube. This band has the variation in intensity characteristic of a triatomic molecule, with no sharp edges such as one would expect in a band due to a diatomic molecule, and may be due to Hg_2O . The other bands used by Mrozowski may be due to a mercury molecule, but not necessarily the same type of molecule which gives rise to 2540.

The writer acknowledges his indebtedness to Professors C. E. Mendenhall and G. Wentzel for helpful criticism in the writing of this note.

THE IONIZATION OF HYDROGEN BY SINGLE ELECTRON IMPACT

BY WALKER BLEAKNEY

PHYSICAL LABORATORY, UNIVERSITY OF MINNESOTA

(Received April 11, 1930)

ABSTRACT

From an analysis of the theoretical potential energy curves for the H_2 molecule as outlined by Condon the theoretical predictions for the types of ions resulting from primary impacts with electrons are described. These predictions include the formation of H_2^+ at 15.25 volts, H^+ at 17.9 volts, H_2^{2+} at about 30 volts which then dissociates with several volts kinetic energy, and H_2^{3+} at about 50 volts which also dissociates with kinetic energy. Using a mass spectrograph the experimental results of a study of the primary ions in hydrogen indicate the formation of H_2^+ at 15.4 ± 0.1 volts, H^+ at 18.0 ± 0.2 volts, and H^+ at 26 to 30 volts, the last having various amounts of kinetic energy.

Curves are given showing the relative number of each of these types of ions from which it appears that at the higher velocities about 92 percent of the total number of ions formed is of the H_2^+ type, 1 percent of the H^+ corresponding to the 18 volt potential, and 7 percent of the H^+ having kinetic energy. The probability of ionization for all types together as a function of the electron velocity is given by a curve, plotted to an arbitrary scale, which exhibits a well-defined maximum at 60 volts.

INTRODUCTION

THE ions produced by electron impact in hydrogen have been studied by the method of positive ray analysis so many times and by so many investigators that it might, at first sight, seem useless to try to make much more progress in this direction. As early as 1916 Dempster¹ designed a mass spectrograph with which he studied the ions produced in hydrogen by 800 volt electrons. Since that time somewhat similar experiments have been carried out by Smyth,² Hogness and Lunn,³ Kallmann and Bredig,⁴ Dorsch and Kallman,⁵ and Brasefield.⁶ The consensus of opinion of these observers is that their experiments have failed⁷ to show that any ion other than H_2^+ may result from a single impact with an electron. The evidence from the experiment to be described⁸ points toward a different conclusion. Moreover certain aspects of the theory of the hydrogen molecule predict several possible modes of production of the H^+ ion at a single impact.

THEORY

Before the present experiment was undertaken Professor Condon drew up an outline of the results one might expect to find in making an e/m analysis of the primary ions in hydrogen. The essential ideas of this outline have been discussed by Condon,⁹ and Condon and Smyth,¹⁰ and the particular points pertinent to the present experiment will be reviewed here in some detail.

Fig. 1. Potential energy curves for the H_2 molecule.

In Fig. 1 are represented some of the theoretical potential energy curves for the hydrogen molecule. The potential energy in volts is plotted as a function of the nuclear separation in Angstrom units. Curves a and b represent the two solutions for the problem of bringing two H atoms in the normal state near each other to form an H_2 molecule as calculated by Sugiura¹¹ from the theory of Heitler and London.¹² Curve a has been altered slightly in order to

⁹ E. U. Condon, Phys. Rev. 35, 658 (1930) (Abstract).

¹⁰ E. U. Condon and H. D. Smyth, Proc. Nat. Acad. Sci. 14, 871 (1928).

¹¹ Y. Sugiura, Zeits. f. Physik 45, 484 (1927).

¹² W. Heitler and F. London, Zeits. f. Physik 44, 455 (1927).

fit the data as given by Birge and Jeppesen¹³ and b has been lowered somewhat in the dotted region. In like manner curves c and d represent the two solutions for the problem of the formation of the H_2^+ molecular ion from a normal H atom and a proton. Curve c is that calculated by Burrau¹⁴ and d is from the paper by Morse and Stueckelberg.¹⁵ Curve e represents the potential energy of the H_2^{++} molecule due to the Coulomb force of repulsion between the two protons. The width of the shaded band corresponds to the range of nuclear separations executed by the hydrogen molecule in its lowest vibrational state.¹⁶ The effect of rotational energy has been disregarded since it would add the same amount of energy to all the curves.

Now if a normal H_2 molecule is transformed by an electron impact from its lowest energy level on a to one of the states represented by the other curves it will, according to the Franck-Condon principle, suffer meanwhile little change in nuclear separation. Immediately after the transition, therefore, there is a high probability that the point representing the energy state of the molecule will lie within the shaded area. Hence, transitions are represented in this diagram by vertical or nearly vertical jumps from one state to another. Transitions from the normal to the state b would result in subsequent dissociation into two normal atoms each having several volts kinetic energy. This transition has no significance in the present experiment since only ions are measured. A jump to the state c results in the ordinary H_2^+ ion which should, according to this scheme, occur at 15.25 to 17.9 volts with various amounts of vibrational energy. An inspection of the figure shows that there is a small chance of a transition to a point on this curve which lies above the dotted line and the molecule in this state would then dissociate. Hence a small number of H^+ ions should be predicted at potentials above 17.9 volts. From 27 to 40 volts should be required to raise the molecule from its normal state to that represented by curve d where dissociation would occur into a normal H atom and a proton each having from 5 to 11 volts kinetic energy. Finally to strip both electrons from the H_2 molecule at a single blow should require from 46 to 56 volts and the two protons would then fly apart each with 7.5 to 12.5 volts kinetic energy. Between the last two stages there are many other transitions possible as a result of which the molecule would dissociate into a proton and an excited atom. Summarizing, then, the theory would predict the following primary reactions;

- | | |
|--|-----------------|
| 1. $H_2 \rightarrow H_2^+ + e$ | 15.4—17.9 volts |
| 2. $H_2 \rightarrow H^+ + H + e$ | 17.9—18.0 volts |
| 3. $H_2 \rightarrow H^+ + H + e + \text{kinetic energy}$ | 27 —40 volts |
| 4. $H_2 \rightarrow 2H^+ + 2e + \text{kinetic energy}$ | 46 —56 volts. |

APPARATUS AND PROCEDURE

The apparatus was the same as that used for the study of mercury ions¹⁷ and the details will therefore not be given here. In the present experiment the

flow method was used, the hydrogen being admitted to the system through a palladium tube. This tube was surrounded on the outside with hydrogen at atmospheric pressure and its temperature was maintained at the required value by an electric heating element. The rate of flow of the gas into the apparatus could be regulated by adjusting the rheostat controlling the heating current. The pressure of the gas in the ionization chamber was not measured but it was estimated to be in all cases in the neighborhood of 10^{-3} mm Hg. A trace of mercury vapor was allowed to remain in the apparatus for calibration purposes.

Fig. 2. A typical e/m analysis curve. Electron velocity = 150 volts. The second curve is the first magnified 40 times.

EXPERIMENTAL RESULTS

Primary ions in hydrogen. Figure 2 illustrates an e/m analysis curve for hydrogen ions produced by 150 volt electrons. The symbol $^{18}\text{H}^+$ is used to designate the atomic ion which begins to appear at 18 volts. The two curves represent the same data but in the second the ordinates have been expanded forty times. These two ions have at the instant of formation very little kinetic energy compared to that given them by the analyzing fields. In Fig. 3 is shown another peak obtained when the field V_2 ordinarily used to draw out the positive ions was made 1 volt per cm negative. In this case all the ordinary ions were prevented from reaching the analyzing chamber but those having high kinetic energy reached the collector. The number, however, was small and it was necessary to increase the sensitivity of the electrometer considerably in order to detect them at all. It will be noticed that the peak is very broad compared to those in Fig. 2. The second curve in Fig. 3 represents the maximum height of this peak as a function of the electron velocity. It is evident that weak ionization sets in at about 26 volts and becomes quite strong at 30 volts. This ion will be designated by the symbol $^{30}\text{H}^+$. These results can only be interpreted as *primary* processes. No trace of secondary reactions such as the formation of H_3^+ could be found.

Critical potentials for ionization. The ionization potentials for H_2^+ and $^{18}\text{H}^+$ obtained by plotting the heights of the peaks as functions of the electron velocity in volts are shown in Fig. 4. The Hg^+ ion is included in order to

determine one point on the voltage scale assuming its ionization potential to be 10.4 volts. In this figure the curve for $^3\text{H}^+$ was obtained by measuring with a galvanometer the positive current reaching the plate, to which the

Fig. 3. A broad peak due to the initial high velocity of the ions. The second curve shows the ionization potential.

total positive ion current is ordinarily measured, against a small retarding field. This curve checks closely the one shown in Fig. 3 which was obtained in a different way. It would indicate that the critical potential for the forma-

Fig. 4. Ionization potentials.

tion of this ion is about 26 volts while strong ionization of this type sets in from 30 to 35 volts. A summary of these results may be expressed in the following way.

Process	Predicted	Observed
1. $\text{H}_2 \rightarrow \text{H}_2^+ + e$	15.25 volts	15.4 ± 0.1 volts
2. $\text{H}_2 \rightarrow \text{H} + \text{H}^+ + e$	17.9	18.0 ± 0.2
3. $\text{H}_2 \rightarrow \text{H} + \text{H}^+ + e + \text{kin. energy}$	27.	$26 \pm 1.$

These conclusions constitute a striking confirmation of the theory.

Relative numbers of the different ions. The number of $^1\text{H}^+$ ions relative to the number of H_2^+ ions was determined by finding the relative areas¹⁸ under the peaks in the e/m analysis curves. Such a procedure was unsuitable, however, for determining the relative number of those ions having kinetic energy

Fig. 5. Relative intensity of the different types of ions.

since only a small fraction is shot out in the direction of the analyzer. A rough estimate of their intensity was made in the following manner. The total positive ion current was measured with the galvanometer in the usual way and then the field V_2 was reversed so that only ions having kinetic energy

Fig. 6. Efficiency curve for hydrogen.

could reach the plate. This number reaching the plate was plotted as a function of the retarding field and the curve so obtained extrapolated to zero field. Knowing the solid angle subtended at the electron beam by the plate and assuming cylindrical symmetry the fraction of the total current due to those ions having kinetic energy was calculated. The results are shown in Fig.

¹⁸ For a discussion of the assumption that the numbers are proportional to the areas see the second paper of reference 17.

5 where the ordinates for $^{18}\text{H}^+$ and $^{30}\text{H}^+$ have each been multiplied by ten. The curve for $^{30}\text{H}^+$ may include ions having kinetic energy as a result of some transition other than the 30 volt variety but it is believed that these are relatively very small in number.

Efficiency of ionization. Since in this experiment the pressure of the gas was not measured the efficiency of ionization could only be determined within an arbitrary constant factor. The result is given by the ratio of the electron current to the total positive ion current plotted as a function of the electron velocity. The curve, Fig. 6, shows a well-defined maximum at 60 volts. From the previous data it may be concluded that over ninety percent of the total number is made up of H_2^+ ions.

There is a marked difference between the shape of this curve and that reported by Compton and Van Voorhis¹⁹ in that the maximum appears at a much lower electron velocity and the curve falls off more rapidly beyond this point. Qualitatively the agreement with the data of Hughes and Klein²⁰ is good.

DISCUSSION

It is believed that the results of this experiment yield, at present, the most direct evidence for the existence of those repulsive forces represented by the potential energy curves for the H_2^+ ion. It will be recalled that such an energy state is contrary to the concepts of the classical theory which predicts only a force of attraction. Indirectly these results also lend support to the reality of the other repulsive curves predicted by the quantum theory.

The determinations of the critical potential for the formation of H_2^+ as made by a large number of observers²¹ cluster about a mean value of about 16.0 volts. That found in this experiment, 15.4 volts, is lower than any experimentally determined value known to the writer but it is believed that the method lends itself to greater accuracy than any of the previous methods. The close agreement with the theory lends support to this view. As Condon⁹ has pointed out, it is now impossible in the light of the theory and these experiments to interpret the critical potential near 30 volts which has been reported by Krüger,²² Horton and Davies,²³ and Vencov²⁴ as double ionization accompanied by dissociation. In the present work a search was made for the 50 volt transition resulting in H_2^{++} but only slight evidence for its existence could be found. An effort is being extended in this laboratory to throw more light on this question with an apparatus designed to measure the velocity distribution of high velocity ions.

The author is greatly indebted to Professors E. U. Condon and John T. Tate for their many helpful suggestions.

ELECTRON ENERGY LOSSES IN MERCURY VAPOR

BY CASTLE W. FOARD

STATE UNIVERSITY OF IOWA, IOWA CITY

(Received March 31, 1930)

ABSTRACT

An improved magnetic spectrum method was used to determine the energy losses sustained by slow speed electrons in mercury vapor. Electron energies up to 60 volts were used, the main region of interest being from 0 to 25 volts. The energy losses detected, below that required for ionization, were; 4.9, 5.4, 6.7, 7.7, 8.8, 9.8 volts. These correspond to practically all the transitions of a valence electron from the basic 1S level up to each of the higher levels to 4P. No evidence of other losses such as are observed by the photoelectric method were found. At voltages above 10.4, the ionization potential, electrons seem to be able to give up any quantity of energy in excess of that required for ionization, the higher losses being favored. A very interesting loss of 11.07 volts has been found, which has not been recorded heretofore. It begins to be resolved at about 18 volts, and grows steadily with increasing voltage in much the same manner as the 6.7 volt loss. It is thought that this loss involves the simultaneous displacement of both valence electrons from their normal levels.

THE pioneer work on inelastic impacts of electrons with mercury atoms, by Franck and Hertz,¹ showed that the energy lost by the electron is quantized. At first there appeared to be but one type of inelastic impact, that in which the loss of energy was equivalent to a drop in potential of 4.9 volts. Since that time, three other types of losses have been found by this or similar methods.^{2,3,4} The photoelectric method, developed by Franck and Einsporn,⁵ is also capable of giving us an insight into the phenomena of impacts. The number of critical potentials found by this latter method is quite large—eighteen, in the work referred to, and a still larger number in the later work of Jarvis.⁶ Some of these critical potentials have been shown^{7,8} to be due to other effects than resonance collisions: but there has persisted a discrepancy between the results of each of these methods, not only with each other, but with the results of spectroscopic study.^{9,10,11,12,13}

It seemed highly desirable that the inelastic impact method, which, in the past, has given the most meager results, should be improved, with a view to determining which of the impacts involve actual quantized energy losses to the electrons. For this purpose, the method used by Whitney⁴ has certain points of advantage over other methods. The electrons which have lost energy are spread out into a velocity spectrum, and can be collected, group by group, without mutual interference. This makes possible the use of greater sensitivity, in the search for the less probable types of losses. While Whitney was primarily interested in the excitation functions of the more probable impacts, his failure, under apparently favorable conditions, to detect the losses observed by the photoelectric method increased the difficulty of a reconciliation between results of the two methods.

A possible explanation of this discrepancy, as Whitney points out, would be that the types of losses which he does not find, are very improbable, except when the electron has little more than the amount of energy required for the excitation. Since Whitney's apparatus was quite insensitive to very slow electrons, we can see how these collisions involving a total loss of energy, would, under this hypothesis, have escaped detection. We therefore set about to remove this limitation by increasing the sensitivity of the Whitney method for slow speed electrons, and at the same time, to improve the resolving power. An additional end has been gained by a change of procedure which allows the energy losses to be read directly in volts from an accurate potentiometer, rather than by means of a calibration curve.

APPARATUS

The apparatus is pictured in Figs. 1 and 2. Electrons evaporating from the unthoriated tungsten filament F , are attracted toward the concentric cylinder C_1 , during which time they may make elastic or inelastic impacts with the atoms of mercury vapor which fills this region. A sample of the electrons arriving at the cylinder pass through the slit S_1 . The second cylinder, C_2 , allows us to control the speed with which the electrons emerge from S_2 . In the electric field free region outside the cylinders, the electrons are spread into a velocity spectrum by means of a uniform transverse magnetic field produced by a large pair of Helmholtz coils. Electrons having some definite speed, determined by the strength of the magnetic field used, will converge at a point 180° distant from S_1 , along an arc of a circle of 5 cm radius. Here they are collected by a probe wire which is shielded from stray electrons. A Compton quadrant electrometer, shunted by a radioactive leak, measures the current to the probe, which is of the order of 10^{-11} amp.

The vacuum tube was made entirely of brass, $3/8$ " thick, 20 cm diameter, and 22 cm long. The only metal parts of other material were the inner (molybdenum) cylinder and the tungsten filament. Two small glass windows and a reentrant liquid air trap, used in freezing out the mercury vapor from the outside region, were carefully shielded with brass wire gauze. The vacuum was kept below 10^{-5} mm, and liquid air traps employed constantly. The mercury vapor was introduced into the impact chamber from a furnace

heated reservoir maintained at various temperatures from 90° to 118° , depending on the pressure desired. The vapor pressure, under these conditions, is hard to estimate, since diffusion through the slit S_1 and the temperature of the impact chamber play an uncertain role; from the probability of certain types of losses, the pressure seemed to be of the order of 0.1 mm.

While a number of changes have been made, the tube, as described above, is essentially of the same type as that employed by Whitney. The chief point of difference lies in the addition of the auxiliary accelerating cylinder, C_2 . By means of this cylinder, the speed of the electrons may be adjusted so that any particular group may be focused on the probe wire, without changing the magnetic field.

Figs. 1 and 2. Plan of apparatus and electrical circuit.

PROCEDURE

In Whitney's method, the electrons emerging from C_1 with various residual speeds, were collected, group by group, by varying the magnetic field. In the present work, the procedure was somewhat different. All of the electrons collected were made to travel the circular path to the probe, with the same speed, regardless of how much energy they had lost. This was accomplished by accelerating them enough between C_1 and C_2 to just make up for their loss in energy at impact. For example, the 6 volt curve in Fig. 4 was taken as follows. E_1 , the potential on C_1 , was set at 6 volts, the desired impact speed. E_2 , the difference of potential between C_2 and C_1 , was set at (say) 2 volts. The magnetic field was then adjusted for maximum probe current, i.e., for 8 volt electrons. E_2 was then varied from 0 to 8 volts, in convenient steps of, generally, 0.1 volt, and the data recorded directly on graph paper. Those electrons which have lost none of their initial 6 volts, will require but two volts to be brought to the probe wire: but those which

have lost 4.9 volts at an inelastic impact, will require that much more energy, or a total of 6.9 volts acceleration between the cylinders, in order to have the proper speed to be collected. The no-loss electrons then have, of course, 10.9 volts, and hence move in too large a circle to interfere. If the arbitrary two volt initial value of E_2 be neglected in plotting, the abscissas of the peaks give the values of the energy losses directly in volts, and the ordinates, approximately the relative probability of each type of impact, at a particular impact speed. The width of the peaks is due to several causes, such as velocity distribution in the original electron stream, imperfect focusing, and finite width of probe.

Fig. 3 shows the degree to which this method was successful in improving the sensitivity for slow speed electrons. The first curve is similar to that

Fig. 3. Efficiency of collection of electrons as a function of their voltage.

published by Whitney, and shows the efficiency of collection of electrons, in the absence of the auxiliary cylinder. Curve 2 shows that, when this cylinder is inserted and maintained at a potential 6 volts above that of the first cylinder, the slow electrons are collected much better than before. In making curve 3, the new method of procedure was used. The total speed of collection was always 6.3 volts, but the speed with which they emerged from S_1 is varied from 0 upward. Slow electrons are still more favored than in the preceding curve, but the direct-reading characteristic of the new method is an additional advantage.

RESULTS

Fig. 4 shows the type of curves that are obtained with electron energies below ionization. The 4.9 volt loss, which is the predominant one up to 9 volts, begins to show itself at as low as 4 volts. In that curve, it appears to be a loss of only 4.3 volts, rather than 4.9 volts. These two illusions, the detection of a loss at too low a voltage, and the apparent smallness of the loss are traceable to the rather large velocity distribution—amounting to about 1.6 V.—which is here present. Since the potential E_1 is measured with respect to the center of the emitting portion of the filament, a certain share of the electrons may well have enough more energy than the average, to be able to lose 4.86 V. After this loss, a subsequent addition of less than 4.86 V. would

be required in order to collect them at the normal speed. This effect is most prominent for the types of losses which increase most rapidly in the vicinity of their critical potentials. The occurrence of a loss by an electron which apparently does not have that much energy might also be due to impacts occurring between the two cylinders, after the electron has acquired part of the added potential E_2 , though this is not considered likely.

At an impressed voltage of 5.2, an energy loss of 5.4 V. is clearly discernible, anticipated in voltage for the same reason as in the case of 4.9. A 6.7 V. loss is seen in the 6.5 volt curve, anticipated less than 4.9 was, and probably less than 5.4 would have been, had the latter not been partly obscured by the 4.9 V. peak.

Fig. 4. Energy losses in Hg below ionization.

The failure of previous users of the inelastic impact method, to find a loss of 7.7 V., or 7.9 V., corresponding to transitions of the valence electron from the 1S to the 2s or 2S levels, has been a serious criticism of the completeness of the results to be obtained by this method. These levels are separated by approximately a volt on either side, from all other levels, and upward transitions to them should be easily observable, if their probability is at all large. That such a loss does occur is seen from the curves of Fig. 4, beginning with the one for 7.5 V. The probability of the loss, while always small, rises to a maximum and falls off to insignificance within two or three volts of its critical potential. The exact loss could not be determined with much accuracy, but appears to be 7.7 V., though 7.9 might also be present. It is interesting to note that Crozier¹³ found that the intensity of the downward transitions from

$2s$ to $2p_{2,3}$, changed in a similar manner, while transitions from $2S$ had but one-third the probability in comparison.

The well-known loss of 8.8 V., and a loss of 9.8 V., sometimes observed, but attributed to two successive 4.9 V. losses, complete the list of losses less than that required for ionization. These may be seen better in Fig. 5, at impact speeds above ionization, because of their increased probabilities of occurrence. At 41 V., the 9.8 V. peak is at least as large as the single 4.9 V. peak, while the multiple collision peaks involving one or more 6.7 V. loss, are, quite properly, but a small fraction of the size of the single loss peak. This

Fig. 5. Energy losses in Hg at higher electron voltages.

consideration, along with a study of the change of size of the 9.8 V. loss with change of vapor pressure, leaves little doubt of its interpretation as a single impact loss.

IONIZATION

In all the curves taken with impact speeds above about 10 V., the threshold current, upon which the inelastic impact peaks are superimposed, rises rapidly in the vicinity of the region indicating total energy loss. It falls again, of course, at a distance beyond the total loss value, equal to half the velocity distribution. In other words, this rather large group of electrons appears to lose any amount of their energy from about that required for ionization up to total loss, the great bulk of them being in the latter category. The absolute number of these electrons is probably a great deal less than would be inferred from the size of the peak, because of the facility of collec-

tion of slow electrons, as previously explained. It was suspected that these slow electrons might have lost their energy at reflection from the walls of one of the cylinders. To test this, the furnace was cooled to 25°C, when the slow speed peak persisted to a certain extent, while the inelastic impact peaks practically vanished. The conclusion derived from this was that a part of the effect was due to reflected electrons from the cylinder walls, but that the major portion was to be attributed to some kind of a loss involving the mercury vapor, presumably associated with ionization. Eldridge³ came to the conclusion that, at ionization, both the impacting electron and the electron born of ionization had but a negligible amount of energy. What to do with the extra loss of energy is a moot question. Some later authors have supposed a sharing of the surplus energy by the two electrons: on this hypothesis, the current due to this source should be symmetrical about a line midway between total loss and ionizing loss; this is decidedly a different distribution than that observed here. This is, admittedly, an unsatisfactory way to leave the problem, but additional information is needed before a better interpretation can be made by this method.

ENERGY LOSSES ABOVE IONIZATION

When relatively high potentials are being used, and the losses under investigation are but a fraction of the total electron energy, it becomes very advantageous to be able to use a retarding potential between the two cylinders C_1 and C_2 , rather than an accelerating one, as was described in the investigation of losses near their critical potentials. Consider, for instance, the two curves in Fig. 5, marked 41 V. The upper curve was taken with a magnetic field set to collect 15.1 V. electrons to the probe wire. In order to collect the electrons which have lost no energy at impact, a retarding potential of 25.9 V. must be applied between the cylinders. As this retarding potential is reduced, which is equivalent to *increasing* the *accelerating* potential in the previous cases, electrons which have lost more and more energy are brought into focus and measured. This results in a controllable increase in the percent separation of the groups of electrons, with an accompanying increase in resolving power which is very desirable. The lower 41 V. curve was taken with a field set for 27.2 V. electrons, and hence with less retarding potential. The one-volt separation between the 8.8 and 9.8 V. losses is now but one-half the fraction of the whole path speed that it was before, and the peaks are no longer separated. With no retarding potential, the resolution was extremely bad. This improvement in resolution has been accomplished at the sacrifice of fidelity in the measurement of probabilities, in which we are not so much concerned in the present paper.

The chief point of interest in the curves of Fig. 5, is the 11.07 V. loss, which is seen to rise to an importance second only to that of the 6.7 V. loss, at this voltage. Its value may be observed very accurately, due to the presence of peaks of known value on either side of it, so that the value given is probably accurate to within 0.03 V. It makes its appearance at a potential unfavorable to its detection, because of the presence of the peak due to the

double impact loss $4.9+6.7$. Rising steadily from about 18 V., where the masking peak drops rapidly, this loss becomes so prominent that, at 41 V., we even see a peak due to the double impact $11.07+6.67$.

Several possible interpretations for this type of energy loss have been studied. No combination of the known losses in either the arc or the spark systems would give this value. Moreover, when the vapor pressure is changed, the size of the peak remains proportional to the single impact peaks rather than to the double impact peaks, which decrease more rapidly. It is therefore thought to involve but a single impact. If this were a *critical potential* method, a delay in the appearance of the loss until the energy of impact was somewhat above the amount required for ionization, might be interpreted as a delay in the process of ionization until some conservative force be overcome: but here, we are measuring the actual amount of the energy lost by the electron, regardless of the total energy possessed. Hence, some other type of quantized loss would have to accompany ionization, in order to account for the excess energy. According to the HgII energy values of Carroll,¹⁴ the simultaneous ionization and spark excitation to the lowest level would involve 16.8 V. Even then, it is doubtful whether the loss would be quantized, because of the possibility of energy sharing by the two electrons, as in ordinary ionization.

The most likely interpretation so far found, seems to be that of simultaneous excitation of both valence electrons in the same atom, without ejection of either. So little is known concerning this interesting type of excitation, that a complete verification of this theory is not to be expected at this time. Sawyer¹⁵ has classified four lines in mercury, which he attributes to such double transitions, and from them, arrives at the values of the three lowest "*p*'" levels.^{16,17} The lowest of these has a wave number of -7860 (negative, because it lies above the ionization level), so that excitation to this level ($1S-p_3'$) would require 11.35 V. This is 0.28 V. more than that found in the present work, which is far too great a difference to be attributed to experimental error in either method. Sawyer points out, however, that this level was determined by a single line, which might have a different interpretation; the other, and higher levels have as many as three transitions observable, and hence are much less in doubt. It is possible that a reclassification of these lines, with a lower level in mind, might bring about a better agreement.

CONCLUSIONS

The energy losses observed in this work are; 4.9, 5.4, 6.7, 7.7, 8.8, 9.8, and 11.07 V.—all save the last named one being those predicted on spectroscopic grounds. The circumstances of the appearance of 7.7 both increase confidence in the data given by the inelastic impact method, and explain the

difficulty of detection of certain losses. Failure to detect 4.7 V. losses is attributed to the extremely large probability and rapid rise of the 4.9 V. loss, together with a rather large velocity distribution. Excitation to the 3S and to all of the "4" levels, involving about 9.2 and 9.5 V. losses, are thought to be even less probable than 7.7 V., and hence not detected. The unexplained losses of the photoelectric method were not observed, although they should have been, had they represented actual quantized losses of electronic energy of any appreciable probability. The energy loss at ionization is not quantized. The new loss, of 11.07 V., is thought to represent new data opening up the question of p' energy levels and simultaneous excitation of two valence electrons. The present method has not yielded spark terms, but may do so, if ionization be accomplished prior to the excitation dealt with here.

In conclusion, the author wishes to express his appreciation for the help and encouragement given him by the staff of the physics department of the University of Iowa, and especially for the constant and generous guidance of Professor J. A. Eldridge.

THE MOTION OF SLOW POSITIVE IONS IN GASES

BY JAMES S. THOMPSON

RYERSON PHYSICAL LABORATORY, UNIVERSITY OF CHICAGO

(Received April 1, 1930)

ABSTRACT

Positive caesium ions with velocities of 3.5 to 600 equivalent volts have been studied in hydrogen and helium. No absorption of the ions in the apparatus used is found for pressures below 0.01 mm of mercury. For the higher velocities this absence of absorption persisted for pressures as high as 0.05 mm of mercury. In all cases the ions were retarded in passing through the gas and there is an approximate probability distribution of ion energies about an average retarded value. The retardation in all cases is found to be proportional to the pressure. For Cs^+ ions in helium the percent loss of initial energy varies from 11.5 for 400 volt ions to 55 for ions of 3.5 volts initial energy. Similar results are found for hydrogen. Values of the constant, h , of the error curve which are characteristic of a particular distribution are given for various velocities and pressures. An interpretation of the absence of scattering and the retardation of the ions is given on the basis of elastic collisions between ion and gas molecule. It is found that no absorption of the Cs^+ ions would be expected until the pressures are high enough to give rise to multiple scattering. The data on retardation give values of the radius of the Cs^+ ion as: 1.78A in helium and 3.09A in hydrogen. The slowing up of the ions offers an explanation of the large absorption of Cs^+ in helium found by Ramsauer and Beeck. Probability considerations show that for increasing velocities the energy loss per collision found in the present experiments is less than that to be expected on the basis of elastic collisions.

The absorption of Li^+ ions has been studied by three methods for velocities of 20 to 900 equivalent volts. The coefficients of absorption, C , representing the effective absorbing cross section have been determined by two methods. The general dependence of C on the ion velocity is the same for the two types of apparatus used, but the values of C are found to depend on the dimensions of the absorbing chamber. The results have led to the interpretation of scattering in which forces other than those due to elastic collisions are effective. No general retardation of the Li^+ ions was found. Values of C found by Ramsauer and Beeck are interpreted in terms of the dimensions of their apparatus. It is concluded that no absolute significance may be attached to values of atomic radii determined from measurements of this kind.

WHEN a beam of positive ions moves through a column of gas there is in general a weakening of the bundle which may be due to a number of different processes of interaction between ion and gas molecule. Neutralization of the ions, either from the capture of a free electron or an ionization of the gas molecule, scattering or a combination of these effects will contribute to a decrease in intensity. In addition, any retardation of the ions may show itself as an absorption unless precautions are taken in the experimental method of measurement. It is customary to express any absorption of the ion bundle in the relation:

$$N = N_0 e^{-xp/760L} \quad (1)$$

where N is the intensity of the beam after passing through a distance, x , of the gas at pressure p ; N_0 the intensity of the incident ions, and L the absorption coefficient, also referred to as the mean free path under standard conditions. Writing L in terms of the radii of the ion and gas molecule,

$$\begin{aligned} L &= 1/\pi n(R_{ion} + R_{mol})^2, \text{ or} \\ C &= \pi(R_1 + R_2)^2 = 1/Ln \end{aligned} \quad (2)$$

where C may be termed the effective absorbing cross section. Most of the experiments on absorption of positive ions have yielded in effect values for L and C .

A study of the motion of hydrogen and helium ions in helium has been made by Dempster using his positive ray apparatus.¹ He found that protons with velocities corresponding to potential differences of 14 to 900 volts passed through many helium atoms without neutralization and with slight changes of velocity and direction; while 900 volt helium ions in helium were absorbed much more readily and showed a mean free path but little greater than the kinetic theory value. These were the first experiments of this kind with low velocity positive ions.

Durbin² and Ramsauer and Beeck³ have studied the slow alkali metal ions in various gases and found in most cases abnormally long free paths varying up to ten times the kinetic theory value. Their experimental methods would not distinguish the three causes of absorption mentioned above.

Kennard⁴ modified the method used by Durbin and Ramsauer and Beeck, and by measuring the ions of various velocities which passed through the gas column was able to detect a change in velocity as well as any weakening due to other causes. He found that for 90 volt Cs^+ ions in hydrogen there was a decrease in speed equivalent to 1.3 volts per collision, but no evidence of scattering or neutralization, for pressures up to 0.008 mm of mercury. Slowing up was also observed for 35 and 90 volt Cs^+ ions in both hydrogen and helium with only a slight weakening of the bundle due to other causes. For Cs^+ in argon no slowing up was observed but there was a rapid absorption of the bundle with pressure, which Kennard interpreted as due to neutralization.

Recently, Cox⁵ has shown from experiments with Li^+ ions in mercury vapor that for gas-ion combinations which show no definite change in speed of the ion, the chief cause of absorption is scattering. The velocities were from 18 to 300 equivalent volts. For the ions of higher velocity range—10,000 to 50,000 equivalent volts—there is evidence of some scattering but the velocity losses are less than one-half of one percent.^{6,7}

Thus it appears that the entire problem of positive ion absorption is quite complex and depends not only on the gas-ion combinations, but on the velocity, gas pressure, apparatus and method used and other experimental variables. For heavy ions passing through light gases at moderate velocities the predominant effect seems to be a slowing up of the ion bundle, whereas for a light ion in a heavy gas the chief cause of absorption is due to scattering. Intermediate cases may show a combination of both effects; for example, Kennard found that for Na^+ ions with a velocity of 455 volts in hydrogen, there was a small but definite slowing up, together with an absorption probably due to scattering. As pointed out by Cox, it seems evident that the importance of any absorption process due to scattering, and, in some cases, of that due to retardation is dependent on the dimensions of the apparatus used and the method of measurement. Thus, the absorption constants usually calculated from such measurements have no absolute significance and cannot be interpreted in terms of any atomic process.

The purpose of the experiments to be described was: first, to make a more complete study of the motion of Cs^+ ions in hydrogen and helium, particularly in the region of low velocities, and, secondly, to investigate the process of absorption of a light ion in a light gas as typified by Li^+ ions in helium; and to study any dependence of this absorption on velocity.

CAESIUM IN HYDROGEN AND HELIUM

The results obtained by Kennard for 35 and 90 volt Cs^+ ions have been obtained for 100 and 200 volt ions in helium. The apparatus used is based on Dempster's method of positive ray analysis and is shown in Fig. 1.⁸ The cylinder *C* was removed in some experiments and a single collector mounted above the slit, S_2 . The ion source contained in the furnace, *A*, is made positive with respect to the slit S_1 , the emission current being held constant and measured with the galvanometer *G*. The ion beam enters the magnetic field and by varying the magnet current, is swept across the slit S_2 , after traversing the gas-path S_1MMS_2 . The dimensions of the path through the armature were, $3.0 \times 10 \times 112$ millimeters. The resultant intensity through S_2 is then measured by balancing the current to the collector against the ionization current from the RaE tubes shown at *R*. A Compton electrometer, *E*, adjusted to a sensitivity of 2500 divisions per volt was used as a null indicator. Helium was introduced into a reservoir by allowing it to pass slowly through a charcoal trap immersed in liquid air; after this preliminary purification the gas was admitted to the apparatus through a drying tube, a fine capillary and a second charcoal trap which was also kept at liquid air temperature. The gas was tested by observing the spectrum with a hand spectroscope, the lines showing distinctly on a dark background.

The gas enters the tube at *D* and is kept in circulation through the apparatus. Various pressures are established by adjusting the rate of pumping of the mercury diffusion pumps connected at *O*. An ionization gauge was

⁸ Dempster, Phys. Rev. 11, 316 (1918).

used in some experiments to show when steady gas pressures were attained, all final measurements being made with McLeod gauge attached at P . For a definite pressure and emission current the current through S_2 is measured as a function of the magnet current, four or five such curves being taken for a single accelerating potential.

Figs. 1 and 2. Diagram of apparatus.

The type of curves obtained are the same as those of Kennard and are shown in Fig. 2. For increasing pressures the peaks of the curves are seen to be shifted in the direction of lower ion velocities, the general symmetry of the curves being retained about the shifted peak. Within the limits of

experimental variation, the areas under these curves remain constant, showing that in traversing the gas-path S_1MMS_2 all the ions of various velocities reach the collector. Kennard observed this behavior for Cs^+ ions in hydrogen and helium for 35 and 90 volts velocities. He concluded that there was a general slowing up of the Cs^+ ions, and for pressures up to 80×10^{-4} mm of mercury, due to the constancy of the areas, that there was no neutralization or scattering of the bundle.

This behavior of Cs^+ ions for the velocities used in the above method indicated the possibility of isolating a single process of interaction between ion and gas molecule and of studying this process over a range of conditions in which it was operative.

In the procedure outlined above it is essential that the emission of ions through S_1 be held constant over a considerable period of time in order that the complete curves of Fig. 3 may be obtained for several gas pressures. This difficulty together with that of obtaining sufficient intensity with low velocity ions limited the range of the method. Also in establishing the equality of the areas under the curves shown, it is difficult to determine the exact range of the base line.

Experiments were tried with the two-cylinder method shown drawn to scale in Fig. 1 and used by Cox in experiments on Li^+ ions in mercury vapor.⁵ Here the ion bundle is accelerated to S_1 as before and bent through 180° in the magnetic field. The collimating slit C directs the beam up the axis of the cylinders C_1 and C_2 . Measurements to detect any absorption were made by first connecting C_1 and C_2 together with the switch B in position (1); then C_1 was grounded and those ions which had travelled over the extra gas-path of length C_1 were collected and measured in C_2 . Both values are determined with the balance method described. No absorption in C_1 for Cs^+ ions in helium was observed for velocities of 25 to 600 volts and pressures up to 0.013 mm of mercury. Here again the difficulty of obtaining sufficient intensity limited the range.

In order to study the behavior of Cs^+ more directly and over a range of velocities not possible with the magnetic methods described, a third tube was constructed and shown drawn to scale in Fig. 2. Tubes of similar construction have been used by Mayer,⁹ Akesson¹⁰ and Eldridge¹¹ in experiments on electron velocity distribution.

The source of ions was contained in the small electric furnace shown at A . The ions were accelerated to the slit B , passed through a field-free space within the nickel cylinder, C_1 , 9.2 cm long and were collected in the Faraday cylinder C_2 . The gas entered at D and was kept in circulation through the tube, various pressures being established by adjusting the rate of pumping of the mercury diffusion pumps connected at O . Pressures were measured with a McLeod gauge connected first at O and later, in order

to insure that no pressure gradient affected the measurements, to the central tube which supports the electrode above *F*. Helium was purified as in the experiments outlined above; hydrogen was admitted through a heated platinum tube sealed into the glass line and about which was circulated commercial hydrogen at atmospheric pressure.

In experiments with a tube of this type a particularly pure source of ions was essential as no magnetic separation was possible. This source was found in the mineral pollucite which is essentially a caesium aluminum silicate containing 27 percent caesium ($\text{H}_2\text{O} \cdot \text{Cs}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 9\text{SiO}_2$). The

Fig. 3

mineral is powdered and packed into the small resistance-wound furnace made of steel tubing 5 mm long and about 2.5 mm inside diameter. In some instances the mineral was mixed with powdered iron to make it conducting and allow it to fuse more readily. It was found that the substance could not be fused on a platinum strip as is the case with the lithium source, spodumene. This source was prepared and always placed in the magnetic analyzing apparatus before use and examined for other ions. No emission other than Cs^+ was detected for temperatures considerably above those normally used. At a dull red heat a very strong and steady emission of Cs^+ ions was obtained. The experimental tube and source were baked out thoroughly for several hours before use.

It was thought that the process of interaction of Cs^+ ion with hydrogen and helium was one of pure retardation, but to make certain of this, experiments were first tried to detect any weakening or absorption of the ion bundle due to causes other than slowing up. For this purpose the gauze shown on the end of C_1 in Fig. 2 was removed. The central electrode supported C_1 at the center, the ground connection through the stem being removed. By connecting the switch F in position 1, the total ion current to $(C_1 + C_2)$ was observed. Then with C_1 grounded, by moving F to position 2, the ions which reached C_2 after traversing the gas-path through C_1 were measured. As in the first type of tube both currents were measured by the balanced electrometer arrangement, intensities being proportional to the slit widths, S_1 . Measurements of the ratio, $C_2/(C_1 + C_2)$ were taken for increasing pressures in the tube so that any weakening of the beam was detectable in a decrease in this ratio. For very low velocity ions this ratio was not equal to unity for low pressures because of the divergence of the bundle caused by the field between A and B so that some of the ions hit the wall of C_1 . However, in all cases, values of the ratio were obtained for several pressures so that any real absorption could be observed.

In this way it was found that for pressures less than 0.01 mm of mercury, no appreciable absorption of the Cs^+ ions in hydrogen and helium took place for velocities of 3.5 to 600 equivalent volts. For velocities above 10 volts this absence of absorption persisted for pressures even higher than 0.03 mm of mercury. Below 10 volts and for pressures above 0.01 mm of mercury a definite weakening of the bundle set in and increased rapidly with the pressure. This absorption is probably due to the effects of multiple scattering as the number of collisions with the slow moving ions is increased, and is discussed later.

Thus for a considerable range of velocity and pressure the Cs^+ ions are not deviated appreciably from their path, making it possible to study the slowing up effect as an individual process over this range.

The arrangement used for observing the retardation of the ions is shown also in Fig. 2. The ions are accelerated as before, by applying a positive potential to A ; B and C_1 are grounded as shown; the ions pass through the field-free space C_1 , and are collected in the Faraday cylinder, C_2 . In some experiments a grounded shield was placed around the two cylinders but this was not used in general as the ion path is well shielded as shown and the grounded cylinder provided an extra leakage path. Any retardation takes place over the gas-path, AC_2 , measured from the ion source to the far end of the collector C_2 or 14.2 cm. With a constant pressure in the tube, increasing retarding potentials are placed on C_2 through the electrometer as shown. This potential is applied with respect to the gauze on C_1 , which gives a more uniform distribution of the field. The current to C_2 is then observed as a function of the retarding voltage. Hence, only those ions with velocities greater than or equal to the retarding potentials will be recorded in C_2 . In this way the velocity or energy distribution of the retarded ions was measured for various pressures. Curves of this type are shown in Fig. 4, which shows

the distribution for 6.4 volt Cs^+ ions in helium at the pressures given. Another set for 100 volt Cs^+ ions in hydrogen is shown in Fig. 5. In both these sets except for the lowest pressure the actual curve drawn represents the theoretical energy distribution fitted to the experimental data as explained below. The points shown were determined experimentally as described. Similar sets were taken for velocities ranging from 3.5 to 600 volts in both hydrogen and helium. Any point on these curves is proportional to the number of ions retaining energies equal to or greater than the corresponding voltages. In all such curves the distribution at low pressure was always taken as

Fig. 4

a control, since here the distribution of energies should be approximately homogeneous. The points shown in the curves of Figs. 4 and 5 were not corrected for small changes in the emission current at the various pressures so that no significance is to be attached to the absolute values of the ordinates shown. As explained above, separate experiments were made to determine any change in the current to C_2 with pressure.

By integration of curves of the form

$$y = ke^{-h^2x} \quad (3)$$

it was found that the resulting curve could be fitted to the experimental points, indicating that when the ions reached the collector there was an approximate probability distribution of energies about the average retarded value. This distribution is what would be expected from probability considerations, due to some ions making more collisions, and some less than the average number in completing the path, L . Each point on the curves of Figs. 4 and 5 represents the number of ions found to retain energies equal to or greater than the corresponding voltage. For a value of the retarding voltage,

V_R , the number of ions retaining energies greater than V_R would be expected to be given by

$$I = k \int_{V_R}^{\infty} e^{-h^2 V^2} dV$$

the constant, h , depending on the particular distribution. In order to obtain the value of h , which is characteristic of a particular energy distribution, we may consider the expression:

$$P = \frac{h}{\pi^{1/2}} \int_0^{V-V_0} e^{-h^2(V-V_0)^2} d(V-V_0) \quad (4)$$

for the probability that an ion will retain an energy between V_0 and V . Here V_0 is the average retarded velocity, represented in the experimental curves

Fig. 5

(Figs. 4 and 5) by the half ordinate, and corresponding to the peak value of the error curve. The constant, h , may be conveniently found by observing the energy, V_1 , at which the probability is one-fourth as indicated in Figs. 6 and 7. Setting:

$$h(V - V_0) = z$$

we then have that:

$$P = \frac{1}{\pi^{1/2}} \int_0^z e^{-z^2} dz = \frac{1}{4}$$

for $z = z_1 = h(V_1 - V_0)$. As, $z_1 = 0.477$, $h = 0.477/(V_1 - V_0)$.

If n is the average number of collisions, the probability of an ion making a number greater than n but less than, $n + z(2n)^{1/2}$ is:

$$\frac{1}{\pi^{1/2}} \int_0^z e^{-z^2} dz.$$

If the energy loss per collision were constant, $z(2n)^{1/2}$ would be proportional to $(V - V_0)$, or z/h . That is, we should expect h^2 to be inversely proportion-

Fig. 6

al to the number of collisions, the pressure, or the average energy lost by the ions, which is $(V_i - V_0)$, V_i being the initial velocity. Thus for a constant

Fig. 7

energy loss per collision, $h(V_i - V_0)^{1/2}$ would be constant. If $h(V_i - V_0)^{1/2}$ is less with ions of high velocity, it signifies that the energy loss per collision is less in this case.

In the case of the 6.4 volt Cs^+ ions in helium at a pressure of 98×10^{-4} mm of mercury, the dispersion, $(V_1 - V_0)$ was 0.55 and $h = 0.87$; $h(V_i - V_0)^{1/2} = 1.41$. Values of h calculated from the experimental data, together with the quantity, $h(V_i - V_0)^{1/2}$ are shown for various velocities and pressures in the Table I. From the values of h given in the table, the expected energy distribution may be calculated and compared with the experimental results. The theoretical curve is obtained for any particular distribution by the use of the proper h in the integral of Eq. (4). The resulting curves are shown for two initial velocities in Figs. 4 and 5 together with the experimental points. It is seen that the agreement is in general better for the low velocity ions and for the higher

pressures. On the high velocity side of the curves the points were obtained with much less precision.

The values of h given in the table are seen to decrease with increasing voltage and the values of $h(V_i - V_0)^{1/2}$ are not constant as would be expected

Fig. 8

if the energy loss per collision were the same for ions of all velocities. As explained above the decrease is what would be expected if the energy loss per collision decreases with the high velocity ions. In hydrogen, the consistently

larger values of h than in helium for corresponding voltages indicate that in this gas there is less loss of energy per collision.

The actual error curve distribution for the case of 6.4 volt Cs^+ ions in helium for a pressure of 98×10^{-4} mm of mercury is shown in Fig. 8. The full line represents the theoretical distribution of the velocities for curve (3) of Fig. 4. Here V_0 is 3.75 volts and V_1 is 4.30 volts; the points shown are obtained by graphical differentiation of the experimental curve.

Each of the curves in Figs. 4 and 5 represents a new distribution of energies about a most probable energy V_0 which is that corresponding to the half ordinate. The difference then between the applied potential and this half ordinate energy gives the retardation of the ions for the pressure shown. For each applied potential this retardation has been plotted as a function of the

Fig. 9

pressure and is found to be linear over a wide range. This slowing up took place over the gas-path AC_2 measured from the furnace source to the far end of the collector, C_2 , or 14.2 cm. From the curves the retardation for 0.01 mm of mercury was obtained since for this pressure no absorption was found. Fig. 9 shows this retardation, expressed as a percent loss of initial energy, as a function of the initial velocity in volts. Points for 600 volt ions, not shown on the curves, would fall on the lower linear portion if extended. The loss in helium is seen to be greater over most of the range as might be expected for the gas molecule of greater mass, especially if the interpretation is that of mechanical collisions. In both cases the loss decreases with increasing velocity. This is in agreement with the data cited for canal rays of 10,000 volts and more which show less than one-half of one percent loss of energy.^{6,7} Below forty volts the curves rise rather rapidly and tend to merge; extending them to the axis of ordinates indicates that the maximum loss for this pressure would be about 66 percent.

These results suggest an interpretation of the results of Ramsauer and Beeck³ for Cs^+ ions in helium that differs from their conclusions. In their experiments the apparatus used was similar to that described in connection with Fig. 1, except that the dimensions were much smaller. The method of observations was to hold the magnetic field constant and observe the weakening of the bundle for several gas pressures. Referring to Fig. 3, this is seen to be equivalent to observing the intensities along a vertical line drawn through the peak value of the lowest pressure curve used. It is evident that this method of observation would show an apparent absorption for the retarded ions. From their results, Ramsauer and Beeck calculate what is designated as the "Wirkungsquerschnitt," which is the value $1/L$ from Eq. (1), reduced to 1 mm of mercury. For Cs^+ ions in helium, they find a considerable absorption of the ions for velocities of 1 to 10 volts; for instance, reducing their values in terms of the effective cross section, C , gives a value of $11.3 \times 10^{-1} \text{ cm}^2$ for ions of 9 volts velocity; or in terms of the mean free path, $L = 33 \times 10^{-6}$

Fig. 10

cm under standard conditions. These values show a large opposing cross section of ion against molecule, whereas for the pressures used by Ramsauer and Beeck,³ no real absorption at all was observed in the present experiments. Fig. 9 shows that 9 volt Cs^+ ions suffer a loss in velocity of about 35 percent, which, as explained above, would account for the large value of C found by Ramsauer and Beeck.³ No relation to atomic constants can be attached to the values of C and to the various values of atomic radii calculated therefrom as they are at once seen to depend on the dimensions of the apparatus and the experimental method used. Thus the mechanism of absorption is of primary importance in the interpretation of these measurements.

It is of interest to compare the results for caesium ions with what would be expected on the basis of elastic collisions between ion and gas molecule. In Fig. 10 consider a Cs^+ ion moving forward with a velocity V among helium atoms at rest. If an elastic collision occurs with the helium atom at A , this atom is projected along OAB with a velocity, $2V \sin \theta$, provided the mass of the Cs^+ ion is very large compared to that of helium. Since the ratio is 133/4 we may take this velocity as a first approximation. The equality of momenta

in a transverse direction shows that the Cs^+ ion then receives a velocity at right angles to its direction equal to:

$$V' = 2V \sin \theta \cdot \cos \theta \cdot 4/133.$$

The angle made by the ion with its original direction is then,

$$\phi = V'/V = 8/133 \cdot \sin \theta \cos \theta$$

since V is only slightly altered. Now the number of collisions in the range, p to $p+\Delta p$ as shown in the figure is proportional to the area presented in the direction, V , i.e., to $2\pi p \Delta p$. Since the total number of collisions is proportional to, πa^2 , where a is the radius of the Cs^+ ion, we may write for the average angle of scattering,

$$\Phi = \frac{1}{\pi a^2} \frac{8}{133} \cdot \int_0^a \frac{p}{a} \left(1 - \frac{p^2}{a^2}\right)^{1/2} \cdot 2\pi p \cdot dp$$

where, from Fig. 10 $\cos \theta = p/a$ and $\sin \theta = (1 - p^2/a^2)^{1/2}$. This upon integration gives,

$$\Phi = \pi/133 = 0.023 \text{ radians.}$$

The maximum angle of scattering, for $\theta = 45^\circ$, gives

$$\phi_{max} = 0.030 \text{ radians.}$$

In the apparatus used, an ion would always reach the collector unless deflected by more than $10/92$ or 0.11 radians. Thus single scattering is unable to produce a weakening of the bundle. Experimentally, no weakening was observed until the pressure was made high enough to give rise to multiple scattering.

We may also calculate the energy loss to be expected on the basis of elastic collisions. In the Fig. 10 let m equal the mass of the helium atom and M the mass of the Cs^+ ion. On the basis of elastic collisions, the energy lost by the Cs^+ ion is equal to the amount gained by the helium atom, or,

$$\Delta E_0 = \frac{1}{2}m(2V \sin \theta)^2$$

for the loss due to a collision at angle, θ . The ratio of this loss to the initial kinetic energy of the Cs^+ ion is then,

$$\frac{\Delta E_0}{E_0} = \frac{\frac{1}{2}m(2V \sin \theta)^2}{\frac{1}{2}MV^2} = \frac{16}{133} \sin^2 \theta.$$

In travelling a distance, L , the average fractional loss per collision may be written, referring to Fig. 11 as:

$$\frac{\Delta E}{E} = \frac{1}{\pi a^2 L n} \int_0^{\pi/2} \{ (2\pi a \cos \theta)(a \sin \theta d\theta) L n \} \left(\frac{16}{133} \sin^2 \theta \right) = \frac{8}{133}$$

where, $a = r_1 + r_2$, the sum of the ion and atom radii; and, n = the number of helium atoms per cc for the pressure considered.

The energy remaining after, $\pi a^2 L n$ collisions may then be written as,

$$\left\{1 - \frac{\Delta E}{E}\right\} = \left\{1 - \frac{8}{133}\right\}^{\pi a^2 L n}. \quad (6)$$

From Fig. 9 we may obtain a value of the percent loss of initial energy of the Cs^+ ion for the smallest velocity observed. The value for helium is 55 percent for 3.5 volt ions. In Eq. (6),

$$L = 14.2 \text{ cm}$$

$$n = 3.48 \times 10^{14} \dots (p = 0.01 \text{ mm of mercury})$$

so that,

$$a = r_{\text{Cs}} + r_{\text{He}} = 2.88 \text{ \AA}.$$

Viscosity measurements give for the radius of the helium atom, $r_{\text{He}} = 1.10 \text{ \AA}$, so that we should expect a value for the radius of the Cs^+ ion,

$$r_{\text{Cs}} = 1.78 \text{ \AA}.$$

Herzfeld¹² gives values of r_{Cs^+} which vary from 0.83 to 2.36 \AA depending on the method of measurement. The radius of the xenon atom obtained from

Fig. 11

viscosity measurements is 2.44 \AA . Similar calculations for hydrogen, where $\Delta E/E = 4/133$ and the percent loss was 61.5, gave a value,

$$a = r_{\text{Cs}} + r_{\text{H}_2} = 4.55 \text{ \AA}.$$

A value for r_{H_2} from viscosity measurements quoted by Jeans as 1.36 \AA leaves for the radius of the Cs^+ ion,

$$r_{\text{Cs}} = 3.19 \text{ \AA}.$$

For ions of greater initial energy the percent loss decreases. This disagrees with the elastic collision interpretation which would make the percent loss a constant. We must conclude that at higher velocities the interaction at a collision of a Cs^+ ion with a helium or hydrogen molecule is different from

¹² Geiger Scheel, "Handbuch der Physik," Band XXII, 386, 1926.

that considered in the kinetic theory of gases and that less energy is lost than would be the case, were the collisions elastic.

LITHIUM IONS IN HELIUM.

With low velocity Li^+ ions in helium the change in the curves produced by increasing pressure was entirely different from that found in Cs^+ ions. We shall find that with the light ion, small angle scattering is the predominant phenomenon, whereas with the heavy Cs^+ ions, scattering was inappreciable in comparison with process of retardation. By using several different experimental arrangements it has been possible to establish the type of absorption that occurs over the range of velocities studied, namely 20 to 930 equivalent volts.

METHOD I

The apparatus used has been described in connection with the experiments with caesium and is shown drawn to scale in Figs. 1 and 2. In this method the cylinders C_1 and C_2 were replaced as before with a single Faraday cylinder, mounted above S_2 . The slit S_1 varied between 1 and 2 mm and in several instances runs were taken with this slit entirely removed.

Fig. 12

In Kennard's experiments the ion sources used were the positive ion iron catalysts supplied by Kunsman. These catalysts usually emit Na^+ and K^+ to an appreciable extent together with an ion possibly arising from the insulating cement of the furnace. This necessitates the assumption that the total emission current held constant and measured with the galvanometer G , is also constant in its composition throughout the series of observations. In order to obviate this difficulty the mineral spodumene (used by Hundley¹³) was investigated for purity in emission. A small crystal, less than 0.2 mm in diameter, was melted down on the center of a constricted platinum filament as shown in Fig. 12. This strip is mounted horizontally over the slit S_1 and replaced the furnace source at A (Fig. 1). At low temperatures in vacuum this source showed a large emission of Na^+ and K^+ but continued heating at a yellow heat removed these ions to less than one-half of one percent. By treating the substance in this way a very pure source of Li^+ was obtained, which in many cases could be used for 100 hours or more, with good intensity and constant emission. Due to the small value of the emission current to S_1 , an electrometer shunted with a high resistance replaced the galvanometer G in most of the experiments in an attempt to attain greater accuracy of observation. Since the method used depends on Eq. (1), the emission current N_0

¹³ Hundley, Phys. Rev. 30, 864 (1927).

must be constant and proportional to the actual ion current passing through S_1 . The current actually recorded represents the total ion current through S_1 as well as to neighboring metal parts connected to the magnet armature. It was not possible, with this arrangement, to determine whether the actual current through the slit remained constant, but it was assumed that a constant fraction of the total emission current entered S_1 . This assumption is not entirely justified as spreading of the beam may occur due to the admission of

Fig. 13

gas, or the actual character of the emission from the source may change, giving a bundle of varying divergence. This indefiniteness accounts partially for the variation of the absorption coefficients obtained by this method, although no difficulty was found in getting reasonable checks.

The method of procedure is the same as that of Kennard and has been outlined above. The type of curves obtained for five different pressures with a constant accelerating potential is shown in Fig. 13 for Li^+ ions of 50 equiva-

lent volts. Sets of curves of this type were taken for velocities varying from 20 to 931 volts and for each velocity at least three such sets were obtained. From each pair of pressures of each set of curves, the value of the mean free path, L , was determined, making use of Eq. (1). The gas path was 11.2 cm in length, so that L was given by:

$$L = 11.2 \times (p_2 - p_1) / 760 \times 2.30 \times \log \frac{N_1}{N_2}.$$

From Eq. (2), C is then obtained, where,

$$C = \pi(R_{Li} + R_{He})^2 = 1/Ln$$

and

$$n = 2.70 \times 10^{19}.$$

Values of C are shown as curve I, Fig. 14 for ion velocities ranging from 20 to 500 equivalent volts; a value of C for 931 volts is not shown on the curve, but

Fig. 14

has a value of $9.5 \times 10^{-17} \text{ cm}^2$, and would fall on the lower linear portion if extended. Using kinetic theory values of the atomic radii as,

$$R_{He} = 1.10 \times 10^{-8} \text{ cm} \text{—viscosity measurements}$$

and, $R_{Li} = 0.41 \times 10^{-8} \text{ cm}$ —crystal lattice data we find for C , $C = 70.1 \times 10^{-17} \text{ cm}^2$ and this value is shown as a dotted line in Fig. 14. In terms of the mean free path, the values of L found vary from about one-half the kinetic theory value at 20 volts to almost eight times this at 931 volts. Reducing Ramsauer and Beeck's values of the "Wirkungsquerschnitt" for Li^+ and helium in terms of C we find for 16 volt ions,

$$C = 42 \times 10^{-17} \text{ cm}^2.$$

This value is about one-third of that found in the present experiments which, from the curve, would give 130×10^{-17} . The difference is accounted for by the dimensions of their apparatus, which had several times the angular aperture used in the present experiments. It has been found that the rate of absorption of the lithium ions depends strongly on the dimensions of the measuring chamber, which indicates that the process is one of scattering. On this basis a considerably smaller value of C would be expected for the wider apertures used by Ramsauer and Beeck.³ As in the experiments of Cox, the interpretation of the behavior of Li^+ in helium as due to scattering is strengthened from the results obtained with a second type of apparatus.

METHOD II

This method has been used by Cox and described by him in detail for the case of lithium ions in mercury vapor.⁵ The experimental tube is shown in Fig. 1, where the dimensions of the various parts are drawn to scale. Measurements of C and L are based on Eqs. (1) and (2), where the length of the absorbing gas path is equal to 11.3 cm. For a given pressure, the total ion current (N_0), to C_1 and C_2 is measured by connecting these two cylinders together with the switch B in position (1). Then with B in position (2), C_1 is grounded and the value of N is measured as the ion current to C_2 . This method allows a more rapid determination of N and N_0 and eliminates the problem of measuring the emission current to S_1 . Values of C and L were determined from observations at three different gas pressures. In all cases the currents to $C_1 + C_2$ and to C_2 were equal for the lowest pressures attainable (10^{-5} mm of mercury). This equality was attained by means of the collimating slit, C , placed over the emergent slit S_2 , which directed the ions up the axes of the cylinders; in this way none of the ions struck the cylinder C_1 at low pressures.

The values of C determined in this way are shown plotted against the ion velocity in Fig. 14, curve II. It is seen that the general shape of this curve is identical with that obtained with Method I, but that in all cases the values of C are smaller. In both cases the values of C rise sharply for velocities below 40 volts, in the one case rising to a value over twice that calculated from kinetic theory values and in the second case approaching the crystal lattice value for low velocities. The dimensions of the absorbing paths for the two methods correspond to those used by Cox and while the actual values of C are smaller, as might be expected with the lighter gas, the same change in these values is found for the two types of apparatus. These results show that the most reasonable interpretation of the process is that of scattering in which forces other than those of elastic collisions come into play. For the large scattering apertures of Method II, a much larger cone of rays may pass over the absorbing path than for Method I, where the angular opening was several times smaller and many more of the ions were lost through deflections to the walls of the chamber. It has been shown by Dempster⁵ that the rate of absorption may show a strong dependence on the dimensions of the apertures, provided some law of force other than that of elastic collisions is effective.

Experiments on the scattering of the Li^+ ions were also tried, using the apparatus shown in Fig. 2. Results obtained for several velocities confirm the conclusions reached above,—that the absorption of the ions is due to scattering and depends on the dimensions of the absorbing chamber and of the collector. Velocity distribution curves were also obtained for Li^+ in helium by the method of retarded potentials, used with Cs^+ ions. This distribution for 50 volt Li^+ ions is shown in Fig. 15. It is seen that the shapes of these curves

Fig. 15

are quite different from those obtained with Cs^+ ; they do not shift to the left as a whole and some of the ions appear to retain approximately their full initial velocity. The decrease in the number of ions of any particular velocity with pressure is probably due to a decrease in the forward component as a result of scattering, so that we have an "absorption" process which involves only a scattering of the ion bundle as distinct from retardation.

Professor A. J. Dempster suggested the experiments reported on in this paper. The writer is indebted to him for the theory of retardation of the Cs^+ ions as well as for invaluable suggestions and advice regarding experimental procedure and interpretation of results.

THE ABSORPTION COEFFICIENT FOR SLOW
ELECTRONS IN GASES

By C. E. NORMAND

DEPARTMENT OF PHYSICS, UNIVERSITY OF CALIFORNIA

(Received April, 1, 1930)

ABSTRACT

The absorption coefficient has been measured in H_2 , He, A, Ne, N_2 , and CO for electrons with velocities corresponding to from 0.5 to 400 volts. As a result of the high resolving power of the apparatus fine structure was found in the curves of all the gases. A minimum in the absorption coefficient curve was found in every case at velocities between 0.7 and 1.1 (volts)^{1/2}. A lack of agreement between the present measurements at velocities below 2 volts and recent results of Ramsauer and Kollath appears to be due to a difference of about 0.5 volts in the velocity scales of the two sets of observations.

THE absorption coefficients for slow electrons in hydrogen, helium, argon, neon, nitrogen, and carbon monoxide have been rather definitely established by the investigations of Ramsauer,^{1,2} Brode,³ and Bruche.^{4,5,6} Measurements in each of these gases have been made by two or more observers. The object in redetermining the absorption coefficient curves for these gases was two-fold: first to detect any fine structure in the curves which might be brought out by the use of an apparatus having a velocity resolving power higher than had previously been used, and second to extend the measurements as far as possible into the low velocity region.

APPARATUS AND METHOD

The apparatus and method employed in this experiment were essentially the same as used by Brode in determining the absorption coefficient in gases.³ The apparatus used in producing the electron beam was the one used by Brode in his determinations of the absorption coefficient in mercury⁷ and the alkali metal vapors.⁸ Except for the tungsten filament the apparatus was constructed entirely of tantalum. The electron source was a 3 mil tungsten filament placed along the axis of a cylinder 7 mm in diameter. The electrons were accelerated to the cylinder. A narrow beam of these electrons passed through a longitudinal slit 0.2 mm wide and 5 mm high in the cylinder, and was bent by a magnetic field into a circular path defined by a system of

four slits. The last slit of this system was 1 mm wide and 10 mm high. Electrons passing through this last slit entered a collector and were measured by a high sensitivity galvanometer placed between the collector and ground. The reading, I , of this galvanometer was taken as a measure of the intensity of the beam at the end of its path.

The initial intensity of the electron beam was taken as proportional to the total emission, M , from the slit in the cylinder which surrounded the filament. That this proportionality holds, even at low velocities, throughout the pressure range used is shown by the fact that the logarithm of the ratio of I to M is a linear function of the pressure. Fig. 1 shows several examples, taken in helium, of this linear relation. The consistency with which the points fall on a straight line is also an indication of the experimental accuracy of the determinations of the absorption coefficient at these low velocities.

Fig. 1. Log of ratio of maximum current I at collector to total current M from slit in cylinder as a function of pressure, for low velocity beams in helium.

Due to the potential drop in the filament and the contact e.m.f. between the tantalum cylinder and the tungsten filament the applied potential will not give the true velocity of the electrons. The true velocity was determined from the magnetic field required to bend the electron beam into the circular path defined by the slit system of the apparatus. If r is the radius of this path, H the magnetic field strength in gauss, and V the energy of the electrons in equivalent volts, $H \cdot r = 3.3 V^{1/2}$. Since r is a constant of the apparatus the electron velocity in root volts is proportional to the magnetic field strength or to the current, I_h , producing the magnetic field. Working with acceleration potentials of 100 volts or more, where the filament drop and the contact e.m.f. were negligible, the square root of the accelerating potential when plotted against I_h gave a straight line passing through the origin, Fig. 2. From the slope of this line the velocity corresponding to any value of I_h could be calculated. For accelerating potentials below 25 volts the influence of the filament drop and the contact e.m.f. becomes appreciable causing the points to lie above the straight line which gives the true velocity.

As a check of this method of velocity determination retarding potential curves were taken at a number of velocities between 0.5 and 1.2 volts. With a given accelerating potential I_h was varied until I was a maximum. From this value of I_h the velocity of the electrons was calculated. A retarding

Fig. 2. Deflecting magnetic field current I_h as a function of the square root of the accelerating potential.

potential was then applied between the collector and ground and the values of I corresponding to measured increasing values of the retarding potential were recorded. The points of inflection of the curves obtained by plotting the collector current, I , against the retarding potential give the velocity of the electrons. Four of these curves are shown in Fig. 3. The vertical lines indicate the velocity as calculated from the deflecting magnetic field

Fig. 3. Intensity of electron current arriving at collector as a function of retarding potential applied between collector and ground.

current I_h , Fig. 2. For six velocities between 0.5 and 1.2 volts the mean deviation of the values as measured by the two methods was 0.014 volts.

These retarding potential curves give also a measure of the velocity resolving power of the apparatus. The width of the half maximum of the

electron velocity distribution curves is found to be 0.035, 0.040, 0.031, 0.030 volts^{1/2} for mean velocities equivalent to 0.56, 0.79, 0.88, 1.18 volts respectively. From the dimensions of the apparatus the maximum variation of the velocity of the electrons passing through the last slit should be about 3 percent of the mean velocity.

RESULTS

The results are shown in Figs. 4 to 9 where the absorption coefficient, α , is plotted as a function of the electron velocity in volts^{1/2}. The previous results of Brode, and Bruche, are also given. All the observed values of α have been plotted in each case. The consistency of the results is shown by the fact that many of the points taken on different days agree within less than one percent. α is expressed in square centimeters per cubic centimeter of the gas at 0°C and a pressure of 1 mm of Hg.

Hydrogen was prepared by the electrolysis of barium hydroxide and was further purified and dried by passage over heated copper and through a phosphorous pentoxide tube. The general form of the curve agrees well with the results of Bruche. A small secondary maximum in the curve appears at 2.2 volts^{1/2}, and at 1.55 volts^{1/2} a sharp peak similar to those observed by Brode in the alkali metal vapors is superimposed on the broad maximum previously observed. A distinct minimum occurs at 1.1 volts^{1/2} beyond which the curve rises rapidly with decreasing velocity.

Helium was purified by slow passage through a charcoal trap immersed in liquid air, the trap having been previously baked at 500°C. At the higher velocities the results are in good agreement with those of Brode. The maximum, however, occurs at a velocity lower than determined by Brode and Bruche and appears as two distinct and almost equal maxima. Beyond the second maximum is a minimum at 0.92 volts^{1/2} and for still lower velocities the curve rises slightly.

Argon was purified by a magnesium arc. There are indications of fine structure between 4.5 and 5.5 volts^{1/2}. The minimum is at about 0.8 volts^{1/2}.

Neon, purchased as 99.5 percent pure, was used without further treatment. The value of α increases steadily to a maximum at about 5 volts^{1/2}. From here the curve drops irregularly to a final minimum at 0.85 volts^{1/2}.

Nitrogen was prepared by the decomposition of sodium azide on being heated. The curve has a small maximum at 12 volts^{1/2}, pronounced fine structure between 2 and 3 volts^{1/2} and a very large and sharp maximum at 1.5 volts^{1/2}. A slight nick occurs at 1.2 volts^{1/2} and a final minimum is reached at slightly below 1 volt.

Carbon monoxide was prepared by the decomposition of formic acid on being dropped into hot sulphuric acid, and was dried by passage through a phosphorous pentoxide tube. The results are in very good agreement with those of previous observers. The similarity between the CO and N₂ curves is seen to persist even in the fine structure.

Fig. 9. The absorption coefficient α for electrons in carbon monoxide as a function of the velocity of the electrons.

LOW VELOCITY RESULTS

For velocities below 1 volt the intensity of the electron beam drops off very rapidly with decreasing velocity. Somewhat greater intensity and extended range toward lower velocity was obtained by applying an accelerating potential of about 1.5 to 2 volts and then retarding the electrons to the desired velocity. The values of α obtained with and without the auxiliary

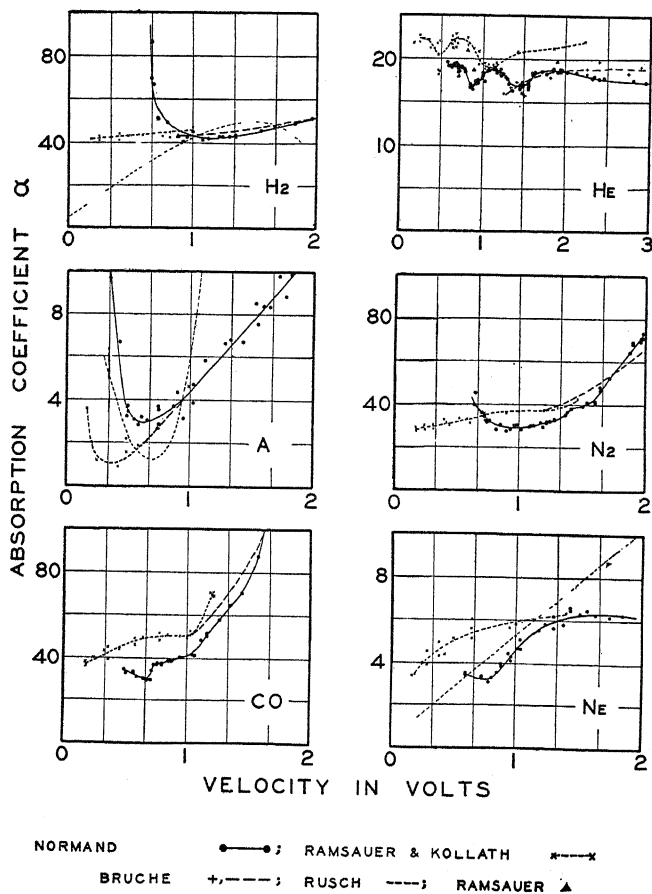

Fig. 10. The absorption coefficient α for very slow electrons in H_2 , He, A, Ne, N_2 , and Co as a function of the energy of the electrons in volts.

retarding potential were identical. The rapid diminution of intensity, however, rendered impossible the determination of α for velocities lower than about 0.5 volts except in the case of argon where measurements were extended to about 0.3 volts.

The results of these measurements for velocities below 2 volts, (3 volts in the case of He), are given in Fig. 10 together with the recent results of Ramsauer and Kollath,^{9,10} the earlier results of Bruche,¹¹ and the points

⁹ C. Ramsauer and R. Kollath, Ann. d. Physik 3, 536 (1929).

¹⁰ C. Ramsauer and R. Kollath, Ann. d. Physik 4, 91 (1929).

¹¹ M. Rusch, Phys. Zeits. 26, 748 (1925).

obtained by Ramsauer¹ in his first measurements. Here α is plotted as a function of the electron energy in equivalent volts rather than of electron velocity, volts^{1/2}. In no case is the agreement with Ramsauer and Kollath as good as might be expected from the accuracy of the measurements in each case.

A comparison of the results in the case of helium is especially interesting. The actual magnitude of the values of α given here are about 17 percent smaller than those given by Ramsauer and Kollath. Neglecting this difference in magnitude, which is of little importance, the two curves are seen to be nearly identical if Ramsauer and Kollath's velocities are increased by about 0.4 volts or if the velocities in this paper are decreased by the same amount. The agreement with the results obtained by other observers is seen to be better for the values of velocity given in this paper than for those given by Ramsauer and Kollath.

What has been said about the disagreement of the values of the velocity for helium is equally true for all the other gases measured. The magnitudes of the coefficient are in somewhat closer agreement but the volt scale is still displaced by about 0.4 to 0.6 volts. As already described, the velocity has been carefully checked throughout these measurements. Ramsauer and Kollath have also checked their velocities by both the retarding potential and the magnetic deflection method. The most probable source of the discrepancy would appear to be a contact e.m.f. The thin sheet tantalum parts of the apparatus used in this experiment were spotwelded together. The apparatus was baked at 500°C for several hours and the tantalum parts were heated to a bright yellow with an induction furnace. At no time were unsteady conditions such as reported by Ramsauer and Kollath observed. The apparatus of Ramsauer and Kollath was constructed of brass and placed under an evacuated bell-jar. The unsteady conditions arising from contact e.m.f.s between the parts of the apparatus made necessary the complete dismantling of the apparatus and the scraping of all metal surfaces at intervals of about 10 days. By this treatment steady and repeatable measurements were obtained with their apparatus.

The author wishes to express his indebtedness to Professor R. B. Brode for proposing this investigation, for his many helpful suggestions, and for his interest throughout the work.

ON THE CONCENTRATION OF METASTABLE MERCURY ATOMS

BY E. GAVIOLA

INSTITUTO DE FISICA, LA PLATA UNIVERSITY, ARGENTINA

(Received March 26, 1930)

ABSTRACT

The concentration of metastable atoms in presence of 3 mm nitrogen obtained using the measurements of Stuart seems to be in contradiction with a calculation given here using observations of Wood. The contradiction disappears if the different statistical weights of the levels 2^3P_1 and 2^3P_0 are taken in account. Corrected curves for the number of metastable atoms as functions of the foreign gas pressure are given for CO, H₂O, N₂, A and He which are to replace the corresponding curves of the previous paper. It is shown that the assumption of the author that by high primary light intensities the number of metastable atoms increases only with the square root of the intensity is strikingly supported by measurements of Wood.

THIS paper is a continuation of a previous one¹ by the author "On life and concentration of metastable atoms and the quenching of mercury resonance radiation." The concentration of metastable mercury atoms produced by collisions of resonance ones optically excited with nitrogen (or other foreign gas molecules) can be calculated numerically from the well-known fact that the introduction of a few mm of nitrogen into the vessel containing the mercury vapour (illuminated by a quartz mercury lamp) produces a many-fold increase in the intensity of the visible mercury lines emitted as fluorescence by the vapour. R. W. Wood² observed increases of the intensity of the green line 5461 ranging from 16 to 32 times. He interpreted this increase as due to the accumulation of metastable atoms when nitrogen is present and he was able to show experimentally by means of the absorption of the line 4046 that metastable atoms actually were present in large amounts. Let us now calculate numerically how many metastable atoms were present in the experiments of Wood, repeated and extended afterwards by the author.³

I

The green line 5461 is emitted by the 2^3S_1 level and its intensity in fluorescence which we will call J_{5461} is equal to

$$J_{5461} = A_{5461} \cdot N_s \quad (1)$$

if A_{5461} is the Einstein spontaneous transition probability and N_s the number of atoms in the level 2^3S_1 . This level can be reached when mercury vapour alone is in the fluorescence vessel ("vacuum" case) practically only³ through

¹ E. Gaviola, Phys. Rev. **34**, 1373 (1929).

² R. W. Wood, Phil. Mag. **50**, 761, 774 (1925); **4**, 466 (1927).

³ E. Gaviola, Phil. Mag. **6**, 1167 (1928).

the absorption of the line 4358 of the arc on the part of the the resonance atoms in the level 2^3P_1 , the number of which we call N_1^0 . It is therefore possible to write

$$N_s(\text{vacuo}) = \frac{1}{c} N_1^0 \cdot I_{4358} \cdot B_{4358} \cdot \tau_s \quad (2)$$

where I_{4358} is the intensity of the line 4358 of the primary light source, B_{4358} its Einstein absorption coefficient and τ_s the mean life of the atoms N_s .

If a few mm pressure of nitrogen gas are admitted to the vessel containing the saturated mercury vapour, many resonance atoms are brought down by collisions with nitrogen molecules to the metastable level 2^3P_0 where owing to

Fig. 1. Diagram of transitions.

is long life they accumulate until a concentration is obtained which, as the absorption experiments show is many times larger than the one of resonance atoms. The level 2^3S_1 is reached now practically only by the absorption of the line 4046 of the primary lamp on the part of the metastable atoms N_0 and consequently

$$N_s(\text{gas}) = 1/c \cdot N_0 \cdot I_{4046} \cdot B_{4046} \cdot \tau_s. \quad (3)$$

It may be thought that the admission of nitrogen might also disturb the atoms in the level 2^3S_1 diminishing their number as a result of collisions, in which case formula (3) would give too large numbers. But according to recent results of Hanle and Richter⁴ it takes at least 80 mm pressure of nitrogen to produce noticeable influence upon the level 2^3S_1 . Formula (3) is therefore correct for all pressures below 80 mm and as our pressures do not exceed 10 mm we can quietly use it. Combining (1) with (2) and with (3) and dividing we obtain

$$J_{5461}(\text{gas})/J_{5461}(\text{vacuo}) = N_0/N_1^0 \cdot I_{4046}/I_{4358} \cdot B_{4046}/B_{4358}.$$

This ratio was photographically measured and found to be equal to 32 in Wood's earlier experiments, therefore

$$N_0/N_1^0 = 32 \cdot I_{4358}/I_{4046} \cdot B_{4358}/B_{4046}. \quad (4)$$

Now, the ratio I_{4358}/I_{4046} of the intensities of the blue and violet lines of the arc has been repeatedly measured and found to be equal to 2. As both lines

⁴ W. Hanle and E. F. Richter, Zeits. f. Physik 54, 816 (1929).

are emitted by the same upper level, the ratio of their intensities gives at the same time the relation of the values of their corresponding Einstein emission coefficients A_{4358} and A_{4046} if that value is not falsified by absorption or reversal of the lines before they leave the mercury lamp. As that ratio is the same for the lines of the primary lamp when the discharge is magnetically deflected against the wall of the tube as for the secondary fluorescence light in the case of "vacuo" when practically no reabsorption can take place, one can write with confidence

$$A_{4358}/A_{4046} = 2 = I_{4358}/I_{4046}. \quad (5)$$

Between the coefficients A and B there is a relation

$$A = B \cdot 2h\nu^3/c^2 \cdot q_1/q_2 \quad (6)$$

where q_1 and q_2 are the statistical weights of the lower and upper levels respectively. The statistical weights of the levels 2^3P_0 , 2^3P_1 and 2^3S_1 are 1, 3 and 3, therefore for 4358 $q_1/q_2 = 1$ and for 4046 $q_1/q_2 = 1/3$. We can then write

$$A_{4358}/A_{4046} = 2 = B_{4358}/B_{4046} \cdot (\nu_{4358}/\nu_{4046})^3 \cdot \frac{1}{3}$$

and since $(\nu_{4358}/\nu_{4046})^3 = 0.8$ we obtain

$$B_{4358}/B_{4046} = 7.5.$$

Introducing the now known numerical values in formula (4) we have finally

$$N_0/N_1^0 = 32 \times 2 \times 7.5 = 480. \quad (7)$$

That means that when a few mm of nitrogen are present in the tube the number of metastable atoms is 480 times larger than the number of resonance atoms when no nitrogen is present. This last number can be easily obtained numerically if the intensity of the primary line 2537.5 is known. N_1^0 is for instance equal to one if 10^7 light quanta are absorbed per second in the volume element considered (since the life of 2^3P_1 is 10^{-7} sec.).

II

In a former paper of mine on the same subject¹ I have made a numerical calculation of the ratio N_0/N_1^0 as a function of the foreign gas pressure for different gases (and among them for nitrogen) using the measurements of Stuart for the quenching of resonance radiation and some other experimental data. Now, Fig. 5 of that paper indicates that for a pressure of about 3 mm of nitrogen (which was the pressure used by Wood to obtain a 32 fold increase of the green line) the ratio N_0/N_1^0 ought to be about 1200. This number is nearly three times larger than the one obtained above. It is therefore necessary to solve this contradiction. This we shall here do. The values of my former paper were all calculated neglecting the fact of the different statistical weights of the levels 2^3P_1 and 2^3P_0 .⁵ If we take this fact into account, none of the previous formulas is changed but the value α which

⁵ Dr. H. Beutler kindly called my attention to this point.

indicates the ratio N_0/N_1 for the case of thermal equilibrium and is given by the formula

$$\alpha = q_0/q_1 \cdot e^{w/kT} \quad (8)$$

where q_0 and q_1 are the statistical weights of the levels 2^3P_0 and 2^3P_1 respectively and w their energy difference, this value α becomes three times smaller than it was assumed to be in the previous paper because $q_0/q_1 = 1/3$. For the same reason the constants b and E_0 of Table I of that paper are three times too small. If we recalculate now the curves for N_0/N_1^0 as a function of

Fig. 2. Number of metastable atoms as a function of the foreign gas pressure if 10^7 quanta are absorbed per second.

the pressure of foreign gases using three times larger values for b and E_0 and a three times smaller α we obtain the curves reproduced in Figs. 2 and 3 which are to take the place of Figs. 5 and 6 of the previous paper. We see in Fig. 2 that the number N_0/N_1^0 for about 3 mm nitrogen pressure has reduced itself to about 700. This number is still larger than the one obtained independently in the first part of this paper but we have to remember that the number 480 corresponds to the experimental conditions of Wood while the number 700

Fig. 3. Number of metastable atoms as a function of the foreign gas pressure for $N_1^0 = 1$ (10^7 quanta absorbed per second).

to those of Stuart. The main difference between the experimental conditions of both observers was that Wood used a considerably larger primary light intensity. As I have shown in the previous paper N_0 increases for large primary light intensities not proportional to the intensity itself but to the

square root of it, while N_1^0 grows on linearly. The relation N_0/N_1^0 must therefore become smaller for large intensities, as in the case of Wood. An interesting confirmation of this result is given by the measurements of Wood himself. In his earlier experiments⁶ he obtained as said above a 32 fold increase of the green line by the admission of nitrogen. After that he increased his primary light intensity considerably by pressing the arc discharge against the wall with a magnetic field. The increase of the green line was now at best only 15 fold.⁷ The ratio N_0/N_1^0 had decreased therefore (compare formulas (4) and (7)) to 225. Since the decrease of N_0/N_1^0 for large intensities is due to collisions between two metastable atoms which destroy both of them (one is excited to a higher level, the other becomes normal) the above result is a striking hint at the fact that the probability of such collisions (collision-section) must be rather large.

THE MOST PROBABLE 1930 VALUES OF THE
ELECTRON AND RELATED CONSTANTS

BY ROBERT A. MILLIKAN

NORMAN BRIDGE LABORATORY OF PHYSICS, CALIFORNIA INSTITUTE, PASADENA

(Received April 8, 1930)

ABSTRACT

The conclusions are reached that: (1) No such empirical oil-drop formula as that suggested by H. A. Wilson can be valid, (2) It is highly improbable that the spectroscopic fine structure constant can be a whole number—either 136 or 137, (3) The most probable 1930 values of e , N , and h , are the same as in 1917, corrections due merely to new determinations of the velocity of light and the absolute value of the ohm being alone needed. These values so corrected are

$$e = (4.770 \pm 0.005) \times 10^{-10} \quad h = (6.547 \pm 0.011) \times 10^{-27} \quad N = (6.064 \pm 0.01) \times 10^{23}.$$

(4) If Lewis and Adam's theoretical equation is considered valid the probable errors are much smaller than the foregoing estimates.

THE first purpose of this paper is to comment on Professor H. A. Wilson's "Note on the Value of the Electric Charge,"¹ in which he concludes that "the oil-drop experiments do not definitely exclude" a value of e one percent higher than 4.774×10^{-10} ; the second purpose is to express an individual 1930 judgment, with the reasons therefor, as to the best values of these constants in view of all that has been done to date in the way of their exact evaluation; the third purpose is briefly to discuss the mutual restrictions which the theorists and the experimentalists impose upon each other; and the fourth is to present evidence bearing on Eddington's contention that the spectroscopic fine-structure constant is a whole number.

I. OIL-DROP METHOD'S PRECISION

If there were nothing more to the oil-drop work than the finding of some empirical equation that would reproduce the experimental data published in my 1917 paper,² then the statement quoted above might have some justification; but the experimental facts are, first, that Professor Wilson's empirical equation merely fits the relatively *short portion* of the oil-drop curve which corresponds to these data, and shoots above a considerable number of *observed points* farther down on the curve, that is, corresponding to smaller values of $1/pa$, then runs into the axis at a point much higher than these observed points permit; second, that it departs very largely from the *observed curve* at its upper end, that is, for large values for $1/pa$. For not only has the complete oil-drop curve from very low to very high values of $1/pa$ been worked out empirically so that we know by experiment

¹ H. A. Wilson, Phys. Rev. **34**, 1493 (1929).

² R. A. Millikan, Phil. Mag. **34**, 1 (1917).

that no such equation as that given by Professor Wilson is valid, but also—and this is more important—in view of a group of papers, some by myself,³ partly experimental and partly theoretical, and a masterly one by Epstein,⁴ *we now know precisely why Stoke's law of fall breaks down*, and why the law of fall embodied in the oil-drop equation takes its place.

I shall later in the paper have reason to insist that the theorist is bound to build his theories so that they do not collide head on with experimental facts; but at this point my insistence is that the experimentalist is not justified in setting up an empirical equation which makes Nature behave in a way which established and well verified theory tells him that she cannot behave. With this my comment upon Professor Wilson's paper is ended, and possibly no further remarks on e , h , and N would be needed had not Professor Zwicky's recent work on the secondary or block-structure of crystals gone far toward clearing the atmosphere surrounding these constants since Birge's masterly review⁵ of last July appeared. This may perhaps justify the following brief historical review and new appraisal of where these constants now seem to me to stand.

II. CHANGES IN e , h , AND N IN FOURTEEN YEARS

Fourteen years ago, at the conclusion of seven years of work on the experimental evaluation of these three constants, the electron, the Avogadro number, and Planck's quantum of action, the following were published as the most reliable values then attainable:²

$$\begin{aligned} e &= 4.774 \pm .005 \times 10^{-10} \\ h &= 6.547 \pm .006 \times 10^{-27} \\ N &= 6.062 \pm .006 \times 10^{-23} \end{aligned} \tag{1}$$

and these values have been incorporated into most of the tables and texts compiled since that time; but quite recently some uncertainty has arisen, and there has been a widespread discussion of these constants, stimulated, in the first instance, by Eddington's theoretical suggestion as to what ought to be the value of the spectroscopic fine-structure constant, and in the second place by the more recent experimental work of Bäcklin,⁶ Wadlund,⁷ and Bearden⁸ on the comparison of x-ray wave-lengths as determined by ruled gratings and by crystals. After this discussion, the following is where the matter now stands from the viewpoint of an experimentalist,—that is, the man who is engaged in making the measurements themselves and who has the feeling and the judgment that possibly only the observer can have about the relative reliability of the readings involved.

³ R. A. Millikan, Phys. Rev. **21**, 67 (January 1923); also **21**, 217 (March 1923); also **22**, 1 (July 1923).

⁴ P. S. Epstein, Phys. Rev. **23**, 710 (June 1924).

⁵ Raymond T. Birge, Phys. Rev. Supplement **1**, 1 (1929).

⁶ E. Bäcklin, "Absolute Wellenlängenbestimmungen der Röntgenstrahlen," Uppsala Dissertation, 1928.

⁷ A. P. R. Wadlund, Proc. Nat. Acad. Sci. **14**, 588 (1928), and Phys. Rev. **32**, 841 (1928).

As to the electron, I think it is generally agreed that the oil-drop method still remains the chief, if not the sole, reliance of the physicist, so far as directness, reliability, and precision are concerned, in arriving at its value. I had myself hoped, and expected, that the comparison of wave-lengths as determined by ruled gratings and by crystals would lead to greater precision in the fixing of both N and e , but I now feel sure that both (1) the experimental results obtained by this method, and (2) Zwicky's theoretical work (Proc. Nat. Acad. March, 1930) on the secondary structure of crystals, show that this method cannot have anything like the reliability which we had hoped that it would show, and therefore that all of the methods which depend upon crystal grating-space, as computed from density and N , had better be left out of the accounting.

† No new work has been done by the oil-drop method that is comparable in elaborateness nor precision with that published in 1917, but the fundamental constants entering into that method, such as the velocity of light and the value of the ohm, have been redetermined within that period, so that *the 1917 data, treated precisely as it was then treated, but combined with Michelson's new value of the velocity of light, namely, 2.99796 instead of 2.999, and the absolute value of the ohm* (my international volts thus are raised 1 part in 2000 to reduce them to absolute volts) *yields*

$$e = (4.770 \pm .005) \times 10^{-10} \text{ absolute electrostatic units}^9 \quad (2)$$

in place of $(4.774 \pm .005) \times 10^{-10}$. *The foregoing is, then, merely the old oil-drop value of e brought up to date by inserting new values of the velocity of light and the value of the ohm.*

‡ This value of the electron is also that at which Birge finally arrives as a result of his survey of the whole field of fundamental constants. It is true that he reanalyzes for himself my individual oil-drop readings and weights them so that he gets from them the value 4.768 ± 0.005 in place of my value

⁸ J. A. Bearden, Proc. Nat. Acad. Sci. 15, 528 (1920).

⁹ The following quotation is made from an article published in Science on May 10, 1929:

"The reason I have not heretofore made the foregoing readjustment in my value of e is, first, that it is of no particular significance any way, since it is in any case within the limits of my estimated uncertainty; and, second, that I have until recently doubted its legitimacy.

"In the presentation of the best values of widely used physical constants I have heretofore questioned the wisdom, or even the correctness, of making a differentiation between so-called international units and absolute units before a suitably authorized international commission had recognized that difference, since otherwise such differentiation would rest merely upon some individual's *estimate* of the superior reliability of some particular new determination or determinations over the weighted mean of the whole series of determinations used by the international commission which in 1908 and 1911 fixed upon the international units. However, Professor Raymond T. Birge has called my attention to the fact that in view primarily of the close agreement between new determinations of the absolute value of the ohm by F. E. Smith (Phil. Trans., 1914) and Grüneisen and Giebe (Ann. d. Physik, 1920), the compilers of tables have actually recently begun to make the foregoing differentiation. It is because of this fact and because of Michelson's undoubted new precision in the measurement of the velocity of light that I have thought it worth while to begin herewith to recognize the effect of these changes upon the value of e ."

4.770 ± 0.005 , a result that is so much nearer mine than my experimental uncertainty that I am quite content—indeed gratified—but I may perhaps be pardoned for still preferring my own graphical weightings, since I thought at the time, and still think, that I got the best obtainable results in that way from my data. The person who makes the measurements certainly has a slight advantage in weighting over the person who does not, and the *graphical method by which I got at my final estimated uncertainty* is, I think, in the hands of the experimenter himself more dependable than least squares. A glance at the 1917 paper will show that I used least squares only to exhibit how well my observed points were distributed about my final graphically chosen *line*. Birge actually chooses for his final value my own foregoing value, 4.770, instead of 4.768, because he attaches enough weight to Wadlund's work to induce him to push the latter value up by 2 parts in 5000. Wadlund's work, however, must now, I think, be thrown entirely out of account, both because Bearden's repetition of it yielded a full percent of divergence from it and because Zwicky's theoretical block-structure work indicates that the method itself involves up to a percent of uncertainty.

The photoelectric evaluation of h , as reported in this same 1917 article, was $(6.56 \pm 0.03)10^{-27}$, but *it was definitely stated in that article* that the value of this constant derived from the Bohr equation

$$R_{\infty} = \frac{2\pi^2 e^5}{h^3 c^2 e/m} \quad (3)$$

was in my judgment the most reliable value then obtainable, the value then resulting from inserting in the foregoing equation $e = 4.774$ and $e/m = 1.767$ was as given in that paper

$$h = (6.547 \pm 0.01) \times 10^{-27} \quad (4)$$

Birge, from his recently published survey, comes to precisely this 1917 value with practically the same estimated error, namely, 0.008, so that these fourteen years have not changed at all the final result as to h . The reason that h remains unchanged while my e suffers a slight decrease is that the new work done by Babcock¹⁰ and Houston¹¹ changes e/m as spectroscopically determined to 1.761, while the value used in the 1917 computations was 1.767, and this change just balances the foregoing change in e . The present numerical equation is

$$h = \left[\frac{2\pi^2 (4.770 \times 10^{-10})^5}{109737.42 (2.99796 \times 10^{10})^2 (1.761 \times 10^7)} \right]^{1/3} = 6.5471 \times 10^{-27} \text{ erg. sec.} \quad (5)$$

The Avogadro number Birge estimates as 6.064 ± 0.006 in place of the 1917 value, namely, 6.062 ± 0.006 . In view of the estimated error in both cases the difference of course has no significance whatever. The reason the agreement is so good is that new work on the electro-chemical equivalent

¹⁰ Babcock, Phys. Rev. 33, 268 (1929).

¹¹ Houston, Phys. Rev. 30, 608 (1927).

leads Birge to choose to modify the Faraday constant in such a way as nearly to offset the influence of the slight change in e on the value of N .

So far, then, as the foregoing estimates by both Dr. Birge and myself are to be depended upon, the last fourteen years have introduced no change into the values of e , h , and N as experimentally determined, save the insignificant one in e due to new precision in the velocity of light and the value of the ohm.

III. THEORETICAL RELATIONSHIPS

What, then is to be said of the demands that the theorists have made upon the relations of these constants? This is a very important and a very interesting question. There are two such relations to be considered, one brought forward by Lewis and Adams¹² in 1914 and one by Eddington¹³ in 1929. With respect to the first, I have nothing to add to Birge's comments, except to emphasize them. Lewis and Adams, from their theory of ultimate rational units arrive at the following relation between h , c , and e :

$$\frac{hc}{2\pi e^2} = 8\pi \left(\frac{8\pi^5}{15} \right)^{1/3}. \quad (6)$$

It will be seen that the right side of this equation involves no physical measurements whatever. It has the value 137.348. The left side, which is Eddington's spectroscopic fine-structure constant $1/\alpha$, contains three physically measured quantities, and if the values $e=4.770 \times 10^{-10}$, $h=6.547 \times 10^{-27}$, and $c=2.99796 \times 10^{10}$ be inserted, *it yields 137.29 in exceedingly close agreement with the right side.*

This Lewis and Adams theoretical relationship is introduced here merely to emphasize the fact that if it is correct, then without recourse to any experiment at all the spectroscopic fine-structure constant—the left side of the foregoing equation—cannot possibly be a whole number, as contended by Eddington. Also, the remarkable agreement of the left side with the demands of the right side lends rather extraordinary experimental credentials to the Lewis and Adams relationship, although I believe that in other particulars it has not behaved itself so well.

But, turning next to experiment alone, what has it to say as to Eddington's suggestion that the spectroscopic constant $1/\alpha$ ought to be a whole number? The number he originally suggested was 136, but, as Birge pointed out, this suggestion was in irreconcilable conflict, first, with the oil-drop results on e ; second, independently of e , it was in conflict with Houston's and Babcock's determinations of the spectroscopic value of e/m ; and, third, it collided with Lewis and Adams' equation. The combined weight of this attack was so great that Eddington's suggestion could not possibly be entertained, provided the principle be admitted that the theorist cannot be permitted to ignore the facts in building his theories.

Quite recently, however, Eddington has changed the theoretical value of his fine-structure constant, still keeping it a whole number, but now

¹² G. N. Lewis and E. Q. Adams, *Phys. Rev.* **3**, 92 (1914).

¹³ A. S. Eddington, *Proc. Roy. Soc. A* **122**, 358 (1929).

making it 137^{14} instead of 136. This might perhaps remove the clash with my experimental oil-drop work, for if h were kept at 6.547 and e pushed up to 4.775—a change only a trifle outside the limits of my estimated experimental uncertainty— $1/\alpha$ would come down from 137.29 to 137. But quite independently of the oil-drop work on e , Eddington would still be in what appears to be an irreconcilable clash with the spectroscopic measurements on e/m and the following series of measurements on the ratio of h/e . To see this, write with Birge the spectroscopic equation in the following form:

$$R_{\infty} = \frac{\alpha^2 \left(\frac{e}{h} \right) 1}{2 \frac{e}{m}}.$$

This fits perfectly with $1/\alpha = 137.29$, $e = 4.770$, $h = 6.547$, and $e/m = 1.761$.

If, then, α^2 is to be pushed up the 0.42% necessary to make $1/\alpha$ equal to 137, then if e/h remains constant, e/m , spectroscopically determined, must go up 0.42%. But e/m , spectroscopically determined, and it is this mode of evaluation which obviously must be used for substitution in a spectroscopic equation, is now known to about one part in a thousand, for not only are both Babcock's and Houston's published determinations extraordinarily precise, but Houston and his associates inform me that the new independent determination that they are now making appears to check with the other two. If, then, there is no flexibility in e/m , the factor e/h must go down 0.42% or h/e up 0.42% to match the 0.42% rise in α^2 .

Now h/e has been determined by four different methods, none of which involve the properties of crystals: (1) the photoelectric method; (2) the ionizing potential method; (3) the c_2 , or Wien displacement-law method; and (4) the σ , or Stefan-Boltzmann-law method. *Not one of these methods will permit h/e to go up 0.42%.* The best result to date by the photoelectric method—which involves simply the equation $h\nu = eV$ —is probably my 1916 value of h/e for sodium; for the length of the line, the slope of which gives h/e , was several times greater than that used by other observers, and in addition the currents were large and stopping potentials accurately determined. The value of h as published both in my 1916¹⁵ and 1917¹⁶ papers, and in "The Electron"¹⁷ (1917) was $(6.56 \pm 0.03) \times 10^{-27}$, and this remains the value when absolute units, Michelson's new c , and $e = 4.770$ are used. Lukirsky and Prilezaev's recent determination¹⁸ made with the metals Al, Zn, Sn, Ni, Cd, Cu, and Pt yields a mean 6.543×10^{-27} , and there has just appeared a paper by Olpin¹⁹ which yields $h = 6.541 \times 10^{-27}$ "significant to three figures." I shall take the mean of these three, 6.560 and 6.543 and 6.541 namely 6.548, as the most probable value of h which combines with $e = 4.770$ to make the best photoelectric value of h/e .

¹⁶ Millikan, Phil. Mag. 34, 14 (1917).

¹⁷ Millikan, "The Electron" (1917), p. 227.

¹⁸ Lukirsky and Prilezaev, Zeits. f. Physik 49, 236 (1928).

¹⁹ A. R. Olpin, Phys. Rev. 35, 670 (1930).

The ionizing potential method, also involving merely $h\nu = eV$ is most accurately used by Lawrence,²⁰ who gets, corresponding to $e = 4.770$, the value $h = 6.560 \pm 0.015$.

I have nothing to add to Birge's estimates of h/e from the Wien Displacement Law method, which corresponds to $h = 6.548 \pm 0.015$. The equation here is $c_2 = hc/k$ where k is determined from, and is proportional to e , so that h/e has here the same error as c_2 and $c_2 = 1.432 \pm 0.003$ cm deg.

The Stefan-Boltzmann Law method does not yield h/e directly, but it does give, through Planck's equation, $h/k^{4/3} \propto \sigma^{1/3}$ and although the variation in the experimental values of σ is large, since the error in $h/k^{4/3}$, or $h/e^{4/3}$, is only one-third that in σ , I am willing to accept Birge's estimate that the probable error in the value of h corresponding to $e = 4.770$ as given by this method is $h = (6.539 \pm 0.010) \times 10^{-27}$.

The mean of the values 6.548, 6.560, 6.548, and 6.539 by these four methods is 6.549, which is very close to my 1917 value 6.547, and *the foregoing analysis shows how extraordinarily unlikely it is that h/e can go up the 0.42% necessary to permit $1/\alpha$ to be 137*, as Eddington wishes it to be, so that even when the theoretical evidence from Lewis and Adam's equation is entirely discarded the *experimental situation alone* renders it highly improbable that Eddington's conclusion can be correct.

If, however, the experimental credentials which have thus far developed for Lewis and Adam's relation are considered significant, then the values of e , h , and N are probably considerably more accurately known than the foregoing estimates of probable experimental error indicate. If both Eqs. (5) and (6) are to be considered correct, then, since (5) is of the form $h/e^{5/8} \propto 1/e/m$, and (6) of the form $h/e^2 = \text{constant}$, when I compare them with the experimental limits of error of h/e I find that the possible range of variation in e , h , and e/m is very small indeed, and I should then write the most probable values of e , h , and e/m as follows:

$$\begin{aligned} e &= (4.769 \pm 0.001) \times 10^{-10} \\ h &= (6.547 \pm 0.001) \times 10^{-27} \\ e/m &= (1.7595 \pm 0.001) \times 10^7. \end{aligned}$$

It will be interesting to see whether new experimental work can check this prediction as to the value of e/m .

However, in view of the theoretical uncertainty in Lewis and Adams' relation, I think it safer not to depend at all upon it, and hence to continue to write, as representing the best 1930 experimental situation, the 1917 values merely corrected for volts and for speed of light, namely,

$$\begin{aligned} e &= (4.770 \pm 0.005) \times 10^{-10} \\ h &= (6.547 \pm 0.010) \times 10^{-27} \\ N &= (6.064 \pm 0.006) \times 10^{-23}. \end{aligned}$$

THE UNIFORM POSITIVE COLUMN OF AN ELECTRIC DISCHARGE IN MERCURY VAPOR

BY THOMAS J. KILLIAN

THE MASSACHUSETTS INSTITUTE OF TECHNOLOGY, CAMBRIDGE, MASS.
and

THE RESEARCH LABORATORY, GENERAL ELECTRIC CO., SCHENECTADY

(Received January 11, 1930)

ABSTRACT

Uniform positive column of an electric discharge in mercury vapor. The uniform positive column was studied in a long circular cylindrical tube by means of the Langmuir probe electrode method. Measurements were made of the space potentials, random electron current densities, and the electron temperatures along the axis and across a diameter of the tube at vapor pressures ranging from 0.27 baryes to 7.13 baryes. The mobility of the electrons was obtained and the results interpreted in terms of the mean free path of the electrons by Langevin's expression for mobility.

($\mu = 0.75e\lambda/m\bar{v}$) These mean free paths were in fair agreement with those obtained in angular scattering experiments by other investigators. The rate of generation of positive ions per electron was obtained from measurements of the positive ion current to the walls and the total number of electrons per unit length of tube. With the probabilities of ionization for electrons of various velocities obtained by other observers, it is found that at vapor pressures above 1.4 baryes the ionization is accounted for by the direct impacts with neutral atoms of electrons whose velocity distribution is Maxwellian. At lower vapor pressures it seems necessary to assume the presence of a larger number of higher speed electrons than is present in a Maxwellian distribution. The ratio of the concentrations of electrons at any two points on a diameter satisfies the Boltzmann equation. As the temperature of the electrons is lowered from 38,000°K to 19,900°K by raising the pressure of the mercury vapor the energy delivered to the walls by the recombination of positive ions and electrons decreases from 48 percent to 14 percent of the total input. Since less than 0.03 percent is lost through elastic collisions of electrons and atoms the remainder of the energy goes into excitation.

I. INTRODUCTION

THE electrical conditions in an ionized gas are completely determined when the densities of the electrons and ions and their distributions of velocities are known at every point within the discharge. The velocity distributions must of course be known both in direction and magnitude. From the densities of the electrons, negative ions and positive ions, n_e , n_n , and n_p respectively, the variation of the electric field can be obtained by means of Poisson's equation. A single integration of this equation gives the field at any point while a double integration the potential at the point. The currents to and the potentials of the various electrodes and walls of the tube furnish the boundary conditions necessary for the complete solution. The current densities of the electrons and ions, I_e , I_n , and I_p , can be determined in any direction at any point from the densities of the electrons and ions and the laws of their distribution of velocities. It is not difficult to understand why

the behavior of some discharges is so complicated since any of the variables may vary in time as well as in space.

In order to gain a general idea of the mechanism of gaseous discharges an investigation should be made of the simplest sort of discharge. In the positive column conditions are primarily dependent upon the pressure and nature of the gas and the current carried by the discharge and not upon the nature and position of the electrodes and the walls of the tube. If, furthermore, the positive column be studied in a long circular cylindrical tube, conditions will not only be constant along its length but in the absence of any transverse magnetic field there will also be radial symmetry. The uniform positive column of a mercury arc was studied in such a tube by means of the Langmuir probe electrode method.^{1,2,3}

The most common type of velocity distribution occurring in nature is the random type known as the Maxwellian distribution. It has been found from an analysis of the volt-ampere characteristics of small electrodes placed in the positive column of a discharge that the free electrons move with a Maxwellian distribution of velocities in nearly random directions.^{1,2,4} A small electrode, placed in the discharge, will repel electrons from its neighborhood and collect positive ions when it is negatively charged. Electrons with energies greater than V_e , where V is the potential of the collector below that of the space and e the charge of an electron, can, however, reach the collector. As the potential of the collector is increased a greater number of the more slowly moving electrons will be collected. Since these electrons have a Maxwellian distribution of velocities the ratio of their concentrations in two regions differing in potential by an amount V is given by the Boltzmann equation

$$n'/n = e^{V_e/kT} \quad (1)$$

where k is the Boltzmann constant and T the temperature of the electrons. Since the velocity distribution is not affected by a retarding field the random current densities are in the same ratio as the electron concentrations. It is thus seen that the logarithm of the electron current to a small collector varies linearly with the voltage of the collector and that the rate of change of the logarithm of the electron current with respect to the voltage is e/kT , where e/k is 11,600 degrees per volt and T is the temperature of the electrons in degrees absolute. This relation is only true when the collector is negative with respect to the space. If the field is an accelerating one the current increases more slowly and according to different laws.³ Thus there is a transition at space potential. If the probe is a small one the break may be sharp enough to fix the space potential as in Fig. 5. When the collector is at space potential there is no sheath about it and its presence does not affect the discharge. Hence the random electron current, I_e , can be obtained by dividing

¹ I. Langmuir, Jour. Frank. Inst. 196, 751 (1923).

² I. Langmuir and H. Mott-Smith, Gen. Elec. Rev. 27, 449, 538, 616, 762, 810 (1924).

³ H. Mott-Smith and I. Langmuir, Phys. Rev. 28, 727 (1926).

⁴ I. Langmuir, Phys. Rev. 26, 585 (1925).

the electron current to the collector at this point by the area of the collector. According to kinetic theory the density of electrons in terms of their temperature and random current is given by

$$n_e = \frac{4I_e}{ev} = \left(\frac{2\pi m}{kT} \right)^{1/2} \frac{I_e}{e} = 4.03 \times 10^{13} \frac{I_e}{T^{1/2}} \quad (2)$$

where I_e is in amperes per cm^2 . There is a second method of finding the space potential which consists in analysing the electron current to a collector when it exerts an accelerating field.^{2,3}

Since the fields existing in the positive column are very small the density of positive ions is very nearly equal to that of the electrons, but due to their much higher mobility the electron current is from 200 to 400 times the positive ion current.

The positive ions do not appear to have a Maxwellian distribution of velocities but seem to obtain their velocities from the fields they move through after being formed.⁵ Therefore the positive ion current to a collector is a measure of the number of positive ions formed per second in a region drained by the collector and surrounded by a surface of maximum potential. This surface will be somewhat blurred due to the thermal energy of the positive ions which is probably very nearly equal to that of the gas molecules.

Fig. 1. Mercury vapor tube with various collectors.

II. METHOD

The tube used in the experiments is represented in Fig. 1. The long cylindrical portion in which the positive column was studied is 6.2 cm in diameter and 140 cm long. Anode *A*, which is above the pool of mercury which served as a cathode, is cone-shaped to prevent the blast of mercury from the cathode spot from affecting the pressure in the tube. Anode *B* consists of an

⁵ L. Tonks and I. Langmuir, *Phys. Rev.* **34**, 876 (1929).

open molybdenum cylinder 5.1 cm long and 3.18 cm in diameter. Probe wires *i* and *g*, 61.1 cm apart, are 3 mil tungsten wires of area 0.0311 cm^2 each. The nickel collectors *f* and *j*, 7.6 cm respectively from *g* and *i* are approximately spherical and of area 1.22 cm^2 and 1.15 cm^2 respectively. The disks *e* and *h* bent to conform with the curvature of the walls and fitting closely against them are each of area 1.99 cm^2 . The movable collector *h* consists of a 4 mil tungsten wire of 0.061 cm^2 area.* It can be moved by magnetic control across a diameter of the tube and also be turned to make any angle with the axis of the tube. In the present experiments it was kept parallel to the axis of the tube.

Before any experiments were made the electrodes were heated by means of a high-frequency coil and the tube allowed to run several days with a large current while being exposed to the radiation of several radiant heaters in order to drive out any water vapor or other occluded gases which might be present. Throughout all of the experiments the tube was being constantly exhausted by means of a two-stage Langmuir condensation pump and the vacuum was always such that a distinct click might be heard when the mercury was slowly raised in the McLeod gauge. The vapor pressure of the mercury in the tube was controlled by means of a water bath about the cathode bulb. When the temperature of the bath was above that of the room, mercury was prevented from condensing in the tube by means of small heating coils on each of the appendices and by exposing the whole tube to the radiant heaters.

In order to insure stable operation resistances were placed in series with *A* and with *B*. In all of the runs the current to *A* was held between 4 and 5 amperes. Sometimes a small current was drawn to *D* but the effect of this upon the stability was negligible. Complete voltage current characteristics were taken of each of the collectors at various vapor pressures. At each of these vapor pressures complete characteristics were made with *h* at different points across the tube.

Large rectangular coils, placed above and below the tube, furnished a means of obtaining a transverse magnetic field. The effects of this transverse field upon the positive column were studied and will be reported in a later paper. In the present experiments the current through the coils was only such as to cancel the effect of the earth's field.

III. EXPERIMENTAL RESULTS

Complete runs were made with the water bath about the cathode at 1.4°C , 18.6°C and 38.6°C . Using the methods of Langmuir and Mott-Smith² the random electron currents, electron densities and temperatures, and the

* After these experiments and others involving much higher current densities had been carried out, it was found that the probe wire *h* had been sputtered so that it varied from 0.0028 inches in diameter at one end to 0.004 inches at the bend into the glass tube. Since the experiments which would cause the most severe sputtering were performed after most of the runs reported here were made it is believed that the area of this probe wire was very close to 0.061 cm^2 when these runs were made.

space potentials were obtained from the semi-log plots of the electron current to the collector and the voltage of the collector for the probe wires i , g and h . Due probably to the small thickness of the sheaths about the probe wires better results were obtained by this method of analysis than from an analysis of the electron currents to the probe wires when they exert an accelerating field and the current to them is limited by orbital motion. In most of these runs the drift current through the tube, i_w , was held at 5 amperes. With smaller currents the agreement of the results obtained by each of the methods was very good. In each case the electron current to the collector was found by adding to the observed current the positive ion current to the collector at this voltage. This positive ion current was found by extrapolating to higher

Fig. 2. Variation of the random electron current across the tube at different vapor pressures. Drift current, 5 amperes.

voltages the positive ion currents obtained at voltages so low that practically no electrons were collected.²

The vapor pressure of mercury was found from the data of Knudsen⁶ and also that of Poindexter.⁷ Since he has taken Knudsen's values at 0°C the values are very similar in the range here considered.

The positive ion current densities to the walls of the tube were obtained by plotting $(i_+)^{1/2}$ against $\nu^{1/2}$ where i_+ is the positive ion current to one of the disk-shaped collectors and $\nu = V^{3/2} [1 + 0.0247(T/V)^{1/2}]$. Here V is the voltage of the collector below that of the space and T is a factor which takes into account the initial velocities of the positive ions on entering the sheath and is about 10,000. If the positive ions had a Maxwellian distribution, T

⁶ Knudsen, Ann. d. Physik **29**, 179 (1909).

⁷ F. E. Poindexter, Phys. Rev. **26**, 859 (1925).

would correspond to their temperature in degrees absolute. Values of the shape factor equal to 1.36 ± 0.17 agreeing fairly well with the values Langmuir and Mott-Smith⁸ found were obtained over a thirty-fold range in vapor pressure.

In Fig. 2 the variation of the random electron current across the tube is represented as measured by h . It is seen that there is a large variation

Fig. 3. Comparison of space potential with $kT_e/e \log I_e$. Cathode bulb at 1.4°C. p , 0.264 baryes.

in this random current. In Figs. 3 and 4 are the space potentials at these points. The electrons move in a retarding field in going from the axis of tube toward the walls. If their density at any point is determined by the Boltzmann equation the space potential curve should be identical with that of the variation of $kT_e/e \log I_e$ across the tube. It is seen that this is very

Fig. 4. Comparison of space potential curve with $kT_e/e \log I_e$. Cathode bulb at 38.6°C. p , 7.13 baryes.

nearly true at 38.6°C. Except for the points near the walls the agreement at 1.4°C is also within the experimental error. Also the semi-log plots of the voltage-current characteristics taken at different points along the diameter should lie on the same straight line as far as the space potential, where a break occurs. This is seen to be the case in Fig. 5. Here the cathode bulb was at 38.6°C where the best results were obtained.

⁸ I. Langmuir and H. Mott-Smith, Gen. Elec. Rev. 27 541 (1924).

IV. MOBILITY OF THE ELECTRONS

If the density of electrons at a distance r from the axis is n_e the total number of electrons per unit length of tube is

$$N_e = 2\pi \int_0^R n_e r dr \quad (3)$$

where R is the radius of the tube. If v_x is the average drift velocity of the electrons toward the anode the total electron drift current is

Fig. 5. Semi-logarithmic plot of the electron current to h against its voltage for various positions of h . Temperature of cathode bulb, 38.6°C . Drift current, 5 amperes.

$$i_- = N_e e v_x \quad (4)$$

Since the current carried by electrons is 300 or 400 times that carried by positive ions the current to the anode B , i_x , can be assumed to be equal to the electron drift current. The mobility of the electrons is given by

$$\mu_- = \frac{v_x}{X} = \frac{i_x}{N_e e X} \quad (5)$$

where X is the longitudinal potential gradient. Assuming the speed gained between successive collisions to be small compared with the average speed of the electrons Langevin⁹ has derived an expression for the mobility of electrons given by

$$\mu_- = 0.75e\lambda/m\bar{v} \quad (6)$$

where λ is the mean free path of the electrons in the gas, m the mass of an electron and \bar{v} the average speed.

Since $\bar{v} = (8kT/\pi m)^{1/2}$ it is possible to combine Eqs. (5) and (6) and obtain

$$\lambda = \frac{(8kTm)^{1/2}i_x}{0.75(\pi)^{1/2}N_e e^2 X} = 2.94 \times 10^9 \frac{i_x T^{1/2}}{N_e X} \quad (7)$$

where T is the temperature of the electrons in degrees absolute, i_x the drift current in amperes and X the longitudinal voltage gradient. N_e was obtained by a graphical integration of Eq. (3), n_e being found by means of Eq. (2). In Column 4 of Table I are the values of the mean free path of electrons in mercury vapor for three different vapor pressures. In reducing to λ_1 , the mean free path at 1 barye and 20°C, it was assumed that the temperature of the gas molecules was 50°C. The kinetic theory value of the mean free path (i.e. $4(2)^{1/2}$ times the mean free path of gas molecules) is usually taken to be about 20 cm at this temperature and pressure.¹⁰ Since, however, the mean free path is dependent upon the velocity of the electrons this value cannot be expected to apply very accurately.

TABLE I

Temperature of Cathode Bulb °C	Pressure of Hg baryes	T_e °K	λ from Eq. (7) cm	λ_1 cm	λ_1' from Eq. (8) cm
1.4	0.27	38,000	27.6	6.78	12.9
18.6	1.38	27,500	5.7	7.14	9.6
38.6	7.13	19,900	1.46	9.45	8.3

The angular scattering of low-velocity electrons in mercury vapor has been studied by various investigators whose results can be interpreted in terms of the mean free path of the electron.^{11,12,13,14} A comparison of the temperature of the electrons in Table I, Column 3, and λ_1 in Column 5 seems to show that as the velocity of the electrons is increased there is a small increase in the effective diameter of the molecules. Minkowski¹¹ seems to have observed this Ramsauer effect for electrons whose velocities were less than an equivalent volt. Beuthe,¹³ using the Ramsauer method, studied the absorption of low-velocity electrons and found that as the velocity decreased

¹¹ R. Minkowski, Zeits. f. Physik 18, 258 (1923).

¹² L. R. Maxwell, Proc. Nat. Acad. Sci. 12, 509 (1926).

¹³ H. Beuthe, Ann. d. Physik 84, 949 (1928).

¹⁴ T. J. Jones, Phys. Rev. 32, 459 (1928).

the absorption increased to a maximum at about 3 volts and then fell off to about 1/6 of this maximum value at 1 volt. Jones¹⁴ using the Ramsauer and another method could find no evidence of this effect in mercury vapor. The results he obtained by his second method are very close to those obtained by Maxwell.¹² If the mean free path of an electron is given as a function of its velocity, i.e. $\lambda(v)$, then the mean free path of electrons with a Maxwellian distribution of velocities at a temperature T is given by

$$\lambda' = 4\pi \left(\frac{m}{2\pi kT} \right)^{3/2} \int_0^\infty e^{-mv^2/2kT} v^2 \lambda(v) dv. \quad (8)$$

Using the values of $\lambda(v)$ as found by Maxwell¹² and reducing the mean free paths found from Eq. (8) to the mean free path, λ'_1 , at 1 barye and 20°C it is seen by a comparison of these values in Column 6 with those in Column 5 that the two vastly different methods of obtaining the mean free path give results in fair quantitative agreement, although the free paths as obtained by each method vary differently with the temperature of the electrons.

One of the assumptions made in the derivation of Eq. (6) is that the speed gained between collisions is small compared with the average speed of the electrons. This is not true at the lower vapor pressures. The average distance the electrons move in the direction of the electric field between collisions, as Compton¹⁵ has shown is given by

$$s = \mu E \lambda / \bar{v} = 0.75 \lambda^2 e X / m \bar{v}^2. \quad (9)$$

The average energy gained between collisions is therefore $\Delta U = Xs$ and since $\bar{v}^2 = 0.849 c^2$ and $eU = \frac{1}{2} mc^2$ the average energy gained between collisions is

$$\Delta U = 0.441 \lambda^2 X^2 / U. \quad (10)$$

This varies from 1.5 percent of the average energy of the electrons when the cathode bulb is at 38.6°C to 12 percent when it is at 1.4°C. However, the degree of the agreement between the values of λ_1 and λ'_1 is an indication of the extent to which the simple classical kinetic theory considerations, which underlie the Langevin mobility equation and the calculation of the free path, are applicable to this case.

V. RATE OF GENERATION OF POSITIVE IONS

a. Experimental. If I_+ is the positive ion current density to the walls, the total positive ion current to the walls per unit length of tube is $2\pi R I_+$ and since the recombination of positive ions with electrons is negligible within the positive column, the number of ionizing collisions per electron per second is given by

$$\alpha = 2\pi R I_+ / e N_e. \quad (11)$$

The values of α as obtained from Eq. (11) are in row 8 of Table II.

b. Theoretical. Consider unit length of tube containing N_e electrons with a Maxwellian distribution of velocities corresponding to a temperature T . Let the gas in the tube have a pressure p and temperature T_g . An electron of

¹⁵ K. T. Compton, Phys. Rev. 22, 333 (1923).

velocity v has an energy of V volts where $\frac{1}{2}mv^2 = Ve$. The probability, P , of such an electron making an ionizing collision in going unit distance is dependent only upon the velocity of the electron and the nature and density of the gas. For an electron of velocity v the probability is given by $P = P'(n/n') = P'(pT'_g/p'T_g)$ where P' is the probability of an ionizing collision per cm path at pressure p' and temperature T'_g . These probabilities have been studied for different gases including mercury vapor by Compton and Van Voorhis¹⁶ and for mercury vapor by Jones¹⁷ and by von Hippel.¹⁸

The probability that an electron of velocity v will make an ionizing collision in one second is Pv . The number of electrons whose velocities lie between v and $v+dv$ is

$$N_e f(v) dv = 4\pi N_e \left(\frac{m}{2\pi kT} \right)^{3/2} v^2 e^{-mv^2/2kT} dv. \quad (12)$$

Hence, the number of positive ions formed per second by electrons whose velocities are between v and $v+dv$ is given by

$$N_e P f(v) v dv = 4\pi N_e \left(\frac{m}{2\pi kT} \right)^{3/2} P v^3 e^{-mv^2/2kT} dv. \quad (13)$$

If v be replaced by $(2Ve/m)^{1/2}$ the number of positive ions formed per second by electrons whose energies lie between V and $V+dV$ is found to be

$$N_e P F(V) dV = 8\pi N_e \left(\frac{m}{2\pi kT} \right)^{3/2} \frac{e^2}{m^2} P V e^{-eV/kT} dV. \quad (14)$$

In the case of mercury it has been found that the probability of ionization for electrons of less than 30 volts, varies linearly with the difference between the energy of the impinging electron and that required to ionize. Thus if V is less than V_i , P is zero but if V is greater than V_i but less than $3V_i$ we may write $P = \beta(V - V_i)$. Since, however, very few electrons have energies greater than $3V_i$ the total number of positive ions formed per second per cm is approximately

$$\nu_p = 8\pi N_e \left(\frac{m}{2\pi kT} \right)^{3/2} \frac{e^2}{m^2} \beta \int_{V_i}^{\infty} (V - V_i) V e^{-eV/kT} dV. \quad (15)$$

Integrating this expression and dividing by the total number of electrons per unit length of tube, the number of positive ions formed per second by each electron is found to be

$$\begin{aligned} \alpha' &= \beta \left(\frac{8kT}{\pi m} \right)^{1/2} e^{-eV_i/kT} \left(V_i + \frac{2kT}{e} \right) \\ &= 6.24 \times 10^5 \beta T^{1/2} e^{-eV_i/kT} \left(V_i + \frac{2kT}{e} \right) \end{aligned} \quad (16)$$

¹⁶ K. T. Compton and C. C. Van Voorhis, Phys. Rev. **26**, 436 (1925); **27**, 724 (1926).

¹⁷ T. J. Jones, Phys. Rev. **29**, 822 (1927).

¹⁸ A. von Hippel, Ann. d. Physik **87**, 1035 (1928).

In order to find out how much Eq. (16) is in error due to the fact that Eq. (15) is integrated to infinity, Eq. (15) may be integrated from $3V_i$ to infinity and the contribution to α' of electrons whose energies are greater than $3V_i$ found. This contribution, α'_1 , divided by α' gives the maximum relative error made in assuming that the expression for the probability holds to infinity. It is found that

$$\frac{\alpha'_1}{\alpha'} = e^{-2V_i e/kT} \left\{ \frac{(6eV_i^2/kT) + 5V_i + (2kT/e)}{V_i + (2kT/e)} \right\}. \quad (17)$$

Since $V_i = 10.4$ volts, α'_1/α' varies from 0.00018 for T equal to $20,000^\circ\text{K}$ to 0.033 for T equal to $40,000^\circ\text{K}$. Thus the error made in integrating Eq. (15) from V_i to infinity is small.

From the work of Compton and Van Voorhis¹⁶ β is given by $0.20 p/T_g$ while from that of Jones¹⁷ it is equal to $0.28 p/T_g$ where p is in baryes and T_g in degrees Kelvin. The values of α' as found by substituting these two values of β in Eq. (16) are in row 9 of Table II. It is seen that at higher vapor pressures the ionization within the positive column may be accounted for by the impacts with neutral atoms of electrons whose velocity distribution is Maxwellian. However at 1.4°C it would appear that only about 40 percent of the positive ions are produced by these electrons. At this low pressure with the mean free path of the electrons several times the diameter of the tube there is probably very little cumulative ionization.

A more acceptable explanation of the relatively large values of α found at low pressures as compared with the calculated values, is to assume that the excess ionization is due to "high-speed" electrons, not belonging to the Maxwellian group considered above. At 0.27 baryes the random current is only 4.3 times the drift current so that there are probably present more "high-speed" electrons than there would be if the electrons were moving in random directions with a Maxwellian distribution corresponding to $38,000^\circ\text{K}$.

In the experiments of Compton and Van Voorhis¹⁶ and also in those of Jones¹⁷ a measured current of electrons of a given speed was passed through an ionizing chamber and the number of positive ions produced measured. For electrons whose energies lay between 10 and 30 volts the effect of the fields necessary to collect the positive ions was less in the arrangement of Jones than in that of Compton and Van Voorhis.

When an electron ionizes an atom it will not only lose an amount of energy corresponding to the ionization potential but will in general divide its energy with the new electron formed. Then the average energy of the two electrons is half of the surplus energy. The impinging electron and that formed by ionization will be considered secondary electrons. The total surplus energy delivered per second to these secondary electrons is given by

$$W' = 8\pi N_e \left(\frac{m}{2\pi kT} \right)^{3/2} \frac{e^3}{m^2} \int_{V_i}^{\infty} PV(V - V_i) e^{-eV/kT} dV. \quad (18)$$

To find the average energy transferred per ionizing collision Eq. (18) is divided by the number of ionizing collisions per second and the average energy of the secondary electrons is found to be

$$\bar{V} = \frac{kT}{e} \left\{ \frac{eV_i + 3kT}{eV_i + 2kT} \right\}. \quad (19)$$

If \bar{V}_e is the average energy of the primary electrons ($e\bar{V}_e = 3kT/2$) the following results are obtained

$$\begin{array}{ll} T=0 & \bar{V}=0.667\bar{V}_e \\ T=10,000^\circ\text{K} & \bar{V}=0.714\bar{V}_e \\ T=40,000^\circ\text{K} & \bar{V}=0.797\bar{V}_e \\ T \rightarrow \infty & \bar{V} \rightarrow \bar{V}_e \end{array}$$

The secondary electrons would have a Maxwellian distribution of velocities if the probability of ionization were independent of the energy of the impinging electron. However, since this probability increases with the energy of the electrons there exists among the secondaries a surplus of higher-speed electrons and a deficiency of the lower-speed ones. Since the rate at which a Maxwellian distribution is reestablished among the electrons decreases with decreasing vapor pressures¹⁹ the discrepancies between the values of α and α' at 0.27 baryes may in part be due to this surplus of higher-speed electrons at this pressure.

TABLE II. Summary of results. Diameter of tube = 6.2 cm.

1. Bulb temperature	°C	1.4	18.6	38.6

* Tonks and Langmuir⁸ derive an expression for α for a cylindrical mercury discharge at low pressures gives by $\alpha = 703.1 T_e^{1/2}/R$. The values of α obtained by means of this expression are: at 1.4°C, 44,200; at 18.6°C, 37,500; at 38.6°C, 32,000.

VI. ENERGY BALANCE

The power input per unit length of tube is

$$W = Xi_x \quad (20)$$

¹⁹ A. F. Dittmer, Phys. Rev. 28, 507 (1926).

where X is as before the longitudinal potential gradient and i_z the drift current in the tube. Part of this energy is delivered to the walls by the recombination of positive ions and electrons, by the absorption of radiation and by the diffusion of metastable atoms to the walls and part goes into radiation which escapes from the tube. The total energy delivered to the walls by the recombination of a positive ion and an electron is the sum of the energy of recombination and the energies of the combining electron and positive ion. Since the electrons are moving in a retarding field their average energy expressed in volts is $2kT/e$. Therefore the total energy delivered to the walls per second by recombination is

$$W_r = 2\pi R I_+ (V_i + 2kT/e + \bar{V}_p) \quad (21)$$

where \bar{V}_p is the average energy of the positive ions. The positive ions acquire most of their energy in the sheath close to the walls. The potential of the walls must be such as to make the current of electrons equal to that of the positive ions. It is therefore that at which zero current flows to a small collector against the walls such as e or k . The potential of a point on the axis opposite e or k can be found from the longitudinal gradient and the space potentials at i or g . Thus the difference between the potentials of points on the axis and the walls opposite can be found. Combining this with the results obtained by means of collector h as given in Figs. 3 and 4 the total variation of potential across a diameter of the tube can be found. Since the temperature of the electrons is constant the rate of production of positive ions at any point is proportional to the electron density. The energy acquired by a positive ion from the time it is formed until it recombines at the walls is equal to the difference between the potentials at the point where it was formed and that at which it recombined. At very low vapor pressures when the probability of a collision is very small it will deliver all this energy to the walls. However, even if it does make collisions and lose energy to gas molecules they in turn will deliver it to the walls. As a first approximation the longitudinal potential gradient may be neglected and the average energy delivered to the walls due to the fields the positive ions move in is given by

$$\bar{V}_p = \frac{2\pi\alpha \int_0^R n_e V_r r dr}{2\pi\alpha \int_0^R n_e r dr} = \frac{2\pi \int_0^R n_e V_r r dr}{N_e} \quad (22)$$

where V_r is the difference between the potentials at r and R and n_e is the electron density at r . \bar{V}_p was obtained graphically from Eq. (22) and found to vary from 7.3 volts at 38.6°C to 14.5 volts at 1.4°C. The fraction of the power input delivered to the walls ($F_r = W_r/W$) by the recombining ions and electrons is in the fourth column of Table III. It is seen that this fraction increases rapidly with the temperature of the electrons.

By multiplying the frequency of collisions between electrons and gas molecules by the average loss of energy per electron per elastic collision the energy lost by the electrons per second through elastic collisions can be found.

When the energy of electrons is much greater than that of the gas molecules Compton¹⁵ has shown that the average fraction of energy lost at an elastic collision is $2m_e/M$. Using the values of mean free paths as found from Eq. (7) and given in column 4 of Table I, the fraction, F_e , of the power input delivered by the electrons to the gas molecules by elastic collisions was found. It is seen from column 5 of Table III that this energy is very small and may be neglected.

TABLE III. Fraction of power input delivered to the walls by the recombination of positive ions and electrons. Arc current = 5 amperes.

Temp. of cathode bulb °C	Temp. of electrons T °K	Power input per unit length W watts	Fraction to walls F_r	Fraction to gas molecules by elastic impacts F_e
1.4	38,000	0.466	0.483	2.8×10^{-5}
18.6	27,500	0.98	0.233	4.0×10^{-5}
38.6	19,900	1.55	0.136	2.5×10^{-4}

In order to obtain a rough idea of the efficiency of excitation it may be assumed that the remainder of the energy input goes into raising the mercury atoms from the normal 1^1S_0 to the 2^3P_1 state, which excitation requires 4.9 volts. This state is between the two metastable states 2^3P_0 at 4.66 volts and 2^3P_2 at 5.43 volts. Making this assumption the average number of resonance collisions per electron per second, α_r , and per atom per second, a_r , can be found. These values are given in the third and fourth columns of Table IV. Using the values of the mean free path found by means of Eq. (7) the probability of ionization, P'_i , and that of resonance, P'_r , can be obtained. These values are given in the fifth and sixth columns of Table IV.

TABLE IV

Temp. of cathode bulb °C	Temp. of electrons °K	Number of resonance collisions per electron per second α_r	Number of resonance collisions per atom per second a_r	Probability of ionization on collision P'_i	Probability of excitation on collision P'_r
1.4	38,000	2.78×10^6	1690	0.0091	0.063
18.6	27,500	4.41×10^6	1030	0.0014	0.024
38.6	19,900	3.74×10^6	354	0.00023	0.0062

Few data are available on the probability of excitation on collision in mercury vapor. Sponer²⁰ found the average efficiency to be about 0.004 for the excitation of mercury atoms by electrons of from 5 to 6 volts energy. Using a different value for the total number of impacts made by the electrons Hertz²¹ recalculated her results and obtained 0.03 for the average efficiency.

VII. DISCUSSION OF RESULTS

The free electrons in the uniform positive column move in nearly random directions with a Maxwellian distribution of velocities. This distribution

²⁰ H. Sponer, *Zeits. f. Physik* **7**, 185 (1921).

²¹ G. Hertz, *Zeits. f. Physik* **32**, 298 (1925).

is being continually disturbed by the loss of higher-speed electrons to the walls and by excitation and ionization. This continuous loss of energy by the electrons is supplied to the drift current by the longitudinal field and in some manner is transferred to the electrons so that they keep their Maxwellian distribution. No satisfactory explanation of the mechanism by which this distribution is maintained has yet been offered. There is evidence that it may be due to oscillations.^{22,23} In any event it has been shown that the temperature corresponding to this distribution of velocities is one of the most important characteristics of the discharge. It determines the ionization and excitation efficiencies of the electrons. Furthermore, since the electrons have a Maxwellian distribution of velocities their concentrations satisfy the Boltzmann equation.

The mobility of the electrons was measured and by means of the Langevin equation the results were interpreted in terms of the mean free path of the electrons. Over a twenty-five fold range of vapor pressures the mean free paths found in this way, when reduced to the values at 1 barye and 20°C, were within 30 percent of each other. It was true even when the mean free path appeared to be five or six times the diameter of the tube. This is probably because the electrons make specular reflections at the walls. Their momentum is unchanged except for the component perpendicular to the walls, which is reversed.

The rate of production of positive ions seems to be accounted for by direct impacts with neutral atoms of the higher-speed electrons of the Maxwellian group when the vapor pressure is greater than 1.4 baryes. At 0.27 baryes only about one half of the ionization can be accounted for in this way. The small ratio of the random to the drift current probably accounts for the additional high-speed electrons.

It is seen that as the temperature of the electrons is lowered from 38,000°K to 19,900°K by raising the pressure the percentage of the energy delivered to the walls by the recombination of positive ions and electrons decreases from 48 to 14.

There are several sources of error in this work which are difficult to eliminate. The space potentials are probably accurate to within two-tenths of a volt. The random electron currents may be in error due to the fact that some electrons are reflected when the collector is at space potential. However, the results of Farnsworth²⁴ show that this coefficient of reflection must be very small under these conditions. The electron temperatures in the tube were usually within 1500°K of each other as measured by any collector during a run. It is therefore believed that the probable error is within five percent.

The author wishes to express his appreciation for the many suggestions and kind assistance of Dr. I. Langmuir and Dr. L. Tonks of the Research Laboratory of the General Electric Company at Schenectady where this work was done. He is also grateful for the considerable aid rendered by Professor K. T. Compton of Princeton University.

ABSORPTION OF RESONANCE RADIATION IN MERCURY VAPOR

BY ANCIL R. THOMAS

VALPARAISO UNIVERSITY, VALPARAISO, INDIANA

(Received April 8, 1930)

ABSTRACT

The theories of absorption in mercury vapor of mercury resonance light of wave-length 2536.7A as formulated by Malinowski and H. A. Wilson are briefly reviewed. It is well established that the absorption coefficient for resonance radiation increases as the number of absorbing atoms decreases. This is probably due to a Doppler effect in the radiating vapor. To diminish the influence of the Doppler effect a jet of mercury vapor was used, and the resonance radiation coming from it was investigated. A series of measurements of the absorption coefficient of this light is given. The maximum atomic absorption coefficient observed is 10.22×10^{-13} , nine times as large as any previously observed. It is shown that Malinowski's assumptions are not in accord with the observed effects.

INTRODUCTION

A NUMBER of people^{1,2,3,4,5,6} have investigated the properties of mercury resonance light of wave-length 2536.7A since it was first discovered by R. W. Wood.⁷ The writer⁸ assisted in one such investigation in which the atomic absorption coefficient was measured. The atomic absorption coefficient, γ , is defined by the equation

$$I = I_0 e^{-\gamma n_a} \quad (1)$$

where I_0 is the intensity of the light as it enters the cell, I the intensity as it leaves it and n_a is the number of absorbing atoms per cm^2 of the cell. As the number of absorbing atoms changed from 1.35×10^{12} to 87.6×10^{12} per cm^2 of the absorption cell the atomic absorption coefficient changed from 11.2×10^{-14} to 2.53×10^{-14} . Several investigators have observed this variation in the absorption coefficient. The cause appears to be the non-homogeneity of the resonance line for in the case of a perfectly homogeneous radiation γ should be constant. Consequently, the values of γ are to be regarded only as average values for the atoms involved.

FORMER THEORIES

The Doppler effect predominates among the various effects⁹ proposed to account for the width of spectrum lines, particularly when the pressure is low, as it is in mercury vapor at room temperature. It has been shown that the visibility in interference patterns^{10,11} is the same as one would expect if the entire width were due to the Doppler effect.

The shift in wave-length $\delta\lambda$ due to the Doppler effect is given by

$$\frac{\delta\lambda}{\lambda} = \frac{v}{c} \quad (2)$$

from which we get that

$$v = \frac{c\delta\lambda}{\lambda} = \beta\delta\lambda \quad (3)$$

where β is a constant. The number of atoms with any particular component of velocity along the line of emission is given by the formula from kinetic theory,

$$dn = Ke^{-v^2/\alpha^2} dv. \quad (4)$$

The intensity, dI , of the light at any particular wave-length, separated from the center of the line by a wave-length difference $\delta\lambda$, is proportional to the

Fig. 1. Distribution of energy in the resonance line. Curve A shows the distribution in the ordinary resonance line, curve B, the distribution in the line used in this experiment.

number of atoms, dn , which have the proper component of velocity, v , to give this wave-length. We then have that

$$dI \propto dn \propto e^{-v^2/\alpha^2} dv \propto e^{-(\beta\delta\lambda)^2/\alpha^2} d(\delta\lambda) \quad (5)$$

⁹ Rayleigh, Phil. Mag. 29, 274 (1915).

¹⁰ A. A. Michelson, Astrophys. J. 3, 251 (1896).

¹¹ Buisson and Fabry, Jour. d. Physique 2, 442 (1912).

where ν and also $\delta\lambda$ varies from $-\infty$ to $+\infty$. This distribution is shown graphically in Fig. 1, curve *A*, when the emitting vapor is at a temperature of 293°K.

Malinowski¹, assuming this line form, has worked out an expression for I/I_0 in terms of n_a (see Eq. (1)). He also assumes that the ability of the atoms in an infinitely thin layer to absorb light of any particular wavelength will be given by

$$k_\nu = k_0 e^{-\nu^2/\alpha^2} \quad (6)$$

where k_0 represents the ability of the atoms to absorb the very center of the line. This equation results from assuming that an atom in the absorption cell can absorb light only near the wave-length which it, itself, can emit, and also that this band over which it can absorb light is very narrow with respect to the entire line. (If, in accordance with the strict quantum theory, we suppose that the correspondence between $\delta\lambda$ and ν must be exact it is evident that there can be no absorption for as we narrow down the velocity range in which an atom must be in order to absorb light of a particular wavelength the number of atoms available for such absorption approaches zero.¹²) On these assumptions Malinowski shows that the absorption coefficient for the very center of the line is the square root of two times the observed value for a cell which is infinitely thin. The atomic absorption coefficient for the very center of the line should, then, also be the square root of two times the observed value for a very thin cell. A reasonable extrapolation of the values secured by Hughes and Thomas gives $\gamma = 12 \times 10^{-14}$ for an infinitely thin layer of vapor and $\gamma_0 = 17 \times 10^{-14}$. If his ideas are correct, it is evident that, if the importance of the Doppler effect could be reduced greatly, the observed atomic absorption coefficient should approach γ_0 , that is, the square root of two times the former value observed for an infinitely thin layer of atoms. Also the coefficient should remain constant for all cell thicknesses.

H. A. Wilson¹³ has also proposed a theory which is applicable in this case. He assumed that the atom absorbs as a simple linear oscillator, the equation of motion of which may be taken to be

$$m\ddot{x} + k\dot{x} + \mu x = Fe \quad (7)$$

where m is the mass of the vibrating particle, k the viscous resistance to the motion at unit velocity, μ a constant, F the electric intensity in the light at the atom, which may be taken as equal to $F_0 \cos pt$, e the charge on the particle and x the displacement of the particle. From this he deduces that

$$\gamma = \frac{\gamma_0}{1 + (4m^2/k^2)q^2} \quad (8)$$

where γ_0 is the atomic absorption coefficient for exact resonance, γ that for a departure from exact resonance given by a frequency difference q (which

¹² A. L. Hughes and A. R. Thomas, *Phys. Rev.* **30**, 472 (1927).

¹³ H. A. Wilson, *Proc. Roy. Soc. A* **118**, 362 (1928).

corresponds to $\delta\lambda$ as used above). He then assumed that the energy distribution in the incident line was given by $Ae^{-\beta^2 a^2}$ which is the form appropriate for a Doppler effect but does not demand this explanation for the finite width of the line. With this added he shows that

$$\gamma_0 = \frac{1}{(n_a)^{1/2}} \left(\log \frac{I_0}{I} \right) \frac{m}{\beta k} \quad (9)$$

when n_a is not too small. Wilson showed that this fitted Hughes and Thomas' results when n_a was greater than about 10^{13} . It is implied in the derivation of Eq. (8) that the emission line is broader than the absorption line.

Both theories predict that if the width of the resonance line could be reduced the observed absorption coefficient should increase and Malinowski's work specifies the amount of this increase. Also according to Malinowski the absorption coefficient should not change with cell thickness. An experimental test of these predictions is described on the following pages.

DISTRIBUTION OF ENERGY IN INCIDENT LIGHT

The most feasible method of reducing the width of the resonance line which presented itself was to use a jet of mercury vapor as a source of resonance light. If the light is taken out at right angles to the jet the component velocities of the atoms in the line of emission will be quite small. The jet was diaphragmed so that five degrees was the maximum angle that any atom's path could make with the line of centers of the diaphragms. The distribution of energy in the radiation from such a jet was computed and the results plotted graphically in Fig. 1, curve *B*. While this distribution curve cannot be represented accurately by a curve of the form e^{-v^2/α^2} , we may, however, find a curve of this form which is roughly superposable on the distribution curve, and so find a value for the "most probable velocity," α , in a direction perpendicular to the jet. This turns out to be about one tenth of the value of the most probable velocity in isotropic mercury vapor at room temperature. This means that laterally its effective temperature as measured by the component velocity of the atoms is about 0.31 times its real temperature, that is 90°K .

APPARATUS AND PROCEDURE

The source of light was a vertical quartz mercury arc. It was kept cool by circulating distilled water around it. Ice was kept in the water most of the time to prevent heating. The current for the arc was supplied by a generator floating across a bank of storage batteries. A preliminary test showed that about four amperes through the arc gave the greatest amount of light from the resonance lamp. The central part of the arc was deflected to the front of the tube by an electro-magnet excited by the same current that was used in the arc. Under these circumstances the arc ran very steadily. No fluctuations could be noticed in the course of an entire day's work.

The light from this arc was focused into a resonance lamp constructed of Pyrex glass shown in Fig. 2. *A* is a cross section, *B* is a vertical section.

Light, not absorbed in the jet, continued into the horn, H_1 , (see Fig. 2A) where it was lost by multiple reflection. The resonance light taken out through the window, W , had the horn H_2 as a background so that any stray light returning from H_1 could not get out in the same direction as the resonance light. The most careful tests made showed no light of this sort whatever. An intensity much less than one percent of the resonance light could have been detected. The jet (see Fig. 2B) was diaphragmed as shown, the upper diaphragm being merely a slight constriction in the tube. The walls of the tube were cooled with solid CO_2 as was the reentrant tube, R , on which the mercury in the jet condensed. A heater, T , to increase the strength of the jet was not used as the jet proved to be quite strong enough without it.

Fig. 2. The resonance lamp used. A is a cross section, B, a vertical section.

Moreover the amount of stray vapor, the atoms of which were moving at random, was greatly increased by heating the mercury. In the final experiment practically the whole of the lamp was surrounded by solid CO_2 in order to diminish the amount of stray vapor as much as possible. In a former unpublished investigation¹⁴ with potassium a method for securing quite strong jets was developed. A diaphragm was placed very near the liquid metal surface, M , and the walls of the tube were kept cool as close down to this diaphragm as possible. By this method it was possible to secure jets several times as strong as is possible with the metal in the bottom of just a straight tube with no diaphragm near the surface of the liquid metal.

The remainder of the apparatus was arranged as in Fig. 3. The resonance light passed through the absorption cell C , on through a quartz lens L , a

¹⁴ Done with L. C. Van Atta.

variable rotating shutter S , and into a photoelectric cell. The active material in the photoelectric cell was aluminum. It was filled with helium to about one mm pressure after the surface had been sensitized by a discharge through hydrogen as is done in making an alkali hydride surface. A potential of 200 volts was used on the cell. The sensitivity to mercury resonance radiation was about seventy five times that of the untreated vacuum cell. The absorption cell, C , consisted of a glass tube 1.622 cm long to which quartz windows were sealed. A side tube contained a drop of mercury. The pressure in the cell and thus the number of absorbing atoms was controlled by cooling the side tube. The absorption cell was fixed so that it could be shifted

Fig. 3. Arrangement of the apparatus.

out of the beam and the electrometer current secured without the cell. The transmission of the cell was approximately matched by the variable rotating shutter and the actual transmission secured by interpolation. The mercury was all frozen out of the cell and its transmission secured by the same method as well as by comparing it with a previously calibrated screen. The transmission was 0.69. Calling the amount of light getting through the cell with the side tube cooled by solid CO_2 I_0 , and the amount at any other temperature I then the fraction transmitted by the vapor will be I/I_0 .

RESULTS

The experimental values for I/I_0 are shown in Fig. 4 plotted against the temperature of the side tube. A smooth curve was drawn through the experimental points and values read off this for purposes of computation. These

values are listed in Table I. The temperatures of the side tube are listed in column one and the corresponding values for I/I_0 in column two. The next column gives the values of the natural logarithms of I_0/I .

Fig. 4. Ratio of transmitted to incident radiation for various temperatures of mercury vapor.

To determine the atomic absorption coefficient we have to calculate the number of atoms involved in the absorption in each case. This must be calculated from the pressure. The fourth column gives the pressures of the

TABLE I.

Temp. °K	I/I_0	$\log I_0/I$	p in side tube in mm	p in cell in mm	n_a	γ
235	0.915	0.0888	1.45×10^{-6}	1.62×10^{-6}	8.71×10^{10}	10.22×10^{-13}

mercury vapor in the side tube for the corresponding temperatures recorded in the first column. The vapor pressures of mercury at different temperatures given in the International Critical Tables were used in this computation. As the same absorption cell was used which Hughes and the writer used in their former investigation the relations deduced at that time can be used. The pressure, p , in the absorption cell and the pressure, p_m , in the side tube are connected by the relation

$$\frac{p}{p_m} = \left(\frac{T}{T_m} \right)^{1/2} \quad (10)$$

where T and T_m are the temperatures of the absorption cell and the side tube respectively. The pressures in the absorption cell, as corrected by this equation, which takes care of thermal transpiration, are listed in column five.

The number of absorbing atoms, n_a , per cm^2 of the cell is connected with the pressure, p , by the equation

$$n_a = (5.38 \times 10^{16})p. \quad (11)$$

The values of n_a are listed in column six. The atomic absorption coefficient, γ , is calculated according to Eq. (1) and listed in column seven. This is an average value for all the atoms present in the absorption cell although it is not absolutely certain that they are all active in absorbing the light.

The atomic absorption coefficient which, according to Malinowski's theory, should have been almost constant for all values of n_a , is shown plotted against n_a in Fig. 5, curve *A*, along with the values of the atomic

Fig. 5. Variation of the atomic absorption coefficient with the number of absorbing atoms. *A* is the curve secured in this experiment, *B*, that secured by Hughes and Thomas.

absorption coefficient from the previous work, curve *B*. The coefficient is definitely not a constant and it is certainly several times greater than the square root of two times any possible extrapolation of the former curve to an infinitely thin cell.

TABLE II.

n_a	$\frac{1}{(n_a)^{1/2}} \log_e \frac{I_0}{I}$	$\frac{(n_a + 6 \times 10^{10})^{1/2}}{n_a} \log_e \frac{I_0}{I}$
8.71×10^{10}	3.01×10^{-7}	3.91×10^{-7}
18.36	3.46	3.99
34.06	3.83	4.13
71.63	3.96	4.13
133.8	4.02	4.11
244.4	3.97	4.01
431.0	3.91	3.94
745.3	3.91	3.92
1266.	4.01	4.02

According to H. A. Wilson's theory, $1/(n_a)^{1/2} \log I_0/I$ should be constant for values of n_a which are not too small. These values are tabulated in Table II column 2. It is seen that they are practically constant for values of n_a greater than about 50×10^{10} . Wilson also proposed an empirical expression which is constant for all values of n_a and by means of which γ for an infinitely thin cell can be deduced. It is

$$\frac{(n_a + K)^{1/2}}{n_a} \log_e \frac{I_0}{I} = C. \quad (12)$$

It is seen that it goes over into the theoretical relation when n_a is large. Values of C are tabulated in Table II, column 3. From it γ for the infinitely thin cell is given by $C/K^{1/2}$ which for this case is 16.33×10^{-13} . This is thirteen times greater than the value secured (1.25×10^{-13}) when the same relation is applied to the results of Hughes and Thomas and about sixty per-cent greater than the maximum experimental value obtained in this experiment, (viz. 10.22×10^{-13}).

DISCUSSION

As the light from the jet is much more absorbable than that from an ordinary resonance lamp the distribution of energy in the line must be very different from the ordinary distribution, certainly the line must be much more homogeneous, probably as homogeneous as light from a discharge tube cooled in liquid air (disregarding, for the moment, the fact that actually all the atoms would be condensed). It would seem from this that the Doppler effect controls emission for no other effect presents itself which will be affected by the jet sufficiently to explain, even qualitatively, the observed effects. It is evident that Malinowski's assumption that the absorption and emission lines have the same width is not justified for we do not get his predicted results. A consideration of these results points to the conclusion that the emission line must be wider than the absorption line, otherwise the absorption coefficient would not increase rapidly as the number of atoms, n_a , diminishes. Since there are good reasons, already mentioned, for believing that the width of the emission line is determined by the Doppler effect, we must, therefore, conclude that, because the absorption line is apparently narrower than the emission line, the width of the absorption line is not controlled by the Doppler effect. It appears, since H. A. Wilson's theory applies to these results, that we may consider the mercury atoms, as far as absorption goes, behaving like simple linear oscillators. It does not seem possible, at present, to interpret the results of these absorption experiments in such a way as to give a satisfactory and consistent picture of the processes involved in emission and absorption of resonance radiation.

The above work was done at Washington University, St. Louis, Mo. The writer wishes to thank Dr. A. L. Hughes for especial assistance and advice given during the course of the experiment. Also he wishes to thank Mr. C. A. Reinhart, instrument maker, for help in the construction of apparatus.

THE DISPERSION FORMULA AND RAMAN EFFECT
FOR THE SYMMETRICAL TOP

BY MORRIS MUSKAT

THE GULF COMPANIES, PITTSBURGH, PA.

(Received March 28, 1930)

ABSTRACT

Schroedinger's theory of dispersion is applied to the symmetrical top. The dipole of the top is assumed to lie along the axis of symmetry, and the wave-length of the incident light to be large as compared with the dimensions of the top. An explicit expression is derived for the index of refraction of a gas composed of symmetrical tops, as a function of the frequency of the incident light. As the perturbed eigenfunction is a linear function of only 3 unperturbed eigenfunctions, the dispersion formula, for a given state, consists of only 2 terms.

The moments for the Raman effect transitions for the symmetrical top are also computed. Simple closed expressions are obtained, again because of the simplicity of the perturbed eigenfunctions. The polarization of the Raman variations is computed with the result that the unshifted lines are unpolarized whereas for the shifted lines: $|m_z|^2/|m_x|^2 = 4/3$.

THE importance of the symmetrical top for the interpretation of molecular spectra makes it of interest to derive the dispersion formula and Raman effect intensities for this mechanical system. Kronig and Rabi,¹ Reiche and Rademacher,² Manneback,³ and Condon,⁴ have developed the theory of the unperturbed state of the top, and its Stark and Zeeman effects. However, explicit expressions have not been yet given for the interaction of the top with time varying fields.

As a mechanical system, the top is defined by the fact that two of its moments of inertia are equal to A , and are unequal to the moment of inertia, C , about the axis of symmetry. It is considered as a rigid system. A dipole, of moment μ , lies along the axis of symmetry and interacts with a small periodic field, $E_0 \cos 2\pi\nu t$, directed along the Z axis, fixed in space.

The wave mechanical treatment of dispersion and Raman transitions is well known, being given originally by Schroedinger.⁵ This treatment in which the dispersion phenomena are considered as pulsating Stark effects, is valid if the wave-length of the incident light is large as compared to the dimensions of the atomic or molecular system; the application made here will also assume that we are dealing with relatively long wave-lengths.

THE DISPERSION FORMULA

We may begin with the well-known expression for the "partial density" to be associated with two states, j and j' , of the system perturbed by the radiation:

$$\begin{aligned} \psi_j \psi_{j'}^* = e^{2\pi i/h(W_{j'} - W_j)t} & \left[u_{j'} u_{j'}^* + e^{2\pi i \nu t} \left\{ u_{j'}^* \sum_r c_{jr}^+ u_r + u_j \sum_r c_{j'r}^* u_r^* \right\} \right. \\ & \left. + e^{-2\pi i \nu t} \left\{ u_{j'}^* \sum_r c_{jr}^- u_r + u_j \sum_r c_{j'r}^{*+} u_r^* \right\} \right]. \end{aligned} \quad (1)$$

In this equation, W_j is the eigenvalue of the unperturbed j state, and u_j is the corresponding unperturbed eigenfunction. The c_{jr} are proportional to the matrix elements of that part of the potential energy of the system that is due to the perturbing field. The * indicates the complex conjugate. If we refer the top to the Eulerian angles θ , ϕ , and χ , the c_{jr} in our case are given by:

$$\begin{aligned} c_{jr}^\pm &= \frac{-\mu E_0 A C^{1/2}}{2(W_j - W_r \pm h\nu)} \int_0^{2\pi} \int_0^{2\pi} \int_0^\pi u_j u_r^* \cos \theta \sin \theta d\theta d\phi d\chi \\ &\equiv \frac{-\mu E_0 z_{jr}}{2(W_j - W_r \mp h\nu)}. \end{aligned} \quad (2)$$

Following Manneback, the eigenfunctions u_j may be expressed as:

$$u_j \equiv u_{jnm} = e^{i(n\chi + m\phi)} y_{jnm}(x), \quad (3)$$

where n , m are quantum numbers associated with χ and ϕ , $x = \cos \theta$, and the y_{jnm} are an orthogonal set of functions satisfying the equation:

$$\frac{d}{dx} \left[(1-x^2) \frac{dy_{jnm}}{dx} \right] - \frac{m^2 - 2mnx + n^2}{1-x^2} y_{jnm} + j(j+1) y_{jnm} = 0. \quad (4)$$

n and m are integral and range independently from $-\infty$ to $+\infty$; j is integral and $\geq |n|$, $|m|$. Furthermore, the y_{jnm} satisfy a recurrence relation of the form:

$$x y_{jnm} = A(jnm) y_{j+1,nm} + B(jnm) y_{jnm} + C(jnm) y_{j-1,nm}. \quad (5)$$

It follows, then, that in our case the c_{jr} vanish unless the values of n and m are the same for both states j and r . They also vanish unless $|j-r| \leq 1$.

When in Eq. (1) we set $j'=j$, we have the "density" determining the dispersion produced by the (jnm) state. The form of (3) and the above remarks about the c_{jr} permit us to rewrite Eq. (1) in the form:

$$\psi_j \psi_j^* = u_j u_j^* + 2 \cos 2\pi \nu t \left[u_j^* \sum_r u_r (c_{jr}^+ + c_{jr}^-) \right]. \quad (6)$$

In this equation the values of n and m are the same in all the terms and hence are omitted from the subscripts. The dispersion moments are now:

$$m(jnm) = m_z = \mu \int \cos \theta \psi_j \psi_j^* d\tau. \quad (7)$$

The moments $m_x = \mu \int \sin \theta \psi_i \psi_i^* d\tau$ and $m_y = -\mu \int \cos \theta \sin \theta \psi_i \psi_i^* d\tau$ are obviously zero. Introducing the matrix elements z_{jr} , defined in Eq. (2), we get for the time varying part of m_z in which alone we are interested:

$$m(jnm) = 2\mu^2 E_0 \cos 2\pi\nu t \sum_r z_{jr}^2 \frac{(W_j - W_r)}{h^2\nu^2 - (W_j - W_r)^2}. \quad (8)$$

Now it may be shown from the formulae given by Manneback that the coefficients in Eq. (5) have the following values:

$$A(j, n, m) = \frac{1}{j+1} \left(\frac{\{(j+1)^2 - m^2\} \{(j+1)^2 - n^2\}}{(2j+1)(2j+3)} \right)^{1/2};$$

$$B(jnm) = \frac{mn}{j(j+1)}.$$

$$C(jnm) = A(j-1, n, m).$$

These give the explicit values of the only non-vanishing matrix elements z_{jr} , which are, clearly:

$$z_{j, j+1} = A(jnm); \quad z_{j, j} = B(jnm); \quad z_{j, j-1} = C(jnm). \quad (10)$$

Recalling that the eigenvalues of the symmetrical top are given by:

$$\frac{8\pi^2 A}{h^2} W_{jnm} = j(j+1) + \left(\frac{A}{C} - 1 \right) n^2, \quad (11)$$

and setting $\eta = -8\pi^2 A\nu/h$, we finally get for m_z :

$$m_z = \frac{32\pi^2 \mu^2 A E_0}{h^2(2j+1)} \cos 2\pi\nu t \left[\frac{\{(j+1)^2 - n^2\} \{(j+1)^2 - m^2\}}{(j+1)(2j+3) \{4(j+1)^2 - \eta^2\}} - \frac{(j^2 - n^2)(j^2 - m^2)}{j(2j-1)(4j^2 - \eta^2)} \right]. \quad (12)$$

As the state (j, n) has a $2j+1$ fold degeneracy in the quantum number m , we must use for our dispersion formula the average of m_z over m , i.e. the value: $\bar{m}_z = (1/2j+1) \sum_{m=-j}^{+j} m_z$. And noting that $\sum m^2 = j(j+1)(2j+1)/3$, where $|m| \leq j$, we get:

$$\bar{m}_z = \frac{32\pi^2 \mu^2 A E_0}{3h^2(2j+1)} \cos 2\pi\nu t \left[\frac{(j+1)^2 - n^2}{4(j+1)^2 - \eta^2} - \frac{(j^2 - n^2)}{4j^2 - \eta^2} \right]. \quad (13)$$

For the state: $j=0$, we must use:

$$\bar{m}_z = m_z = \frac{32\pi^2 \mu^2 A E_0 \cos 2\pi\nu t}{3h^2(4 - \eta^2)}. \quad (13a)$$

We therefore have the result that the index of refraction, r , for a gas in which there are N molecules, of the type of the symmetrical top, per unit volume, and all of which are in the (j, n) state, is given by:

$$\frac{r^2 - 1}{r^2 + 2} \cong \frac{r^2 - 1}{3} \cong \frac{2}{3}(r - 1) = \frac{128\pi^3\mu^2AN}{9h^2(2j+1)} \left[\frac{(j+1)^2 - n^2}{4(j+1)^2 - \eta^2} - \frac{j^2 - n^2}{4j^2 - \eta^2} \right]. \quad (14)$$

For an ensemble of molecules with a thermal equilibrium distribution the index of refraction will be:

$$r^2 - 1 = \frac{128\pi^3\mu^2AN}{3h^2} \frac{\left[\frac{1}{4 - \eta^2} + \sum_{-\infty}^{+\infty} n \sum_{|n|}^{\infty} j \left\{ \frac{(j+1)^2 - n^2}{4(j+1)^2 - \eta^2} - \frac{j^2 - n^2}{4j^2 - \eta^2} \right\} e^{-W_{jn}/kT} \right]}{\sum_{-\infty}^{+\infty} n \sum_{|n|}^{\infty} j(2j+1) e^{-W_{jn}/kT}} \quad (14a)$$

If we denote $h/8\pi^2A$ by ν_k , and if we put in the value of W_{jn} from Eq. (11), (14a) may be rewritten as:

$$r^2 - 1 = \frac{256\pi^3\mu^2NA}{3h^2} \frac{\sum_{-\infty}^{+\infty} n \sum_0^{\infty} p \left\{ \frac{(|n|+p)^2 - n^2}{4(|n|+p)^2 - (\nu/\nu_k)^2} \right\} \sin h - \frac{h\nu_k}{kT} (|n|+p) e^{-h\nu_k/kT \{ (A/C-1)n^2 + (|n|+p)^2 \}}}{\sum_{-\infty}^{+\infty} n \sum_0^{\infty} p (2|n| + 2p + 1) \exp - \left\{ \left(\frac{A}{C} - 1 \right) n^2 + \{ |n| + p \} (|n| + p + 1) \right\} \frac{h\nu_k}{kT}} \quad (15)$$

These formulae are simply special cases of the Kramers-Heisenberg general dispersion formula. And as is to be expected, the two terms in (14) are those corresponding to the only two possible transitions, involving radiation, from the (jnm) state of the unperturbed top.

THE RAMAN TRANSITIONS

To get the intensities of the Raman effect radiations we must compute the moments:

$$m_z = \mu \int \cos \theta \psi_{jnm} \psi_{j'n'm'}^* d\tau \quad (16)$$

$$m_x \pm im_y = \mp \mu i \int \sin \theta e^{\pm i\phi} \psi_{jnm} \psi_{j'n'm'}^* d\tau. \quad (17)$$

From (1), (3) and our remarks about the c_{jr} we immediately get the following selection rules:

$$\left. \begin{aligned} m_z(jnm; j'n'm') &= 0, \text{ unless: } n' = n; m' = m. \\ m_x + im_y(jnm; j'n'm') &= 0, \text{ unless: } n' = n; m' = m + 1. \\ m_x - im_y(jnm; j'n'm') &= 0, \text{ unless: } n' = n; m' = m - 1. \end{aligned} \right\} \quad (18)$$

We may now express the form of the moments as:

$$m(jnm; j'n'm') = \mu e^{2\pi i/h(W_{j'} - W_j)t} \left[q_{jj'} + e^{2\pi i\nu t} \left\{ \sum_r (c_{jr}^+ q_{rj'} + c_{j'r}^- q_{jr}) \right\} + e^{-2\pi i\nu t} \left\{ \sum_r (c_{jr}^- q_{rj'} + c_{j'r}^+ q_{jr}) \right\} \right] \quad (19)$$

where for m_z , $q_{jj'} = z_{jj'}$, as defined in Eq. (2); and for $m = m_x \pm im_y$, $q_{jj'} = \mp i \int \sin \theta e^{\pm i\phi} u_j u_{j'}^* d\tau$. The problem that remains is that of obtaining the values of the $q_{jj'}$ and putting them into Eq. (19).

From Eqs. (2) and (10) we see that the only non-vanishing moments m_z are: $m_z(j; j \pm 2)$ and $m_z(j; j \pm 1)$. Upon putting into (19) the values of the matrix elements as given in Eqs. (9) and (10), we get for these moments:

$$m_z(j; j+2) = \frac{-8\pi^2 \mu^2 E_0 A e^{+2\pi i/h(W_{j+2,n} - W_{j,n})t}}{h^2(j+1)(j+2)(2j+3)} \left(\frac{\{(j+2)^2 - n^2\} \{(j+2)^2 - m^2\} \{(j+1)^2 - n^2\} \{(j+1)^2 - m^2\}}{(2j+1)(2j+5)} \right)^{1/2} \left[\frac{e^{2\pi i \nu t}}{\{\eta - 2(j+1)\} \{2(j+2) - \eta\}} - \frac{e^{-2\pi i \nu t}}{\{2(j+2) + \eta\} \{2(j+1) + \eta\}} \right] \quad (20)$$

$$m_z(j; j+1) = \frac{\mu e^{2\pi i/h(W_{j+1,n} - W_{j,n})t}}{j+1} \left(\frac{\{(j+1)^2 - m^2\} \{(j+1)^2 - n^2\}}{(2j+1)(2j+3)} \right)^{1/2} \left[1 - \frac{16\pi^2 \mu E_0 A m n}{h^2 j(j+2)} \left\{ \frac{e^{2\pi i \nu t}}{\eta \{\eta - 2(j+1)\}} + \frac{e^{-2\pi i \nu t}}{\eta \{\eta + 2(j+1)\}} \right\} \right]. \quad (21)$$

$m_z(j; j-2)$ is to be obtained from $m_z(j; j+2)$ by replacing j by $j-2$ and taking the conjugate; and similarly we get $m_z(j; j-1)$ from $m_z(j; j+1)$ by replacing j by $j-1$ and taking the conjugate.

To evaluate the matrices $q_{jj'}$ from $m_x \pm im_y$ we have to compute integrals of the form: $\int_0^\pi \sin^2 \theta y_{jnm} y_{j'n'm'} d\theta$. For this purpose we make use of the results of Reiche and Rademacher. If we compare the present notation with theirs we find that we have the following relation for the integrals in question:

$$4\pi^2 AC^{1/2} \int_0^\pi \sin^2 \theta y_{jnm} y_{j'n'm'} d\theta = 2L_{a,b,l} / (J_{a,b,l} J_{a',b',l'})^{1/2} \quad (22)$$

where the $L_{abl, a'b'l'}$ and J_{abl} are integrals evaluated by Reiche and Rademacher, the latter being normalization integrals. The parameters a, b, l , are defined by:

$$a = |m+n|; b = |m-n|; l = j - \frac{a+b}{2}.$$

In addition to the selection rules of Eq. (18) we must take account of the four following cases possible for the change: $|m' - m| = 1$.

- a) $\Delta a = +1; \Delta b = +1$; b) $\Delta a = +1; \Delta b = -1$; c) $\Delta a = -1; \Delta b = +1$; d) $\Delta a = -1; \Delta b = -1$.

The Δ_s refer to the difference of the value of the parameter between the primed and unprimed states. Different integrals $L_{a,b,l, a'b'l'}$ must be used for these four cases. It turns out, however, that all four cases give the same final result, so that here only case a will be considered.

For this case, we have, according to Reiche and Rademacher:

$$L_{a+1, b+1, l'} = 0 \text{ for } l' < l-2 \text{ and } l' > l. \quad (23)$$

The non-vanishing integrals have the values:

$$\begin{aligned} & \frac{L_{a, b, l}}{a+1, b+1, l} / (J_{a, b, l} J_{a+1, b+1, l})^{1/2} \\ = & \frac{1}{2l+a+b+2} \left(\frac{(l+a+1)(l+b+1)(l+a+b+1)(l+a+b+2)}{(2l+a+b+1)(2l+a+b+3)} \right)^{1/2} \\ & \frac{L_{a, b, l}}{a+1, b+1, l-1} / (J_{a, b, l} J_{a+1, b+1, l-1})^{1/2} \\ = & \frac{(b-a)(l(a+b+l+1))^{1/2}}{(2l+a+b)(2l+a+b+2)} \quad (24) \\ & \frac{L_{a, b, l}}{a+1, b+1, l-2} / (J_{a, b, l} J_{a+1, b+1, l-1})^{1/2} \\ = & \frac{1}{(2l+a+b)} \left(\frac{l(l-1)(l+b)(l+a)}{(2l+a+b-1)(2l+a+b+1)} \right)^{1/2}. \end{aligned}$$

In these formulae, the following values of the parameters are to be used:

For: $m' = m+1$, $a = n+m$, $b = m-n$, $l = j-m$.

For: $m' = m-1$, $a = -n-m$, $b = n-m$, $l = j+m$.

When these substitutions are made in the values of the integrals and finally in Eq. (17), the results are the following:

$$\begin{aligned} m_x \pm im_y = & \frac{j'=j+2}{h^2(j+1)(j+2)(2j+3)} \left(\frac{\{(j+2)^2-n^2\} \{(j+1)^2-n^2\} \{(j+1)^2-m^2\}^{1/2}}{(2j+1)(2j+5)} \right) \\ & \cdot ((j+m+3)(j \pm m+2))^{1/2} \left\{ \frac{e^{2\pi i \nu t}}{\{\eta-2(j+1)\} \{2(j+2)-\eta\}} - \frac{e^{-2\pi i \nu t}}{\{\eta+2(j+1)\} \{\eta+2(j+2)\}} \right\} \\ m_x \pm im_y = & \frac{j'=j+1}{(j+1)} \mp i \mu e^{2\pi i/h(W_{j+1, n} - W_{j, n})t} \left(\frac{\{(j+1)^2-n^2\} (j \pm m+2)(j \pm m+1)^{1/2}}{(2j+1)(2j+3)} \right) \\ & \left[1 \mp \frac{8\pi^2 \mu A E_0}{h^2 j(j+2)} n(j \pm 2m) \left\{ \frac{e^{2\pi i \nu t}}{\eta \{\eta-2(j+1)\}} + \frac{e^{-2\pi i \nu t}}{\eta \{\eta+2(j+1)\}} \right\} \right] \\ m_x \pm im_y = & \frac{j'=j-2}{h^2(j-1)(2j-1)} \pm \frac{8\pi^2 \mu^2 i A E_0 e^{2\pi i/h(W_{j-2, n} - W_{j, n})t}}{(2j-3)(2j+1)} \left(\frac{\{(j-1)^2-n^2\} (j^2-n^2)(j^2-m^2)(j \mp m-1)(j \mp m-2)^{1/2}}{(2j-3)(2j+1)} \right) \\ & \left[\frac{e^{2\pi i \nu t}}{(2j+\eta) \{2(j-1)+\eta\}} + \frac{e^{-2\pi i \nu t}}{\{2j-\eta\} \{2(j-1)-\eta\}} \right] \quad (25) \end{aligned}$$

The value for $j' = j-1$, is to be obtained from that for $j' = j+1$ by replacing in the expression for the latter j by $-j-1$.

As in the case of m_x , all the moments $m_x \pm im_y$ vanish for which $|j-j'| \geq 3$. It should be noted that as $m_x - im_y = 0$, for $m' = m+1$, $m_x + im_y = 2m_x = 2im_y$; and as $m_x + im_y = 0$, for $m' = m-1$, $m_x - im_y = 2m_x = -2im_y$.

Formally, we can express the general moment $m(jnm; k'n'm')$ as:

$$m(j; k) = m(\nu_{jk}) e^{2\pi i \nu_{jk} t} + m(\nu + \nu_{jk}) e^{2\pi i (\nu + \nu_{jk}) t} + m(\nu - \nu_{jk}) e^{-2\pi i (\nu - \nu_{jk}) t} \quad (26)$$

where $m(\nu)$ is the moment oscillating with the frequency ν , and $\nu_{jk} = (W_k - W_j)/h$. To get the intensities of transitions for these particular

frequencies, we must pick out from the general expression of Eq. (26) the "partial moments" oscillating with that frequency. We thus see immediately that all the $m(\nu_{jk})$ vanish for $|\Delta j| = 2$. This simply means that there is no "unshifted" Raman lines for such transitions; and this is to be expected, since there are no spontaneous transitions for the unperturbed top, for which $|\Delta j| = 2$. To get the total intensities we must know the squares of the resultant moments, given by:

$$R(\nu) = |m_x(\nu)|^2 + |m_y(\nu)|^2 + |m_z(\nu)|^2 \quad (27)$$

From the previous equations we find that:

$$\left. \begin{aligned} R(\nu + \nu_{j,i+2}) &= \frac{64\pi^4 \mu^4 A^2 E_0^2 \{ (j+2)^2 - n^2 \} \{ (j+1)^2 - n^2 \} \{ (j+1)^2 - m^2 \}}{h^4 (j+1)^2 (2j+3)^2 (j+2)(2j+1) \{ \eta - 2(j+1) \}^2 \{ 2(j+2) - \eta \}^2} \\ R(\nu + \nu_{j,i+1}) &= \frac{64\pi^4 \mu^4 A^2 E_0^2 n^2 \{ (j+1)^2 - n^2 \} \{ j^4 + 3j^3 + 2j^2 - 2j^2 m^2 + 9m^2 + 3m^4 \}}{h^4 (j+1)^2 j^2 (2j+1)(2j+3)(j+2)^2 \eta^2 \{ \eta - 2(j+1) \}^2} \\ R(\nu_{j,i+1}) &= \frac{\mu^2 \{ (j+1)^2 - n^2 \}}{(2j+1)(j+1)} \\ R(\nu + \nu_{j,i-2}) &= \frac{64\pi^4 A^2 E_0^2 \mu^4 \{ (j-1)^2 - n^2 \} \{ j^2 - n^2 \} \{ j^2 - m^2 \}}{h^4 j^2 (j-1)(2j-1)(2j+1)(2j+\eta)^2 \{ 2(j-1) + \eta \}^2} \end{aligned} \right\} \quad (28)$$

In the above, the values of R are not listed for the Raman lines of frequency $\nu - \nu_{jk}$. But these may be obtained from those given by replacing η by $-\eta$ wherever it occurs. It may be noted that the values of R for the unshifted lines are independent of m ; this is in agreement with the observation of Reiche and Rademacher that none of the squared moments of the unperturbed top depend on m .

We have finally to sum the given values of R over m , since the unperturbed top is degenerate with respect to m . Using the value of

$$\sum_{|m| \leq j} m^4 = \frac{j}{15} (j+1)(2j+1)(3j^2 + 3j - 1)$$

we get

$$\begin{aligned} I(\nu + \nu_{j,i+2}) &\equiv \sum_{|m| \leq j} R(\nu + \nu_{j,i+2}) \\ &= \frac{64\pi^4 \mu^4 A^2 E_0^2 \{ (j+2)^2 - n^2 \} \{ (j+1)^2 - n^2 \}}{3h^4 (j+1)(j+2)(2j+3) \{ \eta - 2(j+1) \}^2 \{ 2(j+2) - \eta \}^2} \\ I(\nu + \nu_{j,i+1}) &= \frac{448\pi^4 \mu^4 A^2 E_0^2 n^2 \{ (j+1)^2 - n^2 \}}{15h^4 j (j+1)(j+2) \eta^2 \{ \eta - 2(j+1) \}^2} \\ I(\nu_{j,i+1}) &= \frac{\mu^2 \{ (j+1)^2 - n^2 \}}{(j+1)} \\ I(\nu + \nu_{j,i-2}) &= \frac{64\pi^4 \mu^4 A^2 E_0^2 \{ (j-1)^2 - n^2 \} \{ j^2 - n^2 \}}{3h^4 j (j-1)(2j-1)(2j+\eta)^2 \{ 2(j-1) + \eta \}^2} \end{aligned} \quad (29)$$

For $j' = j - 1$, we replace the values of j in the expression for I for $j' = j + 1$ by $-j - 1$ and change the sign. Again, the values for I for $\nu - \nu_{jk}$ are to be obtained from the above by replacing η by $-\eta$, wherever it occurs.

These formulae permit a computation of the intensities of any Raman line emitted or absorbed by a gas whose molecules are of the type of symmetrical tops.

It is of interest to note that in none of these formulae for the Raman moments or for the dispersion by a single state, does the moment of inertia C enter. This might be expected, however, since as observed by Manneback, C does not enter in the corresponding formulae of the Stark effect, and our dispersion theory deals essentially with a pulsating Stark effect. But to formally remove the effect of the moment of inertia C we must make $n = 0$. This makes the top equivalent to the three dimensional rotator. And in fact, putting $n = 0$, in our dispersion formulae reduces them to those derived by Debye⁶ for the rotator. When we put in $n = 0$ in the expression for the Raman moments we see that there will be no Raman lines, with the shift in frequency, for the transitions occurring in the unperturbed state of the rotator; on the other hand, there will be the shifted Raman lines for the transitions that violate the selection rule of the unperturbed rotator, and which are induced by the incident light. This fact may be considered as a special case of the same rule which has been shown by a number of authors to hold in the rotational fine structure of the Raman spectra of diatomic molecules.

Finally we may compute from Eqs. (20), (21), and (25) the polarization of the Raman radiations. The result is that for the unshifted lines we get:

$$|m_x|^2 = |m_y|^2 = |m_z|^2. \quad (30)$$

For the shifted lines, however, we do get a polarization, given by:

$$|m_x|^2 = |m_y|^2 = \frac{3}{4} |m_z|^2. \quad (30a)$$

The writer is indebted to Dr. A. E. Ruark for the opportunity of discussing with him questions arising in this problem.

THE LOCATION OF THE ELECTROMOTIVE FORCE IN
THE PHOTOVOLTAIC CELL

BY W. NORWOOD LOWRY

DEPARTMENT OF PHYSICS, CORNELL UNIVERSITY

(Received April 8, 1930)

ABSTRACT

1. A method was developed to utilize a 4-element vacuum tube to measure small potential differences.
2. The so called photovoltaic e.m.f. appears to be a modification of the electrolyte with light, there being no indication of any effect due to the direct illumination of the electrode or the boundary region between the electrode and the electrolyte.
3. In certain types of experiments with these cells, current measurements cannot be regarded as a quantity proportional to e.m.f.
4. The e.m.f. of the photovoltaic cell increases with the concentration of the electrolyte.

INTRODUCTION

IT IS well known that when two similar electrodes are placed in a suitable electrolyte and one of the electrodes is illuminated while the other is kept in the dark, an e.m.f. is produced. Goldmann¹ attributed the phenomena to a photoelectric effect arising from the illumination of the boundary between the electrode and the electrolyte. Grumbach² introduced near one electrode of a dark cell a small amount of previously irradiated electrolyte and obtained an effect, thus showing that the e.m.f. produced was due, at least in part, to a change or modification of the electrolyte with light.

Murdock³ devised a means whereby the electrolyte flowed by the electrode in such a way that the electrolyte could be irradiated before, while, or after flowing by the electrode, and like Grumbach found the effect largely due to some change in the electrolyte. But in addition having found that the steady state current increased suddenly when the electrode first entered the edge of the illuminated region, he was led to believe that there might be some effect superimposed upon that due to photo-chemical change, when the boundary between the electrode and the electrolyte was irradiated.

Subsequent workers^{4,5} have felt that certain variations in their results might arise from an effect other than the photochemical change of the electrolyte.

The original purpose of this present work was to devise a means of finding some of these variations if they existed, and, if found, to study them.

APPARATUS AND GENERAL DISCUSSION

The apparatus used in the first part of this investigation has been patterned after that of Murdock,⁶ but with some modifications. Briefly, platinum electrodes in the form of long narrow strips were sputtered diametrically opposite on the outside of a pyrex test tube 18×150 mm. Pyrex was used as it was found less likely to crack than the soft glass test tubes, when copper wires were soldered to the top of the platinum films. The sputtered films were about 130×6 mm. After the Cu wires were soldered, the test tubes were covered with bakelite lacquer down to about 8 mm from the end of the film. This left the electrode itself exposed, with dimensions of about 8×6 mm. The rest of the platinum film served only as a conducting lead to the soldered wire. Except for very thin electrodes the platinum leads were the same density as the electrodes, as it was found that cells made in this way stood up over longer periods than those previously used,³ due to the tendency of the bakelite lacquer (used to insulate the lead from the electrolyte) to chip off from the glass with the thicker films, and that higher resistance was not objectionable, in making e.m.f. measurements.

Considerable care was taken with the sputtering process, a special sputtering jar being designed so as to eliminate as far as practicable the occlusion of undesirable gases in the films. A G.E. 10 kv, 100 m.a. D.C. generator was used, which permitted very close control of current and voltage while sputtering. The test tubes were first thoroughly cleaned. After sputtering they were aged slowly by heating to a temperature ranging between 300–360°C for several hours; then they were slowly cooled, lacquered, dried in air, and baked at 135°C. Of the 32 cells made in this way, only a few were found, when first tried, to have a dark e.m.f. of such a magnitude as to prohibit their use.

The test tube was slipped over a vertical brass tube covered with felt so as to hold the test tube snugly, but permit of its rotation about the brass tube. A small rectangular window was cut in the lower end of the brass tube, and a beam of light, caused to pass down the brass tube, was reflected through the window by means of a mirror placed at a 45° angle just behind it. By turning the test tube, the electrode, which was slightly smaller than the window, could be brought directly in front of the window, or on either side of it, through a range of more than 180°, and by a suitable scale and index the position of the electrode in respect to the window could be determined. The test tube was placed in a cylindrical glass bottle (painted black to exclude external light) containing the electrolyte, rhodamine B in absolute alcohol. The mouth of the bottle was just large enough to give about 2 mm clearance around the test tube, in order to reduce evaporation. This bottle was mounted on a rotator, driven by a synchronous motor through a reduction gear, assuring constant speed of rotation. The bottle with its electrolyte thus rotated concentrically about the test tube with its electrodes.

⁶ C. C. Murdock and D. W. Murdock, *Trans. of the Faraday Soc.* **23**, part 5, 593 (1927).

Filters were used to vary the intensity of illumination. They consisted of photographic plates exposed for different lengths of time and developed in the usual manner. The transmission of the filters as well as the electrodes was measured photometrically. In every case the light passed through a water cell to remove the infra red radiation.

All concentrations of electrolyte are given as percent of rhodamine B by weight in absolute alcohol.

Using a similar cell, Murdock obtained the curve previously published³ by plotting the current against the position of the electrode in respect to the window. The current was measured by a high sensitivity galvanometer in series with a suitable resistance, after a steady state had been obtained. He pointed out that his results were in agreement with Grumbach's,² but that the change in slope of the curve at the points where the electrode began to be directly illuminated indicated that some effect other than photochemical change might exist. He also showed that the effect was dependent

FIG. 1

upon the shape of the electrode and that polarization⁶ played an important rôle.

It was felt that the actual e.m.f. produced might not be directly proportional to the residual current that he measured. Therefore it was decided to utilize a potential measuring instrument, that would not draw current.

A Compton type quadrant electrometer was used in the major part of the work, but on account of its long period another device was developed. This consisted of a specially constructed 4-element vacuum tube, built by Osram in Berlin, connected as shown in Fig. 1. The purpose of this tube was to act as a voltage amplifier for the small potentials measured, and by means of the 4th element or "space charge grid" to effectively prevent current being drawn from the source. The filament is surrounded by a helical "space charge grid," which is enclosed by a second helical control grid, with a lead brought out through an amber bushing in the top of the tube. The cylindrical plate is just outside of the control grid. The 4 elements are nearly concentric. B_1 , B_2 and B_3 are storage batteries of 6, 6, and 24 volts respectively. B_4 consists of 3 standard cells, which were used because of the necessity to maintain a constant negative bias in series with the e.m.f. to be measured. Plug type resistance boxes were used for R_1 and R_2 to eliminate variable contact resistance. A highly insulated mercury contact switch was used to quickly connect either the potentiometer or cell circuits

to the measuring system. A galvanometer having a sensitivity of 25,000 megohms was connected in the plate circuit through an Ayrton shunt and an auxiliary resistance to critically damp it.

In operation the control grid was made more negative than its floating potential to prohibit electron current. The space charge grid was made positive (from 2 to 3 volts) in respect to the filament in order to shield the control grid from positive ions. An extremely hard tube, operation of filament at 40 percent of normal temperature, and low plate potential (18 to 22 volts) all contributed to reduce positive ion current. Leakage was reduced by precautions in the insulation of the control grid lead coming out through the top of the tube, and the use of ceresine wax to insulate every lead and piece of apparatus in the circuit. A galvanometer having a sensitivity of 25,000 megohms used at a distance of 3 meters from the scale showed no trace of a deflection when connected in series with the control grid circuit. It should indicate any current greater than 10^{-13} amperes.

E.m.f. measurements were made by noting the change in plate current when the source of potential was connected in series with the standard cells so as to make the control grid more negative.

Sensitivity could be varied by changing R_1 , R_2 , B_3 or B_4 . After proper adjustments were once made R_1 and R_2 were the only controls needed. The system was used with a sensitivity between 3000 and 4000 mm per volt, although 5200 mm per volt was obtained. With suitable amplification higher sensitivities should be possible.

For very small values the e.m.f. was found to be nearly linear with scale deflections.

The advantages of the system lie in the short period of the galvanometer, and freedom from the usual electrometer adjustments.

The disadvantages may be summed up as follows:

1. It was difficult to make comparative measurements over long periods of time due to slight fluctuations in battery voltages.
2. Changes in room temperature changed the constants of the circuit.
3. The tube was found to be photoelectric. (This was taken care of by covering the tube with a metal shield and grounding it.)
4. Special precautions had to be taken against leakage currents.
5. The system was extremely sensitive to high tension discharges or arcs.
6. The filament of the tube had to be burned several hours before using the system.

EXPERIMENTAL

The electrolyte rotating with the bottle had a small region illuminated as it passed in front of the window. The test tube was adjusted vertically while assembling so that the front electrode was symmetrically placed in front of the window. By moving the test tube about the axis of the brass tube, the horizontal position of the electrode in respect to the window could be altered, and thus the electrolyte could be irradiated before, while in contact with, or after passing by the electrode. This arrangement per-

mitted a study of the effect when the boundary region between the electrode and electrolyte was illuminated, as well as the condition when the electrode was displaced from the window so that the effect was produced by the previously irradiated electrolyte flowing by the electrode. The scale which indicated the position of the electrode in respect to the window was arranged to read in millimeters displacement.

There were four variable factors: (1) speed of rotation of electrolyte; (2) thickness of sputtered films; (3) intensity of illumination; and (4) con-

In this experiment a square electrolyte bottle was used.

centration of rhodamine B in the electrolyte. In order to make a thorough study of the effect many sets of data were obtained in which three of these factors were held constant and the fourth varied.

Two distinct types of cell were used in this part of the work. (1) The electrodes were arranged opposite each other, and were of the same length. (2) The back electrode, while opposite, was from 3 to 4 cm above the front one. Hereafter the former will be referred to as a cell with "opposite" electrodes, and the latter as one with "staggered" electrodes. With staggered electrodes the irradiated material from the window should stream around

an annulus the height of the window, and should not come in contact with the back electrode, except for vertical diffusion.

The following curves show a few results which are representative of many sets of data taken. The white rectangles represent the window and the shaded ones the electrode, and the numbers the scale readings for the positions shown. The arrows indicate the direction in which the electrolyte flowed by the window.

Fig. 2 is a set of curves showing the relation between e.m.f. and time for various positions of the electrode in respect to the window. The numbers along the right hand side of the curve represent the positions of the electrode, the scale being laid off so that each unit represented a movement of 1 mm in respect to the window.

FIG. 3

The cell was allowed to rotate in the dark until only a small dark e.m.f. was present; then time was measured from the beginning of illumination. This procedure was repeated for each curve. These shown are only part of the total number of time curves thus studied. No attempt has been made to indicate the points, as the curves were drawn free hand through practically all of them.

They show that after a time a steady state value of e.m.f. is obtained for each position of the electrode. The shape of the curves can be accounted for. If the electrode is at the left of the window, a certain time will elapse before the irradiated material will be carried around to the electrode. When it reaches this point, there will be a sudden rise in the e.m.f. Later some of the material will be carried around to the back electrode giving a differential

effect, and causing a decrease in the e.m.f. As one would expect, the maximum effect is found when the electrode is part way across the window and moving from left to right, because, as the electrode more nearly covers the window, the intensity of illumination is decreased by the electrode itself. When the electrode is at the left of the window the effect grows smaller since diffusion carries away some of the changed material. When the electrode is at the right of the window the back electrode receives the modified material first, which accounts for the negative e.m.f., and which of course is much smaller on account of diffusion as stated above. It is interesting to note that as the electrode approaches the window in either direction

FIG. 4

Opposite electrodes	
Electrode transmission	35 percent
Concentration of electrolyte	2.19 percent
Method of measurement	4-element vacuum tube system

the maximum effect for each curve, which is either a positive or a negative e.m.f., occurs sooner. This represents the time required for the largest amount of changed material to reach the front electrode. It will also be observed that the steady state e.m.f. occurs in a shorter time as the electrode approaches the window. This latter fact was observed in all subsequent experiments.

Fig. 3 represents a curve similar to those in Fig. 2 except "staggered" electrodes were used. The approximate position of the electrode is shown by the diagram, and the arrow shows the direction of flow of the electrolyte. As might be expected, no maximum is found, but the e.m.f. builds up to the steady state value.

Fig. 4 shows a set of e.m.f.—time curves for varying speeds of rotation. The diagram shows the position of the electrode in respect to the window for all curves, and the arrow shows the direction of flow of electrolyte. Numbers on curves represent speeds of rotation. These curves show that the steady state of e.m.f. is independent of speed, within the limits tried. It is also seen that the maximum point is reached in shorter time as the speed increases; this result would be expected from the discussion of Fig. 2. The curves were drawn free hand through practically all of the points.

FIG. 5

Opposite electrodes

Concentration of electrolyte	2.46 percent
Method of measurement	4-element vacuum tube system

Fig. 5 shows the relationship between e.m.f. and position of electrode in respect to window. Each point was taken after a steady state e.m.f. had been reached. The points were not taken on consecutive electrode positions, but at random positions over different parts of the scale. The variations are small when it is considered that the time for taking these data was several hours, and that the voltages used for controlling the vacuum tube system were bound to fluctuate some in this period. The diagrams at the top show the positions of the electrode and the vertical lines on the curve

indicate these positions. This arrangement is similar to that of Murdock,³ the regions *a*, *b*, *c*, *d*, and *e* representing respectively: electrolyte illuminated before passing electrode; electrode partially illuminated; electrode completely illuminated; electrode partially illuminated; and electrolyte illuminated after passing electrode. The arrow shows the direction of flow of the electrolyte.

Fig. 6 shows two curves plotted with positions of electrode in respect to e.m.f. Curve *B* was obtained by reversing the direction of rotation of the electrolyte from that in *A*, the lettered arrows indicating the respective directions of electrolyte rotation. In this case data were taken for consecu-

Method of measurement	Compton electrometer

tive electrode positions, and as a check were again taken consecutively back over the scale. The circles represent increasing scale readings for electrode positions, and the crosses, the return or decreasing scale readings. The symmetry of the two curves is quite marked. Murdock³ was unable to obtain this symmetry when making current measurements, which failure he attributed to the shape of the electrode.

Fig. 7 is another group of curves taken in a similar manner to those in Fig. 6. In this case the intensity of illumination was varied by filters, the other factors being kept constant. Curves *A*, *B*, and *C* represent intensities of 3 percent, 17 percent, and 100 percent respectively. The circles and crosses again have the same meaning as in Fig. 6.

DISCUSSION

If there is an e.m.f., due to the illumination of the electrode or the boundary between the electrode and the electrolyte, measurable with the instruments used, superimposed upon that due to a photo-chemical change

FIG. 7

Opposite electrodes	
Electrode transmission	24 percent
Speed of rotation	14.9 r.p.m.
Concentration of electrolyte	4.2 percent
Method of measurement	Compton electrometer

of the electrolyte, one would expect to find an abrupt change of slope on going from a dark to an illuminated region. A study of Figs. 5, 6 and 7 reveals no such change. Many similar sets of data were taken in which one

of the four factors before mentioned was varied and in every case a smooth curve resulted in going from region "a" to region "b."

This regularity leads to the viewpoint that the phenomenon is due entirely to the modification of the electrolyte with light, and that the effect follows the laws of the concentration cell theory. If one calls the original material *A* and the modified material due to light, *B*, then the e.m.f. will depend upon the difference in concentrations of *B* at the two electrodes, and this has been shown to be a function of $\log C_1/C_2$, where C_1 and C_2 are the concentrations of *B* at the electrodes.

In these cells the concentration of material *B* should be some function of three variable factors: (1) the intensity of the light; (2) time of illumination; and (3) the concentration of material *A*. According to the concentration cell theory, one would expect the effect to increase with these three factors. Rule⁴ has shown that the e.m.f. is a function of the intensity and time of illumination. In an earlier experiment⁷ by him and independently by Mrs. Junkins,⁸ it was found that a maximum effect occurred for a particular concentration of material *A*, and any further increase in concentration of material *A* gave a decreased effect.

From the results in the rotational experiments of the present work in which concentrations were varied, and from the concentration cell theory, it was felt that the effect must increase with the concentration of material *A*. Accordingly ten rhodamine B solutions of varying strengths were made up in small bottles, and in turn were slipped over a test tube with the electrode placed directly in front of the window and the electrolyte at rest. Fig. 8 shows the results where e.m.f. was plotted against time, the numbers on the right hand side of the curves being percent concentrations of rhodamine B. It is seen that the effect increases with the concentration. It was later found that the solution became saturated a little above 8 percent. While care was used in making up the solutions, the concentrations were not afterward checked gravimetrically, as in the case of the former experiments with the rotating electrolyte, and may be slightly in error. In Fig. 9 the data were secured by subtracting the dark e.m.f.'s observed at the beginning of each time curve from the values obtained after ten minutes irradiation. It is quite evident that there is no maximum value for any particular concentration below saturation. Goldmann,¹ while making current measurements, found no maximum sensitivity for any particular concentration. In Rule's experiment⁷ using fluorescein, e.m.f. was measured against concentration, but the electrode was illuminated through the electrolyte. For very dilute solutions not much light would be absorbed in the outer layers of the electrolyte, but on increasing the concentration more and more light would be absorbed. Hence there would be a particular concentration for any given intensity of illumination where the intensity of light near the electrode (and therefore material *B*) would be a maximum. Mrs. Junkins⁸ illuminated the

⁷ W. Rule, *Phil. Mag.* 1, 532 (1926).

⁸ R. Y. Junkins, *Phys. Rev.* 18, 402 (1921), May 1929.

electrolyte through a semi-transparent electrode, as in the present work, but used current measurements as an indication of the effect with concentration, and found that for rhodamine B the maximum value occurred near 3 percent. Subsequent workers^{3,5} used this value, believing it to give a maximum effect. Probably the current measurement was affected by polarization, and the rate of diffusion of polarizing material, which constitutes a quantity proportional to the current measured, must have attained a maximum value at 3 percent concentration.

FIG. 8

In Figs. 5, 6, and 7 it will be observed that in region "e" the values of e.m.f. fluctuate. This is probably due to the fact that the effect is small, and that some light gets to the electrode by scattering and reflection, even though the electrode is at the right of the window, and in this position the back electrode begins to receive some of the irradiated material first. Diffusion also carries some of the new material to the front electrode against the direction of rotation. The fluctuation was observed in all of the data taken. It was also found that a greater length of time was always necessary to reach a steady state condition in this region. This effect was more marked in those curves where the intensity of light or the concentration of electrolyte was very small.

Rule,⁴ using uranine, found at the beginning and end of illumination a small e.m.f. opposite in sign from the major effect. Russell,⁵ working with rhodamine, did not actually observe a reversal, but found that the values of e.m.f., for a short interval of time after illumination began, departed somewhat from the theory he had developed, leading him to believe that some effect similar to the one found by Rule might be superimposed upon that due to photo-chemical change. Grumbach² also observed reversals.

Such an effect would not be compatible with the theory that an e.m.f. due to a pure concentration cell was the only one present, so a careful investigation was deemed advisable. In getting the data for Figs. 8 and 9, readings at the exact beginning and end of illumination were noted for each concentration, but no such effect was observed. Several different types of cell holders were used with rhodamine B and uranine at different concentra-

FIG. 9

tions. No reversal was found either at the beginning or end of illumination, even when a cell was made up and used in exact accordance with the method of Rule,⁴ though the growth-time curves were found to agree consistently with his.

REMARKS

In all of the rotational experiments, in which e.m.f. was plotted against position of electrode in respect to the window, no break in the slope of the curve was found when the electrode first entered the illuminated region. As stated before, in the case of current measurements such a break has been observed. Contradictory to the results of another investigator, no reversal of e.m.f. was observed at the beginning or end of illumination in taking the growth-time curves of a cell. Both of these small effects had been previously interpreted as due to the illumination of the electrode or a region very close to it, and had been thought to be superimposed upon the main effect arising from a photo-chemical change of the electrolyte. The results of the present work thus lead to the viewpoint that there is no auxiliary effect produced by directly irradiating the electrode.

The failure to find a break in the curve when the electrode first entered the illuminated region can be attributed to the fact that e.m.f., instead of

current measurements were made. Likewise the discrepancy between the results of the present work and that of Mrs. Junkins, in which sensitivity of the effect with increasing concentrations was studied, can be explained in the same way. Therefore, it is inferred that current measurements are not satisfactory for studying some of the phenomena occurring in this type of cell, especially in these particular cases mentioned where it was evidently assumed that the current was proportional to the e.m.f. A possible explanation might be that this disagreement in results was linked with some peculiarity of the polarization present in current measurements.

The author wishes to express his appreciation to Professor C. C. Murdock, who suggested the original problem and contributed many suggestions and valuable criticism during its progress. Also to Professors Ernest Merritt and R. C. Gibbs in particular, and to other members of the Physics staff in general, who made helpful suggestions in regard to the work.

THE VISCOSITY OF COMPRESSED GASES

BY JAMES H. BOYD, JR.†

DEPARTMENT OF CHEMICAL ENGINEERING, MASSACHUSETTS INSTITUTE OF TECHNOLOGY

(Received April 7, 1930)

ABSTRACT

New data and a new theory for the viscosity of compressed gases are presented. Data for nitrogen, hydrogen and a mixture of these gases are given, in the calculation of which, the "end effects" are not neglected as has been done in the past. Previous viscosity data are of doubtful validity owing to neglect of this factor. The theory is based on an analogy between the kinetic pressure and viscosity of a gas and is derived using an equation of state of the Lorentz type. Allowance is made for the difference between the viscosity and compressibility covolumes. The theory is substantiated experimentally and further confirmed by the recalculation of other data on the variation of Reynolds' criterion with the pressure, which is here shown to be constant. The mixture data offer a direct opportunity of comparing the Lorentz and linear rules for the calculation of the covolume of a mixture from the covolumes of the components and such comparison indicates that the Lorentz rule is not to be preferred. The substantiation of the new theory is the first direct proof of the validity of the separate treatment of the kinetic and cohesive pressures in the equation of state.

I. INTRODUCTION

THE viscosity coefficient of a gas is defined as the time rate of the net transfer of momentum across an imaginary, plane unit-surface in the interior of a flowing gas when there is a unit velocity gradient normal to the plane surface and normal also to the direction of gas flow. The statement is often encountered that the viscosity of gases is independent of the pressure. At atmospheric pressure and less this is substantially true and is confirmed experimentally but for high pressures theory predicts and experiment concurs in giving greater values of the gas viscosity.

A number of theories of the viscosity at high gas densities have been advanced and Meyer,¹ Brillouin² and Batschinski³ have attempted solutions of this problem. Far more significant are the investigations of Jäger,⁴ H. B. Phillips⁵ and Dubief⁶ who employed equations of state of the van der Waal type in their derivations. H. B. Phillips' paper is of particular interest in view of certain generalizations made concerning the effect of intermolecular forces on gas properties.

In the experimental field Warburg and von Babo⁷ and P. Phillips⁸ determined the viscosity of gaseous carbon dioxide at pressures exceeding one hundred atmospheres and for several temperatures. Wildhagen,⁹ in his study of the flow of compressed air, measured the viscosity of air at room temperature for pressures up to two hundred atmospheres. All of the writers cited used some form of the transpiration method. In all of these investigations end effects were neglected.

The transpiration method of determining viscosity coefficients is that most readily adapted to use at high pressures. This method is based on Poiseuille's law for isothermal viscous flow which may be expressed

$$\Delta p = \frac{k_c M}{\rho} \mu \quad (1)$$

where Δp is the pressure drop in centimeters of mercury at 0°C, occasioned by the flow of M grams per second of an incompressible fluid of viscosity μ and density ρ through a tube of circular section whose dimensions determine the value of k_c . The density and viscosity are in c.g.s. units and k_c equals $8L/13.596 g\pi r^{4*}$ where L and r are the length and radius respectively in centimeters of the tube and g is the gravitational acceleration. When Eq. (1) is integrated assuming the ideal gas laws and an isothermal expansion there results

$$p_1^2 - p_2^2 = 2RTk_c M \mu \quad (2)$$

Here p_1 and p_2 are the upstream and downstream pressures respectively, R the gas constant and T the absolute temperature.

Neither of these equations may be applied directly to experimental data as they neglect "end effects" which are caused by losses in the kinetic energy of the fluid due to changes in the cross-section of the path of flow. As a result the observed pressure difference is greater than it would be were there no such loss. Accordingly Eqs. (1) and (2) should be modified as otherwise the calculated values of the viscosity coefficients would be high. End effects are discussed by Brillouin,¹⁰ Fisher,¹¹ Rapp,¹² Bingham,¹³ Benton,¹⁴ Walker, Lewis and McAdams,¹⁵ and by Trautz and Weizel.¹⁶ The majority of these writers agree, on reducing their results, that the proper form for the end correction is

¹⁶ Trautz and Weizel, *Ann. d. Physik* **48**, 799 (1915).

$$\Delta p_e = \frac{k_e M^2}{\rho} \quad (3)$$

where Δp_e is the end effect pressure drop and k_e is the end effect constant. Eqs. (1) and (2) accordingly become

$$\Delta p = \frac{k_c M \mu}{\rho} + \frac{k_e M^2}{\rho} \quad (4)$$

$$p_1^2 - p_2^2 = 2RT(k_c M \mu + k_e M^2) \quad (5)$$

It is of interest to consider the effect of a change in density of a given gas on the magnitude of the end correction when the latter is negligible at atmospheric pressure. Assume that the pressure drop due to the viscous action of the gas is relatively small and constant and that the viscosity is independent of the density. Eq. (4) is sufficient for this estimate since at the higher pressures the gas density is substantially constant throughout the apparatus. For these conditions M/ρ is constant and therefore the end correction, $k_e M^2/\rho$, is linear in density. For density variations of several hundred-fold the end correction may well be of the order of ten to twenty percent. This approximation shows that all previous high pressure investigations are of questionable quantitative significance in view of the neglect of end effects.

II. THE EXPERIMENTAL METHOD

The transpiration method was used in this investigation and consisted in measuring the pressure drop occasioned by the isothermal flow of a gas of known density at a measured rate through a metal capillary whose constants, k_c and k_e , were determined by direct calibration. This necessitated relatively large amounts of the gases and so precluded the use of highly purified materials. Hydrogen and nitrogen of the highest commercial purity obtainable were used in these experiments.

The capillary used in these experiments was a steel tube about a meter long and roughly 0.025 cm in internal diameter. It was immersed in a stirred water bath thermostat whose temperature was read from calibrated thermometers fully immersed. The temperature variation seldom exceeded 0.2°C and generally was within 0.1°C which was adequate for these experiments. The calibration of the capillary for k_c and k_e will be described later. A metal capillary was used to insure isothermal flow.

The pressure-drop measurements were made with a new type of high pressure manometer. In principle, the instrument consisted of a mercury filled manometer whose arms were of widely different diameters thus giving practically the entire pressure differential in the smaller arm. The change of the mercury level in the smaller arm was detected by successively making and breaking an electrical circuit by means of a platinum tipped screw rod which was insulated from the body of this apparatus. The relative travel of the rod was determined by measuring the distance between its upper end and

a fixed reference plane by means of a micrometer depth gauge. A galvanometer indicated the completion of the circuit through which a feeble current flowed whose source was a thermocouple immersed in ice and water. This very feeble current was desirable to minimize arcing on breaking the circuit. The pressure differential was calculated from the difference between the flow and zero or no-flow readings. In this calculation corrections were made for the drop in mercury level in the larger arm, the gas density, and the temperature variation of the mercury density.

The gas density was computed from the temperature and pressure of the gas flowing. Pressures were measured with a dead weight piston gauge of the type developed by Keyes¹⁷ and his coworkers. The gas temperature was taken to be that of the bath and the density was calculated from these data using Bartlett's¹⁸ compressibility factors. No attempt was made to

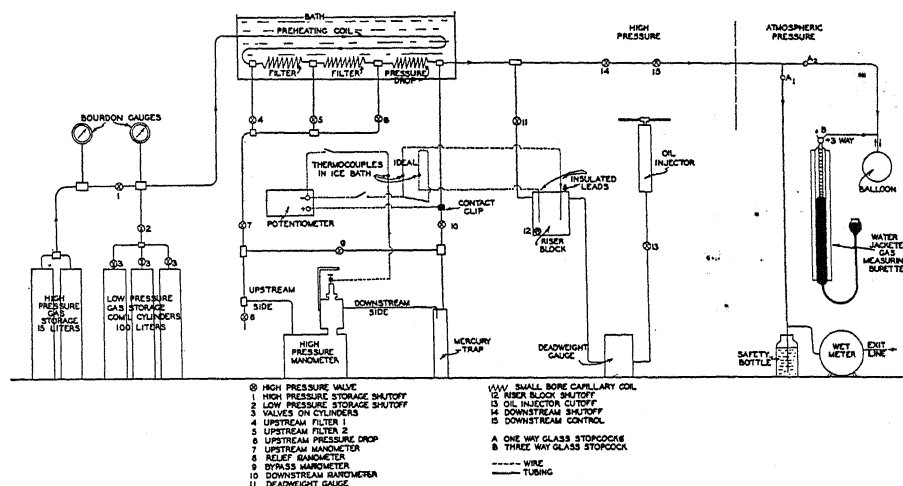

Fig. 1. Diagrammatic sketch of viscosity apparatus.

correct the gas density for the water vapor present since its concentration was very low as has been shown by Bartlett.¹⁹

The transpiration rate was determined by expanding the compressed gas and passing it into an exhausted rubber balloon for an observed time interval measured with a calibrated, split-second stop watch. The gas was then drawn into a water jacketed burette and measured at known temperature and pressure. From these data and the gas composition the transpiration rate was calculated.

The gas mixture was made up in a small holder, allowed to stand for several hours, compressed and then analyzed. The same method of compression was used for the pure gases to obtain pressures exceeding 150 atmospheres.

¹⁹ Bartlett, Cupples and Tremearne, *J.A.C.S.* **50**, 1275 (1928).

The apparatus is shown diagrammatically in Fig. 1. The gas flowed from the storage cylinders through a preheating coil of relatively large capillary tubing and then through two fine steel capillaries employed as dust filters before entering the pressure drop capillary. These capillaries were all immersed in the bath. On leaving the pressure-drop capillary the gas passed through a needle control valve and was reduced to atmospheric pressure. Care was taken that steady viscous flow was maintained during experiments.

The capillary constant k_c was determined by low pressure transpiration experiments which were calculated by Eq. (5) inspection of which shows that $(p_1^2 - p_2^2)/M$ is linear in M . Actually Eq. (5) ignores the effect of the acceleration of the gas in the capillary but since the data plotted by the

Fig. 2.

Fig. 3.

above method were linear the value of k_c was readily calculated on obtaining the intercept by extrapolation to zero gas flow. A very satisfactory check was given by an alternative method based on the determination of the volume of the capillary. This latter procedure required the weight, length and average external diameter of the tubing and further necessitated the determination of the density of the steel in the tubing. From these data k_c was calculated. The excellent agreement of the results obtained by these two separate methods gave great confidence in the validity of the transpiration method for this calibration. The distention of the capillary by changes in temperature and pressure which, if appreciable, would affect the value of the constant, was found to be negligible for the ranges of temperature and pressure employed here. A supplementary transpiration calibration for k_c

was required because of a very slight rusting of the interior walls of the capillary. This rusting was due to the condensation of small amounts of water vapor from the compressed gas which occurred on increasing the pressure in the capillary above that in the supply cylinder from which the gas was drawn. This was avoided in subsequent experiments by performing them in the order of their descending pressures. After establishing this procedure check transpiration calibration experiments showed the value of k_c to be unchanged.

The constant k_c was determined by means of high pressure transpiration experiments which were calculated with Eq. (4) which is linear in $\Delta p \cdot \rho / M$ versus M . The slope of such a plot gave the value of k_c . Here the use of

Fig. 4.

Fig. 5.

Eq. (4) simplified the calculations and was valid because at high pressures the gas density was substantially constant throughout the apparatus. This constancy of the density required that the linear velocity of flow in the capillary also be constant, and thus the acceleration effect previously mentioned was eliminated in the high pressure experiments. Experiments with nitrogen were made proving that the constant is independent of the temperature and pressure ranges covered here. Further experiments with hydrogen checked the value so determined and showed it to be independent of the gas employed. The magnitude of k_c exceeds that predicted from theory but this is believed due to a divergence between the actual experimental conditions and those postulated in the theoretical derivations. In any case this does not invalidate the results reported here.

In the high pressure experiments the system was brought under pressure by permitting the gas to flow through the capillaries to the *downstream* side of the differential manometer, under the mercury seal and into the upstream side. When the pressure was equalized throughout the system the by-pass valve and then the upstream valve were opened. The zero reading was then made after which the screw rod was run up the riser well to a point above the approximate mercury level expected in the experiment. Gas flow at the desired rate was obtained with the downstream control valve. The by-pass valve was then closed and twenty minutes allowed to insure a steady flow

Fig. 6.

Fig. 7.

before manometer readings were taken. In each case the mercury approached its equilibrium position from below thus tending to introduce a compensation of errors. The gas was then passed into the balloon during an observed time interval after which manometer readings were again made and the average of the initial and final readings was taken for computation. The pressure was next measured by means of the dead weight piston gauge. The bath temperatures were noted during each experiment. The volume of the gas in the balloon was then determined at atmospheric pressure and room temperature. These data permitted the calculation of the viscosity coefficients.

III. EXPERIMENTAL RESULTS

Viscosity coefficients for nitrogen and hydrogen were obtained at 30°, 50° and 70°C for pressures from 75 to 180 atmospheres. Similar data were obtained for a mixture containing 64.1 mol percent of hydrogen and 35.9

The new viscosity data are presented in Tables I to III and are shown graphically in Figs. 2 to 7 inclusive.

IV. A NEW VISCOSITY THEORY

In the theory of the equation of state it has been customary to regard the hydrostatic pressure as the net effect of a kinetic (distending) pressure and of a cohesive pressure. The kinetic pressure of a gas is defined as the time rate of the transfer of momentum across an imaginary plane unit surface in the interior of the gas. The viscosity coefficient is, by definition, the time rate of the *net* transfer of momentum in a flowing gas across a similar unit plane when there is a unit velocity gradient normal to the plane surface and normal also to the direction of gas flow. Thus the viscosity and kinetic pressure are similar phenomena whose origin is in the molecular motion and therefore it is logical that the kinetic pressure and the viscosity may be treated by the same analytical method.

Of the quantitative equations of state that of Beattie and Bridgeman²⁰ has had marked success in reproducing the observed pressures of a number of gases for wide ranges of temperature and pressure. Application of this equation to the computation²¹ of the specific heat and Joule-Thomson coefficients of compressed air has shown good agreement between theory and experiment. The derivation of the equation is based on the two main assump-

²⁰ Beattie and Bridgeman, Proc. Am. Acad. Sci. 63, 229 (1928).

²¹ Bridgeman, Phys. Rev. 34, 527 (1929).

tions that the kinetic and cohesive pressures may be treated separately and that the law of intermolecular force be such that it diminish rapidly with distance.

Their evaluation of the kinetic pressure is of interest here. The kinetic pressure of a perfect gas is calculated on the basis of a rectilinear free path, but the existence of intermolecular forces, as in a real gas, alters the linearity of the free path and increases the molecular migration in the gas interior. H. B. Phillips²² on general considerations has pointed out this is so regardless of the nature and law of such forces and, further, that this is independent of the size of the molecules. Beattie and Bridgeman employ a slight modification of H. B. Phillips' method of calculating the kinetic pressure of a real gas and obtain

$$P_a = \bar{p}RT(1 + r) = P_i(1 + r) \quad (6)$$

where P_a and P_i are the pressures of the actual and ideal gases respectively, \bar{p} is the density, R the gas constant, T the absolute temperature, and r the fractional increase in the molecular migration relative to an ideal gas owing to the intermolecular forces. Further, r is a function of the density and covolume

$$r = B_0\bar{p}(1 - b\bar{p}) \quad (7)$$

where B_0 is the covolume in liters per mol, b a characteristic constant of the gas and the density is in mols per liter. These authors also correct the kinetic pressure to allow for the change in the time of molecular encounter with temperature and the complete expression for the kinetic pressure now is

$$P_a = P_i(1 + r)(1 - \epsilon) \quad (8)$$

where ϵ is the encounter factor and equals $c\bar{p}/T^3$, c being another characteristic constant of the gas. Eq. (8) is of the form first derived by Lorentz in his calculation of the kinetic pressure.

In adapting this equation to viscosity theory the viscosity coefficients are substituted for the kinetic pressure terms. It is well known that for isothermal pressure changes at low densities the viscosity of a gas is independent of the density. Thus the viscosity of a real gas at low densities is substantially that of a perfect gas, μ_0 . For high densities the viscosity coefficient of a real gas, μ , corresponds to P_a . In the equation of state the covolume, B_0 , is obtained from compressibility data. Among others, Jeans²³ and Keyes²⁴ have remarked that the compressibility covolume differs from that obtained from viscosity data. Therefore it is consistent and desirable in a viscosity theory to use the viscosity covolume, B_0' and further the relative density effect on the viscosity covolume should be the same as for the compressibility covolume and in addition the time of encounter factor

²² H. B. Phillips, reference 5.

²³ Jeans, *The Dynamical Theory of Gases*, pp. 282, 326, 4 Ed., University Press, Cambridge, 1925.

should be identical for both the kinetic pressure and viscosity. The viscosity equation is then

$$\mu = \mu_0(1 + r)(1 - \epsilon). \quad (9)$$

The constants b and c are the same as before and are derived from compressibility data. The term B_0' is evaluated from the relation given by Keyes²⁵ which on reducing to units employed here is

$$B_0' = \left(\frac{3.159 \times 10^{-7} (M_w^{1/2})}{D} \right)^{3/2} \quad (10)$$

where M_w is the molecular weight and D is a constant in Sutherland's equation

$$\mu_0 = \frac{DT^{1/2}}{1 + C/T}. \quad (11)$$

The relation cited for the calculation of the viscosity covolume requires that the covolume be independent of the temperature which is true for gases obeying Sutherland's Law.

So far the theory has been implicitly limited to pure gases but as Beattie and Bridgeman's equation of state has been found valid²⁶ for mixtures the viscosity theory is readily extended to this case also, provided that μ_0 for the mixture be known. The constants B_0' , b and c for the mixture are calculated from those for the components by the rule of linear combination, where

$$\begin{aligned} B_{0' mix} &= \Sigma(B_{0i}' X_i) \\ b_{mix} &= \Sigma(b_i X_i) \\ c_{mix} &= \Sigma(c_i X_i), \end{aligned} \quad (12)$$

and X_i is the mol fraction of component (1) in the mixture. The viscosity theory is now complete.

The theory derived here is based on the analogous treatment of the kinetic pressure and viscosity of a real gas and uses a viscosity covolume instead of a compressibility covolume which, it is assumed, density changes affect in exactly the same way. The viscosity covolume, B_0' , is calculated from the constants in Sutherland's equation and so it is assumed to be independent of the temperature. The time of encounter factor should be the same in the two cases. By a suitable combination of the constants of the components the theory is applicable to mixtures.

V. DISCUSSION OF RESULTS

Examination of the tabulated results shows that the data prove beyond question that, at high densities, the viscosity of a gas is not independent of

²⁶ Beattie, J. Am. Chem. Soc. 51, 19 (1929).

the density. The maximum relative increase in the viscosity observed for nitrogen is 25 percent, for hydrogen is 10 percent and for the mixture is 20 percent. The increase in viscosity is not as great as might have been expected on the basis of previous work which however is believed to be of gravely questionable validity in view of the neglect of end effects.

The absolute accuracy of the calculated coefficients is not all that could be desired. Errors in the computed values of the viscosity and in the constants, k_0 and k_∞ , are due to errors of observation and the presence of impurities in the gases used. This latter factor is significant in the case of hydrogen as its viscosity at low pressures and its density are both extremely sensitive to traces of impurities. This source of error is not significant for nitrogen and the mixture. The method of calculation is of itself not conducive to accuracy since it involves the taking of differences and so the error in the calculated viscosities is generally greater than that of the observations.

	C	$D \times 10^6$
Nitrogen	101.3	1.386
Hydrogen	35.8	0.588

The new data afford a test of the theory derived above which is graphically shown in Figs. 2 to 7. The time of encounter factor was neglected in all calculations as for the least favorable case, lowest temperature and highest density, the correction is less than one percent for nitrogen and is much less for hydrogen. Numerical comparison of the mean observed and calculated viscosity coefficients for nitrogen are given in Table IV. Both viscosity and compressibility covolumes were used in computing the viscosities.

In general there is excellent agreement between experiment and theory when the viscosity covolume is used, but with the compressibility covolume there is a progressively greater difference between the observed and calculated values. The evidence is decidedly in favor of the new theory using the viscosity covolume and the three discrepancies between theory and fact are all attributed to experimental error. In the 30° isotherm two thirds of the maximum pressure is attained without introducing a trend in the comparison and the disagreement is attributed to experimental error. The discrepancy in the 70° isotherm occurs at a point where but two experimental values were available so the disagreement here is not regarded as serious.

A numerical comparison for the hydrogen data is not given as the graphical comparison shows reasonably good agreement in view of the sensitivity of the hydrogen density and low pressure viscosity to traces of impurities. The hydrogen data are of a confirmatory nature.

The mixture data are of especial interest in that they are believed to be the first data of this nature and they afford the opportunity of a direct comparison of the linear and Lorentz²⁷ rules for the calculation of the covolume of a mixture from those of the components. This comparison is particularly significant in view of the appreciable difference in magnitude of the covolumes of the components. The Lorentz rule of combination for a binary mixture is

$$B'_{0\text{ mix}} = B'_{01}X^2 + B'_{012}(1 - X_1)X_1 + B'_{02}(1 - X_1)^2 \quad (13)$$

where X_1 is the mol fraction of component one and

$$B'_{012} = [\frac{1}{2}(B'_{01})^{1/3} + \frac{1}{2}(B'_{02})^{1/3}]^3 \quad (14)$$

The calculated and observed values are given in Table V. A slight but not significant trend in favor of the Lorentz rule is shown. The highly desirable

simplicity of the linear rule leads to its recommendation here. A plot of the theoretical (using the linear rule) and observed values gives good agreement as shown in Fig. 7.

Further confirmation of the theory is obtained by a recalculation of Wildhagen's²⁸ data which purport to show a variation of Reynolds' criterion with the pressure. This quantity is defined by the equation

$$M/r\mu = \text{constant} \quad (15)$$

and the variation claimed above is in contradiction with a vast amount of experimental evidence which has shown that the value of the criterion is independent of the fluid employed.

Viscosities were computed with the new viscosity theory and values of Reynolds' criterion recalculated for Wildhagen's data. The results are given in Table VI and yield a constant for Reynold's criterion which is strong evidence in support of the new viscosity theory. The chief source of error in

Wildhagen's results lies in the neglect of end effects and may attain the order of thirty percent at high densities. The magnitude of the end effects in the cases of Warburg and von Babo²⁹ and of P. Phillips³⁰ is not easy to estimate but is believed to be of the order of at least ten per cent on the basis of previous considerations.

The author wishes to acknowledge his appreciation of the financial aid given him by the Research Laboratory of Applied Chemistry and the committee on Graduate Courses and Scholarships of the Massachusetts Institute of Technology. He is particularly grateful to Dr. T. E. Warren for his assistance and to Dr. J. A. Beattie for his many helpful suggestions. Further, the author wishes to thank Drs. W. K. Lewis, F. G. Keyes and P. K. Frolich for their advice and criticism.

LETTERS TO THE EDITOR

Prompt publication of brief reports of important discoveries in physics may be secured by addressing them to this department. Closing dates for this department are, for the first issue of the month, the twenty-eighth of the preceding month; for the second issue, the thirteenth of the month. The Board of Editors does not hold itself responsible for the opinions expressed by the correspondents.

A New System of Bands in Carbon Monoxide

A new system of CO bands have been obtained when a trace of CO was excited in a long atomic hydrogen tube. Under the best conditions of the experiment, the spectrum of CO showed features that are usually obtained when a trace of CO is excited in the presence of the inert gases.

Under low dispersion, the new bands resemble the third positive group and its two associated groups, 5B and 3A. Each band apparently contains six heads and in addition shows the complex structure that is typical of the above mentioned multiple-headed bands of CO. Because of this striking resemblance it was suspected that the final level of these new bands coincides with the final level of the third positive group and its two associated groups. Only three of the new bands have been found and the separations of similar heads show that they correspond to transitions from an initial level (that may be called "e") to the $v=1, 2$, and 3 levels associated with the "a" level. A rough measurement of these heads has been made

and they have been found to have wavelengths 2518A, 2630A and 2750A, yielding a value of ν_e for the initial level of 88954 cm^{-1} . This value depends of course on the assumption that the upper level is the zero vibrational state.

The failure of these bands to appear under ordinary conditions shows that the initial level must be either a metastable quintet state or a triplet or singlet state. It has not been possible to excite the Cameron bands in the present conditions and this, together with the fact that the Cameron bands have been obtained only very weakly under the best conditions that have been found, shows that intercombinations are very improbable. Until further evidence is available it seems that the most probable identity of the new "e" level is as a metastable quintet state.

Boundary Conditions in Wave Mechanics

In the April 15 issue of this Journal¹ H. A. Wilson attempts to construct a Schrödinger equation whose solutions shall be known and represent the case of an electron approaching a potential barrier. He neglects to state the interpretation of his procedure explicitly; there are two possible, the second of which is probably the one intended, and I discuss the first only as a basis for the second.

The first interpretation depends on the assumption that any function $F(x, E)$ x =coordinate, E =total energy of the electron) is the solution of some problem in wave

mechanics. The assumption is obviously false, but a proof of its falsity will clarify the discussion of the second interpretation. It is true that a differential equation,

$$\phi'' + k^2(E - V)\phi = 0 \quad (1)$$

can always be found such that $\phi = F(x, E)$ is a solution for any value of E . While this is superficially identical with the Schrödinger equation, it usually differs from the latter in the fundamental fact that V , the potential energy, depends on E , the total energy of the electron. The fact that V is independent of E is one of the fundamental postulates of the Schrödinger theory, hence

¹ Wilson, Phys. Rev. 35, 948 (1930).

only those functions $F(x, E)$ which yield a V independent of E can be considered as solutions of a wave-equation.

The alternative interpretation suppose that V in Eq. (1) is really independent of E , but dependent on another parameter (call it W) which happens to be numerically equal to E ; but then $F(x, E)$ is not in general a solution of (1), but only if $E=W$. The original goal (the construction of a wave-equation, all of whose solutions shall be known) has thus been missed. To put it in another way, $F(x, E_1)$ and $F(x, E_2)$ are solutions of two different wave-equations, corresponding to two physical systems which differ in both their potential and total energies. In order to obtain a complete set of solutions for any one physical problem (single value of the parameter W) it will be necessary to find a function $\phi(x, E, W)$.

This function may satisfy the condition $\phi(x, E, E) = F(x, E)$, but there are other solutions which do not, since electrons may move in either of two directions along the x -axis. The conclusion is that Wilson has not found a complete set of characteristic functions for a given system, but rather one particular function for each of a large number of systems. This seriously restricts the generality of his results.

Turning to these, the only one I shall discuss is the conclusion that electrons are not reflected by a potential barrier if their total energy is greater than the maximum value of the potential energy. From the foregoing remarks it follows that this is true for only one particular value of E , and it becomes of interest to find the physical reason for the distinction enjoyed by this particular value of E . This becomes apparent on an examination of Figs. (2) and (3) reference 1, which represent the potential energy, i.e., qualitatively the index of refraction of the de Broglie waves. It is seen that the optical problem analogous to this dynamical one is that of an etalon consisting of one very thin plate placed at a distance of $\frac{1}{4}$ wave-length in front of a much thicker plate. Elementary optical considerations show that such an etalon will not reflect any light but will transmit all of it. If the wave-length of the incident light be changed (variation of E) keeping the separation between the plates constant (fixed W) this situation will change, and for some other wave-length, the reflection will be complete, the transmission zero.

Photographic Record of First Order Diffraction of Hydrogen Atoms by a Lithium Fluoride Crystal

I have recently obtained a photographic record of the diffraction pattern resulting from the reflection of a beam of monatomic hydrogen atoms from a crystal of lithium fluoride.

The atom beam, which was of nearly circular cross section, was incident upon the crystal at an angle of 30° from grazing and the plane of incidence made an angle of 45° with the cleaved edges. In this position rows of similar ions run parallel and perpen-

dicular to the plane of incidence with a spacing between two consecutive rows of 2.835\AA . The reflected atoms were recorded on a plane surface coated with MoO_3 which was placed perpendicular to the plane of incidence and parallel to the incident beam.

The atoms of the beam were moving with the velocities of thermal agitation in equilibrium at a temperature of about 200°C . Their deBroglie wave-length $\lambda = h/mv$ had a distribution corresponding to the Maxwellian velocity distribution with the most probable wave-length equal to 0.89\AA .

A diffraction pattern appeared on the plate reproduced in the figure which satisfies the cross grating formulae

$$\cos \theta_0 - \cos \theta = n\lambda/d$$

$$\cos \phi_0 - \cos \phi = m\lambda/d$$

where θ and ϕ are, respectively, the angles between any beam and the parallel and perpendicular rows of ions on the surface of the

crystal. The subscript 0 refers to the incident beam. The beams corresponding to $n=0$, $m=\pm 1$ were the most intense and are reproduced quite clearly. They appear in the figure as the parabolic intersection of the detecting plate with the cone $\theta=\theta_0$. The positions of calculated maxima of intensity corresponding to $\lambda=0.89\text{\AA}$ are opposite the white dots and agree well with the observed maxima.

The beams corresponding to $m=0$, $n=\pm 1$ were possibly visible on the original plate but were too faint to reproduce. The maximum corresponding to $n=+1$ is calculated to be at the upper dot but that corresponding to $n=-1$ lies below the plane of the crystal.

BOOK REVIEWS

Photo-Processes in Gaseous and Liquid Systems, R. O. GRIFFITH AND A. McKEOWN. Pp. 690. figs. 52. Longmans, Green and Co., London and N. Y., 1929. Price \$8.50.

The authors have brought together in one volume two subjects which have usually been dealt with separately: spectroscopy and photochemistry. Their purpose in presenting the former as an introduction to experimental photochemistry will be generally recognized and approved. The importance of such a ground-work is evident in that the entire first half of the book is concerned with the nature of radiation, series and band spectra, the application of the quantum theory to atomic structure, excitation, spectral absorption of atoms, life of the excited state, molecular spectra, fluorescence and chemiluminescence. This material has been treated not only with all the clarity which is essential in presenting the fundamental principles to chemists, but with a directness and simplicity that may recommend itself to any one interested primarily in this field.

The second half of the book deals with photochemical processes and presents a very careful review of the most important literature. The authors have been generous in their treatment of the views and hypotheses which have been put forward in support of various reaction mechanisms. One chapter is devoted to photochemical reactions in general, two to Einstein's law and photochemical reaction mechanisms, one to the hydrogen-chlorine and carbon monoxide-chlorine reactions, one to photo-sensitization and one to photochemical catalysis and inhibition, temperature coefficient and after effects. An appendix of four and a half pages is devoted to chemical effects of X-rays, alpha-particles and electrons, which affords a brief summary of the field and serves to show that the three quite different agents of chemical activation have common ground in ionization at one stage of the process.

S. C. LIND

Jetziger Stand der grundlegenden Kenntnisse der Thermoelektrizität. C. B. BENEDICKS. Special reprint of 42 pages from volume VIII of *Ergebnisse der exakten Naturwissenschaften*, Julius Springer, Berlin, 1929.

It is so unusual that the Physical Review should be asked to write a review of one of the single articles in the series of the "Ergebnisse" that one looks for some special feature in the situation in explanation, and indeed on reading the article one feels that only special considerations could account for its publication in the series at all. It is well known that in 1916 Benedicks discovered certain thermoelectric phenomena which he claimed rounded out the classical scheme of thermoelectric effects embraced in the Seebeck, Peltier, and Thomson effects, and also that this claim has been received with considerable scepticism, and that the consensus of opinion has been unfavorable. Benedicks has always defended his ideas. In the last few years several papers by other authors have appeared not unfavorable to Benedicks views, and this has apparently impressed the editors of the *Ergebnisse* as lending sufficient interest to the whole subject to justify an invitation to Benedicks to expound from the beginning his whole argument, which he does. It seems to me unfortunate that this new exposition by Benedicks embraces very little new material, and in fact does not discuss at all recent developments which entirely alter the significance of his whole point of view. For example, the relation between Benedicks' "phoretic" theory of conduction in metals and his thermoelectric ideas is expounded. If the ideas of the phoretic theory are to be taken seriously today, one has a right to expect some discussion of the connection between them and the wave mechanics picture of conduction, but wave mechanics is not mentioned.

Perhaps the briefest characterization of Benedicks' position is that he does not accept as correct the law of Magnus, which states that the thermal e.m.f. of a couple depends only on the temperatures of the two junctions, and not on the details of the temperature distribution in the two homogeneous branches. Benedicks fails to recognize that as a general statement applied to solid metals this "law" of Magnus is reduced to a purely academic position in view

of our new knowledge of thermoelectric phenomena in single crystals (as I stated in a paper in 1926), because it is now recognized that there may be thermoelectric currents in a single crystal of a non-cubic metal in which there are temperature differences. It follows that in any ordinary bar or wire of a non-cubic metal in which the size of the individual grains is appreciable, the law of Magnus would not be expected to hold. If I understand Benedicks' position correctly, he would say that this is not the sort of thing he understands by his effect, but he would expect the e.m.f. in an infinitely thin single crystal rod to depend on the manner of temperature distribution along the rod. It follows, therefore, that Benedicks' experiments should now be performed with material so chosen as to rule out this newly recognized possibility, but Benedicks' gives no consideration at all to this sort of thing. It is perhaps significant that he found by far his largest effects in graphite, which is non-cubic.

Benedicks' other experimental evidence leaves me personally unconvinced. I still am confident that an experiment which I made some time ago with liquid mercury to show the non-existence of his effect in mercury constitutes a valid objection, and I have since then tried without success to duplicate his experiment on the temperature difference between two ends of a long wire of constantan carrying a current. (This experiment has not been published.) Finally there is the fact that it has not been possible to find numerical magnitudes for any properties of metals connected with the new effect, neither has it been possible to introduce the constants of the new effect into any thermodynamic discussion or to show their quantitative connection with other phenomena.

The reader cannot but be pleased with the undogmatic attitude of Benedicks in describing his measurements and his ideas. Should any one else be predisposed to examine this subject by independent experiment, he should be fully conscious of the enormous difficulty of eliminating or correcting for all extraneous effects, such as those arising from stresses inevitably associated with temperature gradients in solids, and getting a clean cut proof of the existence of the effect.

P. W. BRIDGMAN

La Théorie de la Relativité et la Mécanique Céleste, Tome II, JEAN CHAZY. 258 pp. Gauthier-Villars et Cie, Paris, 1930. Price fr 60.

This is the second volume of the work of this author on the theory of relativity and celestial mechanics.

In the first volume the author has assumed the Schwarzschild line element as the starting point for investigating the problems of celestial mechanics, and has given from this basis a discussion of the motions of the planets and the curvature of light in passing the sun. The volume includes a detailed chapter on the calculations of Le Verrier and Newcomb on the motions of the planets.

In the present volume, the author presents an exposition of the fundamental principles of general relativity, and proceeding from this basis obtains the results of particular interest for celestial mechanics. These include a derivation of the Schwarzschild line element and the line element inside a fluid sphere, approximate methods for the solution of gravitational problems, a treatment of the effect of the rotation of the attracting mass on the motion of a particle, a discussion of the problem of n bodies with application to the motion of the planets, a treatment of the motion of the moon, and a discussion of the cosmological line elements of Einstein and de Sitter.

RICHARD C. TOLMAN

THE PHYSICAL REVIEW

THE PENETRATION OF A POTENTIAL BARRIER BY ELECTRONS

BY CARL ECKART

RYERSON PHYSICAL LABORATORY, UNIVERSITY OF CHICAGO

(Received April 21, 1930)

ABSTRACT

A potential barrier of the kind studied by Fowler and others may be represented by the analytic function V (Eq. (1)). The Schrödinger equation associated to this potential is soluble in terms of hypergeometric functions, and the coefficient of reflection for electrons approaching the barrier with energy W is calculable (Eq. (15)). The approximate formula,

$$1 - \rho = \exp \left\{ - \int \frac{4\pi}{h} (2m(V - W))^{1/2} dx \right\}$$

is shown to agree very well with the exact formula when the width of the barrier is great compared to the de Broglie wave-length of the incident electron, and $W < V_{\max}$.

THE "failure" of the law of conservation of energy in quantum dynamics, as evidenced by the penetration of an electron through a region of space in which its potential energy is greater than its total energy, has been advanced as the explanation of several phenomena. Gamow,¹ Gurney and Condon,² and others have discussed it in relation to the Geiger-Nuttall law of the radioactive decay constants; Fowler and Nordheim³ in its relation to the lowering of the thermionic work-function by surface impurities, and to the emission of electrons from cold metals under the influence of strong fields.

The mathematical discussions in these papers have all been based either on a potential function which has discontinuous derivatives, or else on approximate treatments involving asymptotic (i.e., divergent) series. It is therefore of some interest to note that there is an analytic function which represents some of the types of potential barriers which have been discussed and whose associated Schrödinger equation is soluble. This function is

$$V(x) = -A\xi/(1 - \xi) - B\xi/(1 - \xi)^2, \quad \xi = -\exp(2\pi x/l), \quad (1)$$

¹ G. Gamow, *Zeits. f. Physik* 51, 204 (1928).

² R. W. Gurney and E. U. Condon, *Phys. Rev.* 33, 127 (1929).

³ R. H. Fowler, *Proc. Roy. Soc. A* 122, 36 (1929), A117, 549 (1927). L. Nordheim, *Zeits. f. Physik* 46, 833 (1928).

in which x is the cartesian coordinate, and A , B , and l are constants. The graphs of this function for various values of A and B are shown in Fig. 1. It is seen to approach zero for large negative values of x and a constant value

Fig. 1. Graphs of the function $V(x)$. The numbers on the curves are the values of B/A .

A for large positive values. The width of the transition region is, practically speaking, $2l$. When $|B|$ is greater than $|A|$ it possesses an extremum at

$$x_m = \frac{l}{2\pi} \log [(B + A)/(B - A)],$$

whose height is

$$V(x_m) = V_m = (A + B)^2/4B. \quad (2)$$

In the following, it will be assumed that $B \geq 0$ so that the extremum is a maximum, when it exists at all.

The wave equation governing the dynamical problem of an electron moving under the action of this potential is

$$\frac{d^2u}{dx^2} + \frac{8\pi^2m}{h^2} \{A\xi/(1-\xi) + B\xi/(1-\xi)^2 + W\}u = 0 \quad (3)$$

or if differentiation with respect to ξ be indicated by an accent

$$\xi^2 u'' + \xi u' + \frac{2ml^2}{h^2} \{A\xi/(1-\xi) + B\xi/(1-\xi)^2 + W\}u = 0. \quad (4)$$

This equation⁴ is of the hypergeometric type, and its solutions may therefore be written down at once in terms of the hypergeometric series:⁵

⁴ Special cases ($A=0$, and $B=0$) of this equation were discussed in the Colloquium at Pasadena by Professor P. Epstein in 1925, the occasion being the work of Epstein and Robertson on the reflection of radio waves by the Heaviside layer.

⁵ F. Klein, Ueber die hypergeometrischen Reihen, (Göttingen, 1894) pp. 3-7. A. R. Forsythe, Treatise on Differential Equations, (2^d, one vol. ed.) (New York, 1888) p. 185.

$$F(a, b, c, y) = 1 + \frac{a \cdot b}{1 \cdot c} y + \frac{a(a+1) \cdot b(b+1)}{1 \cdot 2 \cdot c(c+1)} y^2 + \dots \quad (5)$$

Before proceeding to study the exact solutions, it will be well to consider their asymptotic behavior for very large positive and negative values of x . In both cases, the potential is practically constant and therefore the solutions should be monochromatic de Broglie waves to a first approximation. For large negative values of x the wave-length will be $\lambda = h/(2mW)^{1/2}$, for large positive values, $\lambda' = h/(2m(W-A))^{1/2}$. It may be assumed that $W \geq A$, since the interest in the other case is not very great. The solution may be specified even more precisely if we confine ourselves to the case in which the electrons are incident on the barrier from $x = -\infty$. Then there will be a single (transmitted) wave

$$\exp(2\pi i x/\lambda') = (-\xi)^{i\beta}, \quad \beta = l/\lambda' \quad (6)$$

for large positive values of x , and two waves (incident and reflected) for large negative values of x :

$$a_1 \exp(2\pi i x/\lambda) + a_2 \exp(-2\pi i x/\lambda) = a_1(-\xi)^{i\alpha} + a_2(-\xi)^{-i\alpha}, \quad \alpha = l/\lambda. \quad (7)$$

As will be shown, the condition that the exact solution reduce approximately to these values for large values of x , suffices to determine it uniquely, and also to determine the constants a_1 and a_2 . The quantity $\rho = |a_2/a_1|^2$ is the reflection coefficient, whose value is required for the applications mentioned in the first paragraph.

In working with the hypergeometric series, Eq. (5), it must be borne in mind that it converges only for $|y| < 1$. It then appears that of the twenty-four well-known ways⁶ in which solutions of the hypergeometric equation can be expressed in terms of $F(a, b, c, y)$, only eight converge for large values of ξ ($x > 1$); of these only four approach $(-\xi)^{i\beta}$ (the other four approaching $(-\xi)^{-i\beta}$) when $|\xi|$ increases indefinitely. The four solutions approaching $(-\xi)^{i\beta}$ are only formally different, so that it suffices to study any one of them; we single out the form

$$u = (1 - \xi)^{i\beta} (\xi/\xi - 1)^{i\alpha} F\left[\frac{1}{2} + i(\alpha - \beta + \delta), -\frac{1}{2} + i(\alpha - \beta - \delta), 1 - 2i\beta, 1/(1 - \xi)\right] \quad (8)$$

in which α and β have the values of Eqs. (6) and (7) and δ is to be defined immediately. If we define a quantity C by the relation $(2mC)^{1/2} = h/2l$, it becomes possible to write

$$\alpha = \frac{1}{2}(W/C)^{1/2}, \quad \beta = \frac{1}{2}[(W - A)/C]^{1/2}, \quad (9)$$

and the quantity δ is then defined by

$$\delta = \frac{1}{2}[(B - C)/C]^{1/2}. \quad (9a)$$

⁶ Klein, pp. 76-80; Forsythe, pp. 189-194.

C is the energy of an electron whose de Broglie wave-length is $2l$, the total width of the region of variable potential.

The function u of Eq. (8) obviously approaches $(-\xi)^{i\beta}$ for large values of ξ , since $F(a, b, c, 0) = 1$. Its value for very small values of ξ cannot be determined at once, however, since the series $F(a, b, c, 1)$ diverges. It is necessary to have recourse to the so-called process of analytic extension, and to express u in terms of series which do converge for small values of $|\xi|$. The result of the analytic extension of the hypergeometric series has been known, practically speaking, since the times of Euler and Gauss; it is summarized in the formula⁷ for compounding two hypergeometric series:

$$\begin{aligned} y^a(1-y)^c F(a+b+c, a+b'+c, 1+a-a', y) \\ = \phi(c, c')(1-y)^c y^a F(a+b+c, a+b'+c, 1+c-c', 1-y) \\ + \phi(c', c)(1-y)^{c'} y^a F(a+b+c', a+b'+c', 1+c'-c, 1-y) \end{aligned} \quad (10)$$

where

$$\phi(c, c') = \frac{\Gamma(1+a-a')\Gamma(c'-c)}{\Gamma(1-a'-b-c)\Gamma(-a'-b'-c)} \quad (11)$$

This equation is an identity for those values of y for which all the series converge, and may be used as a definition of $F(a, b, c, y)$ for $|y| > 1$, $|1-y| < 1$. If we set y equal to $1/(1-\xi)$, $a = -a' = -i\beta$, $b = -b' = \frac{1}{2} + i\delta$, $c = -c' = i\alpha$, and

$$\begin{aligned} a_1 &= \frac{\Gamma(1-2i\beta)\Gamma(-2i\alpha)}{\Gamma[\frac{1}{2} + i(-\alpha - \beta - \delta)]\Gamma[\frac{1}{2} + i(-\alpha - \beta + \delta)]}, \\ a_2 &= \frac{\Gamma(1-2i\beta)\Gamma(+2i\alpha)}{\Gamma[\frac{1}{2} + i(\alpha - \beta - \delta)]\Gamma[\frac{1}{2} + i(\alpha - \beta + \delta)]}, \end{aligned} \quad (12)$$

it reduces to

$$\begin{aligned} u &= a_1(\xi/\xi - 1)^{i\alpha}(1-\xi)^{i\beta} F[\frac{1}{2} + i(\alpha - \beta + \delta), \\ &\quad -\frac{1}{2} + i(\alpha - \beta - \delta), 1 + 2i\alpha, \xi/(\xi - 1)] \\ &+ a_2(\xi/\xi - 1)^{-i\alpha}(1-\xi)^{i\beta} F[\frac{1}{2} + i(-\alpha - \beta + \delta), \\ &\quad -\frac{1}{2} + i(-\alpha - \beta - \delta), 1 - 2i\alpha, \xi/(\xi - 1)]. \end{aligned} \quad (13)$$

The two series on the right side of this equation converge when $|\xi/(\xi-1)| < 1$ hence certainly when $|\xi| < \frac{1}{2}$. For very small values of ξ the value of u may be computed from this equation, and is seen to be exactly the expression of Eq. (7) with a_1 and a_2 defined by Eqs. (12). Eqs. (8) and (13) thus define the function u for all real values of x ; it may readily be shown that it satisfies⁸ Eq. (4), and is finite, continuous, and possesses continuous derivatives

⁷ Klein, pp. 88-91; Forsythe, pp. 194-201.

⁸ For it is a linear function of two of Kummer's twenty-four solutions (cf. reference 6).

throughout this range. It is therefore the wave-function we are seeking, and the coefficient of reflection is hence

$$\rho = \left| \frac{a_2}{a_1} \right|^2 = \left| \frac{\Gamma[\frac{1}{2} + i(\delta - \beta - \alpha)] \Gamma[\frac{1}{2} + i(-\delta - \beta - \alpha)]}{\Gamma[\frac{1}{2} + i(\delta - \beta + \alpha)] \Gamma[\frac{1}{2} + i(-\delta - \beta + \alpha)]} \right|^2 \quad (14)$$

since $|\Gamma(2i\alpha)/\Gamma(-2i\alpha)|$ is obviously 1.

In the numerical evaluation of this formula the two cases, δ =real and δ =imaginary, are to be distinguished. These two cases are separated by the condition $B=C$; since B will in general be of the order of magnitude of W , the case of a real δ corresponds to a potential barrier whose region of inhomogeneity is wide compared to the wave-length of the incident electron (cf. Eq. (9)) while an imaginary δ corresponds to a narrow region of inhomogeneity.

If δ is real, the arguments of all the gamma-functions have the form $\frac{1}{2} + iv$, where v is real. It is known that⁹

$$|\Gamma(u + iv)| = \Gamma(u) \exp[-P(u, v)]$$

and that

$$\exp[P(\frac{1}{2}, v)] = [\cosh(\pi v)]^{1/2}.$$

Hence

$$\begin{aligned} \rho &= \frac{\cosh[\pi(\delta - \beta + \alpha)] \cosh[\pi(\delta + \beta - \alpha)]}{\cosh[\pi(\delta - \beta - \alpha)] \cosh[\pi(\delta + \beta + \alpha)]} \\ &= \frac{\cosh[2\pi(\alpha - \beta)] + \cosh[2\pi\delta]}{\cosh[2\pi(\alpha + \beta)] + \cosh[2\pi\delta]}. \end{aligned} \quad (15)$$

If δ is imaginary, both the numerator and denominator of Eq. (14) have the form

$$|\Gamma(u + iv)\Gamma(1 - u + iv)|$$

with $u = \frac{1}{2} + |\delta|$. Now,

$$\exp[P(u, v) + P(1 - u, v)] = [(\cosh 2\pi v - \cos 2\pi u)/2 \sin^2 \pi u]^{1/2}$$

and hence

$$\rho = \frac{\cosh[2\pi(\alpha - \beta)] + \cos[2\pi|\delta|]}{\cosh[2\pi(\alpha + \beta)] + \cos[2\pi|\delta|]}. \quad (15a)$$

The two Eqs. (15) and (15a) are identical, if it be remembered that

$$\cosh[2\pi\delta] = \cos[2\pi|\delta|]$$

⁹ The formulae regarding $\Gamma(u + iv)$ which are used in the following are all to be found on pp. 23-25 of N. Nielsen, *Handbuch der gammafunktion*, (Leipzig, 1906).

when δ is imaginary; the separate derivation of the two is necessary, however, for $|\Gamma(u+iv)|$ is not an analytic function. The expressions for ρ are plotted in Fig. 2 for $B=8A$ and various values of l .

Fig. 2. Graphs of the reflection coefficient. The numbers are the values of A/C .

It is instructive to compare this expression for the reflection coefficient with the values which have been obtained by other writers. If $W < V_m$, the expression

$$1 - \rho = \gamma \exp \left\{ -\frac{4\pi}{h} \int (2m(V - W))^{1/2} dx \right\} \quad (16)$$

has been used, in which the integral is to be extended over all values of x for which $V > W$, and $\gamma \sim 1$. It may be shown that this is a valid approximation to Eq. (15) when l is very large, C very small. In this case, α and β become very large, so that

$$\cosh [2\pi(\alpha \pm \beta)] \sim \frac{1}{2} \exp [2\pi(\alpha \pm \beta)]$$

and $\delta \sim \frac{1}{2}(B/C)^{1/2}$. Hence, approximately,

$$\rho = \frac{1 + \exp [\pi(W^{1/2} - (W - A)^{1/2} - B^{1/2})/C^{1/2}]}{1 + \exp [\pi(W^{1/2} + (W - A)^{1/2} - B^{1/2})/C^{1/2}]}$$

The argument of the exponential in the denominator of this expression is very much greater than 1 when $W \gg V_m$, and very much less than -1 when $W \ll V_m$. Hence

$$\rho = \exp [-\pi(W^{1/2} + (W - A)^{1/2} - B^{1/2})/C^{1/2}] \quad (17)$$

when $W \gg V_m$, and

$$(1 - \rho) = \{1 - \exp[-2\pi((W - A)/C)^{1/2}]\} \exp [\pi(W^{1/2} + (W - A)^{1/2} - B^{1/2})/C^{1/2}]$$

when $W \ll V_m$. When l is very large, therefore, ρ is practically zero if $W > V_m$ and practically 1 if $W < V_m$; these formulae are valid except when $|W - V_m| \sim C$. Comparing the second of Eqs. (17) with Eq. (16) it is seen that the latter is verified if

$$-\frac{4\pi}{h} \int (2m(V - W))^{1/2} dx = \pi(W^{1/2} + (W - A)^{1/2} - B^{1/2})/C^{1/2}.$$

The integral on the left is readily evaluated by the method of residues,¹⁰ and does prove to be equal to the right side of the equation.

For very small values of l (C very large) $\cosh 2\pi\delta$ approaches -1 regardless of B and

$$\cosh 2\pi(\alpha \pm \beta) = 1 + \pi^2[W^{1/2} \pm (W - A)^{1/2}]^2/8C$$

so that

$$\rho = [W^{1/2} - (W - A)^{1/2}]^2/[W^{1/2} + (W - A)^{1/2}]^2.$$

In this limit, therefore, all effect of the maximum of potential function vanishes and the reflection coefficient has the value characteristic of a rectangular potential barrier of infinite width,¹¹ and height A .

For values of W very much larger than A , B , or C ,

$$\cosh [2\pi(\alpha - \beta)] \sim 1, \quad \cosh [2\pi(\alpha + \beta)] \sim \frac{1}{2} \exp [2\pi(W/C)^{1/2}],$$

so that

$$\rho = [1 + 2 \cosh (2\pi\delta)] \exp [-2\pi(W/C)^{1/2}].$$

For $W \leq A$ the reflection coefficient is always unity, as may be most readily deduced from general principles.

THE QUANTUM MECHANICS OF ELECTRONS IN CRYSTALS

BY PHILIP M. MORSE

PALMER PHYSICAL LABORATORY, PRINCETON, N. J.

(Received April 18, 1930)

ABSTRACT

A general solution is developed for the motion of electrons in the potential field of the nuclei in a crystal lattice. As usual the energy interaction terms due to nuclear vibration and to the presence of other electrons are neglected; they are to be included later by approximation methods.

It is shown for low energies the wave function becomes a linear combination of the atomic wave functions, the allowed energies approximating the discrete atomic levels; and for high energies the wave function approaches that of the free electron, with the allowed energies a nearly continuous range. However, for electrons coming into the crystal from outside, the crystal becomes impenetrable for those electronic wave-lengths and directions analogous to the beams producing Bragg and Laue beams in x-rays.

The solution is computed for a simple form of potential lattice, and the results are shown to be in quantitative agreement with the experimental results of Davisson and Germer. The phenomenon they call anomalous dispersion is shown to be a natural consequence of the characteristics of the wave function.

INTRODUCTION

THE problem of determining the behavior of electrons in crystals has applications in several types of phenomena: in the scattering of electrons from metal surfaces, instanced by the experiments of Davisson and Germer,¹ of G. P. Thomson and others; and in the behavior of metallic conductors.

The first problem in the study of the theory of any of these phenomena is the study of a single electron in a crystal lattice made up of atomic nuclei fixed at their equilibrium centers. The perturbation terms due to nuclear vibration and to the presence of other electrons must then be dealt with by approximation methods.

The simplest possible assumption for the unperturbed electron is that used by Sommerfeld,² the wave function being approximately like that of a field-free electron:

$$\psi_e(W) = N_e \exp i(W)^{1/2}(ax + by + cz) \quad (1)$$

where W is $8\pi^2\mu/\hbar^2$ times the electronic kinetic energy inside the crystal, and a , b and c are the direction cosines of the electronic motion. This type

¹ This work was begun under the supervision of Dr. Davisson, at the Bell Telephone Laboratories. The writer wishes to express his appreciation of the help the Laboratories in general, and Drs. Davisson and Germer in particular, have given him. He also has obtained many helpful suggestions from Professor E. Wigner.

² Sommerfeld, *Zeits. f. Physik* 47, 1, (1928).

of wave function is most nearly correct for the most loosely bound electrons, but is not sufficiently correct, even for them, to explain the experiments of Davisson and Germer.

The other type of approximation is to consider the electron behavior as primarily determined by the electric fields of the crystal nuclei. Since the potential wall between the atoms is not infinite, there is a finite probability of an electron belonging originally to one nucleus to change to any other nucleus. This means that in equilibrium the wave function for the electrons in the crystal will be any one of the large number of linear combinations of terms, each term representing the electron in the n th quantum state about the s th nucleus.³ This is an example of equivalence degeneracy similar to the simple case of the hydrogen molecular ion, and as a result the energy level corresponding to the n th quantum state of a free atom will be split into a large number of very slightly separated levels; in fact, if the crystal is considered infinite in extent, the levels of the free atom will be spread into bands of allowed energies which may or may not be separated from their neighbors by bands of forbidden energies. Of course the wave functions for the electron will be somewhat modified by this proximity of other nuclei, and Bloch⁴ has used a wave function which becomes, for an infinitely large crystal:

$$\psi_e(E) = N_e \exp i(W)^{1/2}(ax + by + cz) \cdot u(W_a)$$

where E is a function of W and W_a , and u is a linear combination of wave functions representing the electron about the various nuclei with an energy W_a .

This assumption is fairly good for the more tightly bound electrons, in the inner orbits, but for the loosely bound ones, the ones contributing most to the electric conductivity, the field due to the nucleus is so greatly distorted by the neighboring atoms that the undisturbed atomic functions are not particularly good approximations.

At any rate, whatever the potential function happens to be, it can always be represented by the three dimensional Fourier series of the type

$$V = -\frac{h^2}{8\pi^2\mu} \sum_{l,m,n=-\infty}^{\infty} A_{lmn} \exp i(l\alpha x + m\beta y + n\gamma z) \quad (2)$$

where $\alpha, \beta, \gamma = 2\pi/(d_x, d_y, d_z)$, where the d 's are the lengths of sides of the unit lattice cell in the x, y and z directions respectively. The A 's are chosen so that V is real and $A_{000} = 0$. This series is applicable to the cubic, tetragonal and orthorhombic systems of lattices, and the generalization to the other systems is obvious. The wave function for such a potential will be obtained, and its properties investigated, in this paper.⁵

³ Heisenberg, *Zeits. f. Physik* **49**, 619 (1928). A very good resumé of the subject is given by Slater, *Phys. Rev.* **35**, 509 (1930).

⁴ Bloch, *Zeits. f. Physik* **52**, 555 (1928).

THE WAVE FUNCTION

A somewhat less general, but considerably simpler form of potential function

$$V = -\frac{\hbar^2}{8\pi^2\mu} \left[\sum_{l=-\infty}^{\infty} \alpha^2 A_{xl} e^{il\alpha x} + \sum_{m=-\infty}^{\infty} \beta^2 A_{ym} e^{im\beta y} + \sum_{n=-\infty}^{\infty} \gamma^2 A_{zn} e^{in\gamma z} \right] \quad (3)$$

will first be considered. The crystal will at first be considered as infinite in extent, and the average potential as zero, so that $A_{x0} = A_{y0} = A_{z0} = 0$. If the electronic energy is $\hbar^2 W / 8\pi^2\mu$ then the Schrodinger equation which must be satisfied can be separated into three equations of the type

$$\Xi'' + \left(W_x \alpha^2 + \alpha^2 \sum_l A_{xl} e^{il\alpha x} \right) \Xi = 0 \quad (4)$$

where $W_x \alpha^2 + W_y \beta^2 + W_z \gamma^2 = W$. The complete wave function is $\Psi = \Xi(x) \cdot H(y) \cdot \Omega(z)$, where the equations for H and Ω are similar to Eq. (4).

The independent variables are now changed to $\xi, \eta, \zeta = \alpha x, \beta y, \gamma z$ and then all three equations have the form

$$\Xi'' + (W_x + \sum_l A_{xl} e^{il\xi}) \Xi = 0. \quad (5)$$

The solution of this equation was given by Hill,⁶ and is

$$\Xi = N \cdot e^{ik_x \cdot \xi} \cdot \sum_{r=-\infty}^{\infty} b_{xr}(k_x) \cdot e^{ir\xi} \quad (6)$$

where k_x and the b 's are to be determined. k_x is given by the equation

$$\sin^2 \pi k_x = \sin^2 \pi (W_x)^{1/2} \cdot \square(0) \quad (7)$$

where $\square(0)$ is the infinite determinant

$$\begin{vmatrix} \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ \dots & \frac{-A_{x,-1}}{1-W_x} & 1 & \frac{-A_{x,1}}{1-W_x} & \frac{-A_{x,2}}{1-W_x} & \frac{-A_{x,3}}{1-W_x} & \frac{-A_{x,4}}{1-W_x} \dots \\ \dots & \frac{-A_{x,-2}}{-W_x} & \frac{-A_{x,-1}}{-W_x} & 1 & \frac{-A_{x,1}}{-W_x} & \frac{-A_{x,2}}{-W_x} & \frac{-A_{x,3}}{-W_x} \dots \\ \dots & \frac{-A_{x,-3}}{1-W_x} & \frac{-A_{x,-2}}{1-W_x} & \frac{-A_{x,-1}}{1-W_x} & 1 & \frac{-A_{x,1}}{1-W_x} & \frac{-A_{x,2}}{1-W_x} \dots \\ \dots & \frac{-A_{x,-4}}{4-W_x} & \frac{-A_{x,-3}}{4-W_x} & \frac{-A_{x,-2}}{4-W_x} & \frac{-A_{x,-1}}{4-W_x} & 1 & \frac{-A_{x,1}}{4-W_x} \dots \\ \dots & \frac{-A_{x,-5}}{9-W_x} & \frac{-A_{x,-4}}{9-W_x} & \frac{-A_{x,-3}}{9-W_x} & \frac{-A_{x,-2}}{9-W_x} & \frac{-A_{x,-1}}{9-W_x} & 1 \dots \\ \dots & \dots & \dots & \dots & \dots & \dots & \dots \end{vmatrix}$$

⁵ Equations similar to those considered here were discussed by Bethe, Ann. d. Physik 87, 55 (1928), but no solution was obtained, Peierls, Ann. d. Physik 4, 121 (1930) gets an approximate solution, Strutt, Ann. d. Physik 86, 319 (1928) discussed a one-dimensional case.

⁶ Hill, Acta Mathematica 8, 1 (1886).

This determinant can be expanded into a convergent series of the form

$$\begin{aligned} \square(0) = & 1 - (C_{11}A_{x1}^2 - C_{12}A_{x1}^4 + C_{13}A_{x1}^6 \cdots) \\ & - (C_{21}A_{x2}^2 \cdots) \cdots \\ & + (C_{121}A_{x1}^2A_{x2} - C_{122}A_{x1}^4A_{x2} + \cdots) \\ & - (C_{131}A_{x1}^3A_{x3} \cdots) + \cdots \\ & + (C_{1231}A_{x1}A_{x2}A_{x3} \cdots) + \cdots \end{aligned} \quad (8)$$

The values of some of the C 's as functions of W_x are given in Fig. (1).⁷ When the series of A 's converge at least as rapidly as $A_{xn} = 1/2^n$, this expansion

Fig. 1. Values of some of the coefficients in the expansion of $\square(0)$.

is accurate to one part in a thousand if only the terms written above are used.

The b 's are obtained by solving the equations

$$[(k_x + r)^2 - W_x]b_{x,r} - \sum_{l=-\infty}^{\infty} A_{xl}b_{x,r-l} = 0 \quad (9)$$

where r can have any integral value from plus to minus infinity.

⁷ The writer is very much indebted to Mr. B. L. Snavely for computing the values of a number of the functions discussed in this paper.

A generalization of Hill's arguments shows that a solution of the Schrodinger equation using the general potential function given in Eq. (2) will be of the form

$$\psi = N \exp i(\kappa_x x + \kappa_y y + \kappa_z z) \sum_{r,s,t=-\infty}^{\infty} B_{rst} \exp i(r\alpha x + s\beta y + t\gamma z) \quad (10)$$

where the relations between the κ 's are given by the equation

$$S(\kappa_x, \kappa_y, \kappa_z; \alpha, \beta, \gamma) = S(aW^{1/2}, bW^{1/2}, cW^{1/2}; \alpha, \beta, \gamma) \cdot \square(0, 0, 0,) \quad (11)$$

where $\square(0, 0, 0,)$ is a determinant similar to $\square(0)$. The function

$$S(x, y, z; \alpha, \beta, \gamma) = (x^2 + y^2 + z^2) \prod'_{l,m,n=-\infty}^{\infty} \left[1 - \frac{2l\alpha x + 2m\beta y + 2n\gamma z - x^2 - y^2 - z^2}{l^2\alpha^2 + m^2\beta^2 + n^2\gamma^2} \right]$$

where the infinite product does not include the term for which $l=m=n=0$, and a , b and c are the direction cosines which the electronic motion would have if all the A 's were zero. For a two-dimensional case $S(x, y; \alpha, \beta)$ is the product of the elliptic functions $H(x+iy) \cdot H(x-iy)$, where the periods of these functions are $K=\alpha/2$ and $K'=\beta/2$. For the one-dimensional case discussed by Hill, $S(x; \alpha)$ is $\sin^2(\pi x/\alpha)$ as given in Eq. (7). The B 's are given by the equations

$$[(\kappa_x + r\alpha)^2 + (\kappa_y + s\beta)^2 + (\kappa_z + t\gamma)^2 - W]B_{r,s,t} + \sum_{l,m,n} A_{lmn} B_{r-l, s-m, t-n} = 0.$$

Expression (10) is of natural form; that of a free electron whose direction cosines of motion are proportional to κ_x , κ_y and κ_z , multiplied by a function representing the distortion of the wave function due to the periodic variation of the potential function. For low energies this distorting function will be a Fourier expansion of one of the linear combinations of atomic wave functions discussed earlier. In this case Eq. (9) is the form used by Bloch.

One property of (9) must be emphasized, however. The coefficients κ_x , κ_y , κ_z , in the "field-free-electron" factor are not equal to $W^{1/2}(a, b, c)$ as they would be if the A 's all equalled zero, as for Eq. (1). For values of $a(W)^{1/2}$ near $l\alpha/2$, or $b(W)^{1/2}$ near $m\beta/2$, or $c(W)^{1/2}$ near $n\gamma/2$ (i.e., near the singular points of the determinant or near the maximum points of the function S) the κ 's differ considerably from the values $(W)^{1/2}(a, b, c)$, and for certain ranges become complex.

In crystals of infinite extent, the values of W and a , b and c for which any of the κ 's become complex are not allowed; for in these cases the wave function contains a real exponential factor which becomes infinite at plus or minus infinity. Even in the case of finite crystals, it is seen that the amplitude of wave functions for which a κ becomes complex is negligible in the interior of the crystal. Thus for crystals of size greater than, say, a thousand atoms along a side, electrons with energies for which a κ is complex are not present inside the crystal.

This means that the periodic variation of potential inside the crystal creates bands of forbidden energies inside the crystal, even for electronic energies greater than the maximum potential energy, a somewhat surprising result. However, this only means that when electrons outside a crystal have energies such that their wave-number components are integral multiples of the reciprocal lattice spacing, they are reflected strongly back at the surface of the crystal. That this is true experimentally has been shown by Davisson and Germer.

These bands of forbidden energies are very wide for low energies, but become very narrow for higher energies. In other words, the allowed bands of energy are very narrow for low energies, corresponding quite closely to the atomic levels; but for energies larger than the maximum potential energy nearly every energy is allowed. Thus the general solution shows a gradual transition from purely atomic states to states of the free electron, as general considerations have shown it should.

A SIMPLE EXAMPLE

It will be of interest to examine in detail the solution for a very simple form of potential variation. The form

$$V = -\frac{\hbar^2}{8\pi^2\mu} [2\alpha^2 A_x \cos \alpha x + 2\beta^2 A_y \cos \beta y + 2\gamma^2 A_z \cos \gamma z] \quad (12)$$

is not a particularly good approximation to the lattice field, but its solution is not too difficult, and the quantitative check of the computed results with experiment leads one to believe that it is not too bad an approximation when dealing with electrons of high energy. It is, of course, a very poor approximation for the low energy, "bound" electrons, and care should be used in applying its results.

The three Schroedinger equations which must be solved are Matthieu equations

$$\Xi'' + (W_x + Ae^{i\xi} + Ae^{-i\xi})\Xi = 0. \quad (13)$$

The solution is the generalized Matthieu function,⁸ of the form given in Eq. (6), where the values of k_x are given by Eq. (7) when $A_{x1}=A_{x-1}=A$, and $A_{xn}=A_{x-n}=0$, for n greater than unity, in the determinant $\Delta(0)$.

The values of k_x^2 as a function of A and W_x are shown by means of the contour map in Fig. 2. The shaded areas are the values of A and W_x where k_x is complex. It is to be noticed that these areas are larger the larger A is, and are smaller the larger W_x is. The area included between the diagonal dotted lines radiating from $A=W_x=0$ represents the values of W_x less than the maximum and greater than the minimum potential energy. The values of the contours for k_x^2 are equal to the values of W_x when $A=0$, as would be expected. The narrowing of the unshaded bands of energy as A increases

⁸ E. C. G. Poole, Proc. Lond. Math. Soc. 20, 374 (1921); B. van der Pol and M. J. O. Strutt, Phil. Mag. 5, 18 (1928).

illustrates the transition from the continuous allowed levels when $A = 0$ to the discrete levels when A is infinite.

Fig. 2. Values of k_x^2 as a function of A and W_x . Shaded portions represent areas where k_x is complex and equals $(n/2) + ig(W_x)$, where g is real.

The difference between the character of the levels for one atom and for an infinite lattice is shown in Fig. 3. Curve (a) gives the potential energy cross section for a single "atom" with its discrete set of allowed levels, and

Fig. 3. Potential function and allowed energies for a single "atom" and for a crystal of infinite extent. Horizontal lines represent discrete levels, and shaded areas represent continuous allowed bands.

curve (b) gives the potential function for an infinite lattice with its bands of allowed levels.

The difference between W_x and the real values of k_x for a given value of A can be given by considering W_x as a function of k_x and defining

$$f_x(k_x) = W_x(k_x) - k_x^2. \quad (15)$$

Values of f_x for real values of k_x are given in Fig. 4 for a particular value of A .

The value of A will be chosen to be $1/4$ for the calculations below, since for this value, and for a lattice spacing of 3.5 Angstrom units, the difference between the maximum and minimum potential energy in the crystal will be about 36 electron volts, a reasonable variation.

Fig. 4. Values of $f(k_x)$ for real values of k_x , for $A=1/4$.

The Fourier coefficients, $b_{xn}(k_x)$, can next be computed by means of Eq. (9), which in this special case can be transformed⁹ into one or the other of the following continued fractions

$$\frac{b_{x,r}}{b_{x,r+1}} = \frac{A}{S_r - \frac{A^2}{S_{r-1} - \frac{A^2}{S_{r-2} - \dots}}} \quad (16)$$

$$\frac{b_{x,r}}{b_{x,r-1}} = \frac{A}{S_r - \frac{A^2}{S_{r+1} - \frac{A^2}{S_{r+2} - \dots}}}$$

⁹ E. C. G. Poole, Proc. Lond. Math. Soc. 20, 382 (1921).

where $S_r = (k_x + r)^2 - W_x$. Values of b_{xr} are computed in terms of b_{x0} and the value of b_{x0} adjusted so that $\sum_r b_{xr}^2 = 1$, for normalization purposes. Values of the b 's for $A = 1/4$ for various real values of k_x are shown in Fig. 5.

It can be shown in general, by symmetry arguments, that when $k_x = n/2$ (n an integer) $b_{x,r} = \pm b_{x,-n-r}$. In intermediate cases, as is seen in the curves, b_{x0} is very much larger numerically than any of the other b 's.

Fig. 5. Values of the Fourier coefficients $b_r(k_x)$ for real values of k_x , for $A = 1/4$. Coefficients not shown in this figure are negligibly small.

SCATTERING FROM CRYSTAL SURFACES

Thus for this simple case it is possible to obtain an exact solution for the motion of electrons inside a potential lattice. Let us see how nearly these results check with experiments with electrons of high energies.

Such experiments have been chiefly concerned with the scattering of electrons from the surface of a crystal. A simple model of this experiment would be a plane electron wave of kinetic energy $\hbar^2 E / 8\pi^2 \mu$ outside the crystal. If the potential outside is zero, that inside will be $\hbar^2 V_0 / 8\pi^2 \mu$ plus the V given in Eq. (12), since the average potential inside the crystal is less than that outside. The values of the W 's used will then be such that $W_x \alpha^2 + W_y \beta^2 + W_z \gamma^2 = W = E + V_0$.

The wave function inside the crystal (positive values of x) will be given by the product of three factors similar to Eq. (6). Then, since the wave

function must be continuous in value and normal gradient at the crystal surface, the wave function outside must be

$$\begin{aligned} \Psi_0 = & \sum_{m,n=-\infty}^{\infty} C_{mn} \exp i \{ [E - (k_y + m)^2 \beta^2 - (k_z + n)^2 \gamma^2]^{1/2} \cdot x \\ & + (k_y + m) \beta y + (k_z + n) \gamma z \} \\ & + \sum_{m,n=-\infty}^{\infty} D_{mn} \exp i \{ - [E - (k_y + m)^2 \beta^2 - (k_z + n)^2 \gamma^2]^{1/2} \cdot x \\ & + (k_y + m) \beta y + (k_z + n) \gamma z \} \end{aligned} \quad (18)$$

where the C terms represent beams impinging on the surface and the D terms represent beams coming from the surface. But to fit the case we were considering, where there was only one incident beam with the direction cosines a , b and c , we must make all the C 's equal to zero except, say, C_{00} , and then make $b^2 E = k_y^2 \beta^2$ and $c^2 E = k_z^2 \gamma^2$. To do this we must introduce other internal beams, due to the secondary internal reflections from the surface.

Then the complete wave function inside the crystal is

$$\begin{aligned} \Psi_i = & \sum_{r,s=-\infty}^{\infty} F_{rs} \exp i [k_x(rs) \alpha x + (k_y + r) \beta y + (k_z + s) \gamma z] \\ & \cdot \sum_{l,m,n} B_{lmn}(rs) \cdot \exp i (l \alpha x + m \beta y + n \gamma z) \end{aligned} \quad (19)$$

where $B_{lmn}(rs) = b_{xl}(k_x(rs)) \cdot b_{ym}(k_y + r) \cdot b_{zn}(k_z + s)$, and where F_{00} , the coefficient of the primary internal beam, can be taken as unity. The value of $k_x(rs)$ is determined by the value of $W_x(rs)$, where

$$\alpha^2 W_x(rs) = E + V_0 - (k_y + r)^2 \beta^2 - (k_z + s)^2 \gamma^2 - \beta^2 f_y(k_y + r) - \gamma^2 f_z(k_z + s).$$

No negative value of k_x is included, since the other boundary of the crystal is considered as being at x equals positive infinity, and no beams reflected from its surface are present.

The intensity of these secondary internal rays is determined by $|F_{rs}|^2$ and will be shown to be small compared to $|F_{00}|^2$. Since also the B 's decrease rapidly (except for special cases considered later) for increasing l , m , n , to a good approximation we can neglect all except the $B_{l00}(rs)$ for every beam except the primary one, where $r = s = 0$.

Then the boundary conditions determining the relative magnitudes of the D 's and F 's for all C 's equal to zero except C_{00} are, approximately

$$\begin{aligned} C + D_{00} &= \sum_l B_{l00}(00) \\ & \quad \sum_l (k_x + 1) \alpha B_{l00}(00) \\ C - D_{00} &= \frac{\sum_l (k_x + 1) \alpha B_{l00}(00)}{(E - k_y^2 \beta^2 - k_z^2 \gamma^2)^{1/2}} \end{aligned} \quad (20)$$

for the incident and primary reflected and refracted beams. Here $C = C_{00}$ and $k_x = k_x(00)$ for brevity. Also

$$D_{rs} = \sum_l [B_{lrs}(00) + F_{rs} B_{l00}(rs)]$$

$$-D_{rs} = \frac{\sum_l [(k_x + l) B_{lrs}(00) + F_{rs} (k_x(rs) + l) B_{l00}(rs)] \alpha}{(E - (k_y + r)^2 \beta^2 - (k_z + s)^2 \gamma^2)^{1/2}} \quad (21)$$

for the secondary beams outside and inside, since all the other C 's are zero.

These equations will hold to a good approximation except in the special cases when F_{rs} becomes of the same order of magnitude as F_{00} (this can only happen when $B_{lrs}(00)$ is of the same order as $B_{000}(00)$, and then not necessarily). In this case the D 's other than D_{rs} will be small anyhow, and the resulting inaccuracy in the determination of the reflected intensities will be small even in this special case.

Then the ratio between the incident current of electrons and the regularly reflected current is

$$\left| \frac{D_{00}}{C} \right|^2 = \frac{\left| \sum_r [(a(E)^{1/2}/\alpha) - k_x - r] b_{xr}(k_x) \right|^2}{\left| \sum_s [(a(E)^{1/2}/\alpha) + k_x + s] b_{xs}(k_x) \right|^2} \quad (22)$$

When k_x is not near half integral values, it is nearly equal to $(a^2 E + V_0)^{1/2}/\alpha$, and b_{x0} is the only not-negligible b_x . Then the formula reduces to

$$\left| \frac{D_{00}}{C} \right|^2 = \left[\frac{a(E)^{1/2} - (a^2 E + V_0)^{1/2}}{a(E)^{1/2} + (a^2 E + V_0)^{1/2}} \right]^2$$

which is the intensity of reflection when $A=0$. That is, except for special values of k_x , the crystal behaves as though it were a hollow of uniform potential $-\hbar^2 V_0/8\pi^2\mu$ with no periodic potential variation at all.

When $k_x = n/2$, however, we have seen that $b_{x,s} = \pm b_{x,-s-n}$, and substituting $-(s+n)$ for r in Eq. (22) it is seen that

$$\left| \frac{D_{00}}{C} \right|^2 = \left[\frac{\pm \sum_s [(aE^{1/2}/\alpha) + (n/2) + s] b_{xs}}{\sum_s [(aE^{1/2}/\alpha) + (n/2) + s] b_{xs}} \right]^2 = 1.$$

For the complex values of k_x , $|D_{00}/C^2| = 1$, but there is a change of phase on reflection. That is, the crystal is perfectly reflecting for every value of electronic energy and direction of incidence which has a value of W_x for which k_x is a half integer or is complex. These values of W_x for any value of A are represented by the shaded areas in Fig. 2.

Of course in an actual crystal the reflected intensity for these values of W_x will be considerably less than unity, because a number of electrons will interact with the crystal atoms as they traverse the lattice. In any case, however, the maximum reflection intensity will be for values of W_x somewhere within the shaded areas in Fig. 2, and can be represented by the equation

$$W_{zn} = (n^2/4) + G_n(A) \quad (23)$$

where G is a small quantity compared to $1/4$, except for the case $n = 1$.

When the incident electron stream is normal to the crystal surface, $W_y = f_y(0)$ and $W_z = f_z(0)$, since k_y and k_z must both equal zero. Equation (18) reduces to

$$W_z \alpha^2 = E + V_p$$

where $V_p = V_0 - \beta^2 f_y(0) - \gamma^2 f_z(0)$, which is larger than V_0 since the $f(0)$'s are negative quantities.

In this case the relative intensity of the reflected beam will be a maximum when

$$E_n = (n^2 \alpha^2 / 4) + \alpha^2 G_n(A) - V_p \quad (24)$$

from Eq. (23). The ideal curve for a typical case is given in Fig. 6. In the actual case, as was previously pointed out, the maxima are less than unity and probably decrease in height for increasing n , since the peaks are narrower and the chance of losing energy is greater. The experimental curves of Davisson and Germer¹⁰ for nearly normal incidence show just such characteristics.

Fig. 6. Relative intensity of the regularly reflected beam as a function of the electronic wave number. The incident beam is normal to the 111 surface of a nickel crystal. Lines marked 1st order, etc., indicate positions of strong x-ray reflection for the same crystal.

There will also be the other scattered beams represented by the coefficients D_{mn} in Eq. (19) whose direction cosines will be $(E - m^2 \beta^2 - n^2 \gamma^2)^{1/2} / E^{1/2}$, $m\beta / E^{1/2}$ and $n\gamma / E^{1/2}$, whose relative intensities will vary with E , but will in general be much smaller than unity.

For an obliquely incident beam whose plane of incidence is parallel to the z axis we have

$$W_z \alpha^2 = E \cos^2 \theta + V_a - \beta^2 f_y \left(\frac{E^{1/2} \cdot \sin \theta}{\beta} \right)$$

¹⁰ Davisson and Germer, Proc. Nat. Acad. Sci. 14, 622 (1928).

where $V_a = V_0 - \gamma^2 f_z(0)$ is larger than V_0 but smaller than V_p , and where θ is the angle of incidence.

The values of θ and E for a regularly reflected beam of maximum intensity will be such that

$$W_{zn} \alpha^2 = (n^2 \alpha^2 / 4) + \alpha^2 G_n(A)$$

similarly to Eq. (23). Substitution in the equation for $W_{zn} \alpha^2$ gives

$$E_n \cos^2 \theta_n = (n^2 \alpha^2 / 4) - V_n + \beta^2 f_y \left(\frac{(E_n)^{1/2} \sin \theta_n}{\beta} \right) \quad (25)$$

where $V_n = V_a - \alpha^2 G_n$, and where E_n and θ_n signify the values of E and θ for maximum regular reflection. Since the quantity f_y is small for most values of its argument (see Fig. 4) we see that the wave-length $1/E_n^{1/2}$ plotted against $\cos \theta_n$ gives in general a straight line going through the origin. However since f_y is large and discontinuous for values of E_n and θ_n near where

$$E_n^{1/2} \sin \theta_n = m\beta/2 \quad (26)$$

Fig. 7. Values of electronic wave number and angle of incidence of electron beam for strong regularly reflected beam. The crystal is nickel, the surface the 111 plane. Broken lines indicate positions of analogous x-ray reflection.

the curve deviates from a straight line near these values, and is discontinuous. A curve of $1/E_n^{1/2}$ against $\cos \theta_n$ for values of α , β and A corresponding to a nickel crystal is shown in Fig. 7.¹¹

¹¹ The analysis here has been for the case when the crystal surface is the 100 plane, perpendicular to a crystal axis. In the experiments of Davisson and Germer, the crystal surface was the 111 plane, oblique to the crystal axes. In this case, both f_x and f_y vary, and although the discontinuities are of the same character as that given above, their shape is more complicated. Eqs. (25) and (26) still hold, however, if α and β are now considered as the distance between atom planes parallel and perpendicular to the surface, respectively, and $\Phi(E_n^{1/2} \sin \theta_n / \beta)$, a function of f_x and f_y , be substituted for f_y in Eq. (25). Fig. 7 has been computed by means of these revised equations.

When the experimental curves¹² for this case are studied it is seen that not only is the general form of the curves similar, discontinuities and all, but that the positions of the discontinuities correspond. The shape of the curves near the discontinuities does not fit exactly, but if a better approximation to the actual potential function were used in the calculations, the correspondence would probably be better.

The physical explanation of these discontinuities is that for $E_n \sin^2 \theta_n = m^2 \beta^2 / 4$ there is resonance, and therefore strong damping, in the y direction, and nearly all the electrons are reflected back in a direction exactly opposite to the incident beam, leaving none to be regularly reflected. This phenomenon was given the tentative name of "anomalous dispersion" by Davisson and Germer, and in a way this term is correct, for it is due to a simultaneous resonance of the x and y components of the electronic wave number, and a consequent damping out of the wave function in the interior of the crystal.

The other scattered beams in the x, y plane come off at angles ϕ_m , where

$$\sin \phi_m = \sin \theta + m\beta/E^{1/2}. \quad (27)$$

It can be seen from Eq. (21) that their relative intensities will be

$$\left| \frac{D_{m0}}{C} \right| = \left| \frac{b_{ym}(E^{1/2} \sin \theta)}{b_{y0}(E^{1/2} \sin \theta)} \times \frac{\sum_{rs} (k_x' + s - k_x - r) b_{xr}(k_x) \cdot b(k_x')}{\sum_{ln} \left(k_x' + l + \frac{E^{1/2} \cos \Phi}{\alpha} \right) \left(k_x + n + \frac{E^{1/2} \cos \theta}{\alpha} \right) b_{xn}(k_x) b_{xl}(k_x')} \right|^2 \frac{E \cos^2 \theta}{\alpha^2}$$

where k_x' is the $k_x(m0)$ of the beam reflected back into the crystal at the surface, and is a function of the energy W_x' , where

$$\alpha^2 W_x' = E + V_a - (E^{1/2} \sin \theta + m\beta)^2 - \beta^2 f_y \left(\frac{E^{1/2} \sin \theta}{\beta} + m \right)$$

These secondary internal beams will make a slight change in the magnitude of the primary internal beam, but this can be neglected. The quantity b_{ym} is only large when $E^{1/2} \sin \theta$ is near the value $-m/2$, corresponding to reinforcement due to the y, z planes of atoms, and, when E and θ also satisfy Eq. (23), corresponding to the case of "anomalous dispersion" of the regularly reflected beam. The quantity $|D_{m0}/C|^2$ also shows other maxima analogous to the various Laue beams in x-ray scattering.

CONCLUSION

Thus it has been seen that for high energy electrons even the simple potential function used above gives results in good accordance with experiment. This accordance becomes less and less good as we consider electrons with less and less energy, and the results probably do not fit at all for the

¹² Davisson and Germer, Proc. Nat. Acad. Sci. 14, 624 (1928). Later (unpublished) curves show a more complete agreement.

tightly bound electrons in the inner atomic shells, where the allowed energies are narrow bands very slightly different from the simple discrete atomic levels. For these electrons, also, the interaction between electrons cannot be neglected.

However for those electrons whose energy is greater than $-\hbar^2 V_0/8\pi^2\mu$ it seems likely that the results of the simple case discussed above will be indicative. So that while this simple case will not tell us anything about ferromagnetism, for instance, or of any other crystal property which depends on the inner bound electrons, it may be of help in discussing those properties which depend primarily on the high energy free electrons, such as electric conductivity. We have seen that for the still higher energy electrons used in scattering experiments, the agreement with experiment is very good.

When the stationary states inside a crystal of finite size (say a rectangular one whose edges are Ld_x , Md_y , Nd_z respectively, where L , M and N are integers) are considered, it is seen that the wave functions are

$$\psi_{rst} = \frac{(2)^{1/2}}{(L^2d_x^2 + M^2d_y^2 + N^2d_z^2)^{1/2}} \sum_{l,m,n} B_{lmn}(r,s,t) \sin \left[\left(\frac{r}{2L} + l \right) \alpha x + \left(\frac{s}{2M} + m \right) \beta y + \left(\frac{t}{2N} + n \right) \gamma z \right]$$

where the fractions $r\alpha/2L$, $s\beta/2M$ and $t\gamma/2N$ (r , s , t integers) replace the variables κ_x , κ_y and κ_z , and where the B 's are normalized so that $\sum_{l,m,n} B_{lmn}^2 = 1$. From this it can be seen that the distribution of electrons in terms of $r^2\alpha^2/L^2$, $s^2\beta^2/M^2$, $t^2\gamma^2/N^2$ is a normal Fermi one. But, since the energy is a complicated function of these quantities, the electron distribution in energy is different from that of the completely free electron.

AN EXTENSION OF HOUSTON'S AND SLATER'S
MULTIPLY RELATIONS

By S. GOUDSMIT

DEPARTMENT OF PHYSICS, UNIVERSITY OF MICHIGAN

(Received April 21, 1930)

ABSTRACT

Expressions giving the change in the positions of the energy levels with change in electron coupling are derived. The change in g -values is discussed also. The method of derivation is a short-cut of the rigorous detailed method and therefore simpler. One knows the form of the equations of which the desired energies must be roots. The coefficients of these equations are determined by the known results for extreme couplings. This method does not always give all coefficients, but even in complicated cases useful relations between the energy levels are found.

FOR the case of two electrons one of which is in an s -state, Houston¹ obtained expressions for the four resulting levels for any coupling strength. Houston considered the coupling and the spin-orbit interaction as perturbations and calculates by quantum mechanics the first order perturbations to the energy. He also derived expressions for the g -values and for the intensities to show their variation with change of coupling.

As soon as one removes the restriction that one of the two electrons is in an s -state the method used by Houston becomes very complicated. Dr. Laporte has informed me that one can apply Houston's results to configurations like p^5s and d^9s by considering the p^5 and the d^9 group as if it were a single p , or d electron and by taking, in addition, the spin orbit interaction with a negative sign. This remark led to the considerations outlined in this paper.

It is possible to get the main results and often even the complete results of the detailed theory as used by Houston by a simplified procedure. One knows from perturbation theory exactly what type of equations will be obtained for the first order perturbations to the energy. Furthermore one knows from simple considerations of the vector model the energies in extreme (j, j) coupling and in the extreme Russell-Saunders coupling.² In the latter case the results of the vector model have to be supplemented with the results derived by Slater³ which give relations among the distances of various multiplets of a configuration. Our knowledge of these extreme cases is sufficient to fix the most important coefficients, sometimes all coefficients, in the general equation for the energy perturbation.

¹ W. V. Houston, Phys. Rev. **33**, 297 (1929).

² Extreme (j, j) coupling means no interaction between the electrons, extreme Russell-Saunders coupling large interaction, much larger than the interaction between spin and orbit.

³ J. C. Slater, Phys. Rev. **34**, 1293, (1929).

From the formulas obtained in this way one hopes to be able to predict the position of unknown levels but in this respect the results are rather disappointing. First of all one must not forget that we consider only the first order perturbation; thus neither the coupling nor the spin-orbit interaction may be too large. This excludes the very light and the very heavy elements. In the former the singlet-triplet and similar distances are often of the same order as the total energy, in the latter this is the case for multiplet separations. But much worse for their use as predictors of levels is the special form which most of the resulting expressions have. Consider for instance a triplet and a connected singlet level. If one knows the singlet and two levels of the triplet one can predict with great accuracy the position of the third triplet level. This great accuracy, however, is due to the fact that this triplet level is not displaced very much in going from one extreme coupling to the other. A mere guess would have given a fair result. In practice, on the contrary, one always knows the triplet and wants to know the position of the singlet. Its variation in position with change of coupling is very large and a small error in the known triplet causes a large error in the predicted position of the singlet. Of course the percentage error one makes in predicting the triplet level is the same as for the singlet level, but for the latter this corresponds to a much larger absolute error in position. In general the predictions will be most accurate if the singlet is not very far away from the triplet. It is to be regretted that in practice one just always needs the cases where the prediction is most unusable! What is said here for the simple example of a singlet and a triplet holds also for more complicated cases.

Before demonstrating the method by examples we will describe the general equation for the energy perturbation mentioned above. Let us denote the perturbation energies by X_1, X_2, \dots . For instance in the case of two electrons X_1 is the coupling energy, X_2 and X_3 are the spin orbit interactions⁴ for both electrons, X_4 might be the energy in an external magnetic field in case we want the g -values, etc. If, in the configuration which we consider, a certain value of the total moment J occurs for n levels, their energy perturbations E will be the roots of an equation of the n th degree, homogeneous in E and all the X 's.

$$E^n + E^{n-1}\sum a_k X_k + E^{n-2}\sum b_{kl} X_k X_l + E^{n-3}\sum c_{klm} X_k X_l X_m + \dots = 0. \quad (1)$$

It is obvious that only in a few cases our knowledge of the extreme couplings is sufficient to determine *all* the unknown coefficients. But we can be glad that such rather simple cases form quite an interesting group for which there is a large amount of known material and which is also of some interest with regard to the prediction of levels.

In more complicated cases not all coefficients can be found. For example, the coefficients of products of different X 's are often not obtainable by our method. But even if we know only the first coefficient, that of E^{n-1} , it gives

⁴ We neglect the interaction between the one spin and the other orbit. See W. Heisenberg. *Zeits. f. Physik* 39, 499 (1926).

us interesting information. This coefficient is the sum of the roots, with the negative sign, and is, as we see from (1), a linear function of the perturbation energies. From this one can derive relations among the energies similar to the constancy of g -, Γ -, and intensity sum rules.

DEMONSTRATION OF THE METHOD BY EXAMPLES

The configuration p^4 . As we are dealing with equivalent electrons we have only one coupling parameter X and one parameter to measure the spin orbit interaction, which will be denoted by A . This configuration gives rise to one level with $J=1$, two with $J=2$ and also two with $J=0$. In the extreme

Fig. 1. Change in coupling for configuration p^4 .

Russell-Saunders coupling they would be arranged in an inverted $3P$, a $1D$ and a $1S$. The total separation of the triplet is equal to the doublet separation which one of the p electrons would show if it alone were present.⁵ We will measure the energies in wave number units and for convenience put the ideal triplet separation equal to $3A$. The arrangement in the extreme (j, j) coupling can be found as follows.⁶ The lowest state will have as many electrons as are allowed by the Pauli principle with their individual $j = \frac{1}{2}$. Thus in this state there are two electrons with $j = \frac{1}{2}$ and the remaining two have $j = 1\frac{1}{2}$,

⁵ S. Goudsmit, Phys. Rev. 31, 946 (1928).

⁶ L. Pauling and S. Goudsmit, The Structure of Line Spectra, McGraw-Hill 1930, page 256.

giving rise to one level with $J=2$ and another with $J=0$. Next higher will be the state with one electron with $j=\frac{1}{2}$ and three with $j=1\frac{1}{2}$, producing two levels with $J=0$ and 1. The distance between these levels and the former group will be just the doublet separation of one of the p electrons, as just one changed its j from $\frac{1}{2}$ to 1 and this is again the distance which we call $3A$. Finally again $3A$ higher lies one level with $J=0$ which results from all four electrons having $j=1\frac{1}{2}$. In Figure 1 the left side represents the extreme (j, j) coupling, the right side tends to the extreme Russell-Saunders coupling. As reference level we will take the single level with $J=1$ and give the other levels by their distance E from this level.⁷ Our equations (1) are thus for this example:

$$\begin{aligned} J = 1: E_1 &= 0 \\ J = 0: E_0^2 + E_0(aX + bA) + cX^2 + dXA + eA^2 &= 0 \\ J = 2: E_2^2 + E_2(pX + qA) + rX^2 + sXA + tA^2 &= 0. \end{aligned} \quad (2)$$

Now for $X=0$, in the extreme (j, j) coupling the results must be

$$X = 0: E_0 = -3A \text{ and } +3A; E_2 = 0 \text{ and } -3A.$$

From this follows immediately for the coefficients:

$$b = 0, e = -9; q = 3, t = 0.$$

In the extreme Russell-Saunders coupling we consider first the finite roots.

$$X \text{ large: } E_0 = +A; E_2 = -2A.$$

This gives

$$c = 0, d = -a; r = 0, s = 2p.$$

The large roots in that case will be

$$E_0 = -aX; E_2 = -pX.$$

They represent the 1S_0 and the 1D_2 . Now we need the result obtained by Slater in his above quoted paper, informing us that in the extreme Russell-Saunders coupling the order of the levels is as in our Fig. 1 and that the distance between 3P and 1S is $5/2$ times that between 3P and 1D . If we thus put $-p=2$, we must take $-a=5$ in order to agree with those results. The total set of expressions for p^4 thus becomes

$$\begin{aligned} J = 1: E_1 &= 0 \\ J = 0: E_0^2 - 5XE_0 + 5XA - 9A^2 &= 0 \\ J = 2: E_2^2 - (2X - 3A)E_2 - 4XA &= 0. \end{aligned} \quad (3)$$

For practical purposes it is easiest to choose A as the unit of energy as is done in Fig. 1. The figure shows the interesting crossing over of the triplet

⁷ In some cases the formulas become somewhat simpler if one chooses the center of gravity of a multiplet or of all the levels as reference level, but in practice it is easier to do it the way it is done here.

levels with $J=0$ and $J=1$. This explains for instance the partial inversion of this triplet as observed in tellurium.⁸ With this same example we can check our expressions. The sum of observed E 's for the levels with $J=0$ is $5X = -44 + 18441 = 18397$. For the levels with $J=2$ this sum is equal to $2X - 3A$ and is observed to be $-4751 + 5808 = 1157$. It follows

$$X = 3680 \quad A = 2068, \quad X/A = 1.78.$$

The energies calculated with these values are:⁹

$J = 0$ calc.	- 13	obs.	- 44
	+ 18410		+ 18441
$J = 2$	- 4970		- 4751
	+ 6127		+ 5808.

Figure 2 represents the interval ratio of the triplet as a function of X/A . This figure may be useful to predict roughly the singlets if one knows the trip-

Fig. 2. Interval ratio for $p^4 \ ^3P$ for change from (j,j) to Russell-Saunders coupling.

let in cases near the Russell-Saunders coupling. In such an extreme one may take for A one third of the observed total triplet. The triplet intervals must be known with accuracy however and it is therefore impossible to do this in the very important case of the oxygen spectrum. Assuming the interpretation of the auroral line to be correct, we can predict the position of the singlets with respect to the triplet and find (this time referred to the lowest level 3P_0):

$$^1D_2 = 11984 \quad ^1S_0 = 29909$$

which is very near the estimate of McLennan and Crawford.¹⁰

⁸ J. C. McLennan and M. F. Crawford, *Nature* **124**, 874 (1929).

⁹ As was said above one can check the formulas in such a way as to make them come out either in good or rather bad agreement with the experiments. The way it is done here, however, is probably the least objectionable, being between the two.

¹⁰ They give 10587 and 28512 which again proves that for predictions of this kind the intuition of an experienced spectroscopist is at least as good as any formula. *Nature* **124**, 874 (1929).

The configuration p^2 . Figures 3 and 4 give the result for this configuration. As was to be expected it differs from p^4 only in the sign¹¹ of the coefficients of A . Here there is not such an interesting crossing over of levels as in the p^4 case. The total triplet distance is the same in both extreme couplings, but in between it is somewhat *larger*, which is the remarkable fact discovered by Sawyer and Humphreys.¹² It does not check, however, quantitatively.

Fig. 3. Change in coupling for configuration p^2

We find a good fitting example in Sn I. By the same method used in the example for p^4 one obtains:

$J = 0$	calc. - 1633	obs. - 1692
	+ 15412	+ 15471
$J = 2$	+ 1649	+ 1736
	+ 7008	+ 6921.

The configuration p^3 . This configuration gives one level with $J = 2\frac{1}{2}$ one with $J = \frac{1}{2}$ and three with $J = 1\frac{1}{2}$. In the extreme Russell-Saunders coupling they

¹¹ It might perhaps have been better to take A negative in the case of p^4 and then the formulas for both cases would have been identical.

¹² R. A. Sawyer and C. J. Humphreys, Phys. Rev. **32**, 582 (1928). The explanation which I suggested at that time and which is mentioned in that article is now of course to be considered as pure nonsense.

form a 4S , a 2D and a 2P , the first one being the lowest and from Slater's paper we obtain that their distances are in the ratio 3:2. From the theory of multiplet separations⁵ we know that in the ideal case the 2D and 2P would show no multiplet splitting at all. For the extreme (j, j) coupling we find¹³ a lowest level with $J=1\frac{1}{2}$, a distance $3A$ higher we find three levels with $J=\frac{1}{2}, 1\frac{1}{2}$ and $2\frac{1}{2}$. Finally again $3A$ higher there is the third level with $J=1\frac{1}{2}$. We will choose the level with $J=2\frac{1}{2}$ as reference level. For the level with $J=\frac{1}{2}$ we

Fig. 4. Interval ratio of $p^2 \ ^3P$ for different strengths of coupling.

expect a linear equation but for the three levels with $J=1\frac{1}{2}$ we must have a cubic equation. Writing down these equations with unknown coefficients gives us:

$$\begin{aligned} J = 2\frac{1}{2}: E_{2\frac{1}{2}} &= 0 \\ J = \frac{1}{2}: E_{\frac{1}{2}} &= pX + qA \\ J = 1\frac{1}{2}: E_{1\frac{1}{2}}^3 + E_{1\frac{1}{2}}^2(aX + bA) + E_{1\frac{1}{2}}(cX^2 + dXA + eA^2) \\ &+ fX^3 + gX^2A + hXA^2 + iA^3 = 0. \end{aligned} \quad (4)$$

It is easily found that the coefficient q for $E_{\frac{1}{2}}$ must be 0. With regard to Slater's result we will most conveniently choose $p=2$. For $J=1\frac{1}{2}$ we have the following known roots:

$$\begin{aligned} X = 0: \quad E_{1\frac{1}{2}} &= -3A, 0, +3A. \\ X = \text{large}: \quad E_{1\frac{1}{2}} &= -3X, 0, 2X, \text{ from Slater's results.} \end{aligned}$$

This gives

$$\begin{aligned} i &= 0, & b &= 0, & e &= -9; \\ f &= 0, & a &= 1, & c &= -6. \end{aligned}$$

We still can determine two more coefficients by remembering that the doublets in the extreme Russell-Saunders case must have zero separation. This means that their levels must fall together even if we take the first order terms of A into account for large X . From this it follows that

$$d = 0 \quad \text{and} \quad g = 0.$$

I see no way, however, to find the coefficient h by the method used here. The final equations are thus

¹³ Pauling and Goudsmit, reference 6, 256.

$$J = 2\frac{1}{2}: E_{2\frac{1}{2}} = 0$$

$$J = \frac{1}{2}: E_{\frac{1}{2}} = 2X$$

(5)

$$J = 1\frac{1}{2}: E_{1\frac{1}{2}}^3 + XE_{1\frac{1}{2}}^2 - (6X^2 + 9A^2)E_{1\frac{1}{2}} + hXA^2 = 0.$$

The first coefficients tell us that the sum of the levels with $J=1\frac{1}{2}$ is half the distance of the level with $J=\frac{1}{2}$, all referred to $E_{2\frac{1}{2}}$. In As for instance we find $E_{\frac{1}{2}}=7271=2X$ and the sum for $J=1\frac{1}{2}$ is 3580 which indeed checks very well.¹⁴ No good agreement can be found in Bi and in N, in the former case A and in the latter X is probably too large for a first order perturbation calculation to be sufficient.

Fig. 5. Addition of an s -electron to a 3P -state for different strengths of coupling.

The configuration ${}^3P+s$ and similar ones. It sometimes occurs that an electron is added to a very regular multiplet state of the next ion for which the connected multiplets of the same configuration are far away. Under such circumstances one may sometimes consider this multiplet as a state in itself and neglect the presence of the other states of the configuration. For such cases we can derive expressions for the variation of the levels with coupling, if we assume that the multiplet state to which the electron is added does not change at all. We will demonstrate this with the simplest example, a 3P state with an added s -electron. In the extreme (j, j) coupling we find the triplet itself, slightly split up by the addition of the electron, as shown at the left of Figure 5. The total triplet separation we put equal to $3A$. In the extreme Russell-Saunders coupling we obtain a 4P and a 2P . The theory of multiplet separations¹⁵ tells us that the separations in the quartet are $5/3 A$ and A , and the doublet separation is $2A$. With the method described before one now finds, choosing the level with $J=2\frac{1}{2}$ for reference, the following equations:

¹⁴ As the doublets in this example are small it proves Slater's relations rather than our formulas.

¹⁵ For this case see S. Goudsmit and C. J. Humphreys, Phys. Rev. 31, 960 (1928).

$$\begin{aligned}
 J = 2\frac{1}{2}: E_{2\frac{1}{2}} &= 0 \\
 J = 1\frac{1}{2}: E_{1\frac{1}{2}}^2 - (X - 2A)E_{1\frac{1}{2}} - 5/3AX &= 0 \\
 J = \frac{1}{2}: E_{\frac{1}{2}}^2 - (X - 5A)E_{\frac{1}{2}} - 8/3AX + 6A^2 &= 0.
 \end{aligned}
 \tag{6}$$

Though these formulas may give the qualitative change very well, one can hardly expect a quantitative agreement except perhaps in a few extreme cases. Sb I is an example where the 2P overlaps partially with the 4P as shown in the left of Fig. 5.

It is not difficult to obtain the formulas for the addition of an s -electron to any multiplet, but if a p - or d - electron is added, it becomes much more complicated.

The configurations d^2 and d^8 . As final examples in this paper we shall give the results for these configurations. They can be treated simultaneously and will differ in the sign of A , which will be positive for d^2 and negative for d^8 . The levels arising from these configurations are

two	with $J=4$
one	with $J=3$
three	with $J=2$
one	with $J=1$
two	with $J=0$.

We shall use the single level with $J=3$ as reference level. In the extreme Russell-Saunders coupling one finds 3F , 3P , 1G , 1D , 1S . The distances of the centers of gravity of the various multiplets in the extreme Russell-Saunders coupling from the center of gravity of the 3F , to which our reference level belongs, will be denoted by

$$\begin{aligned}
 ^3F \text{ to } ^3P &= \alpha X \\
 ^1G &= \beta X \\
 ^1D &= \gamma X \\
 ^1S &= \delta X.
 \end{aligned}$$

From Slater's results one obtains among the coefficients the following relations (for d^2 only):

$$\begin{aligned}
 \alpha &= 15 - 15t \\
 \beta &= 12 + 2t \\
 \gamma &= 5 + 9t \\
 \delta &= 22 + 27t.
 \end{aligned}
 \tag{7}$$

In these expressions t is a new parameter, which from Slater's estimates is about $1/4$. Slater showed for this configuration that the coupling energy depended upon two integrals, which will be different from case to case. These two integrals determine our coefficients. In d^8 and many other configurations more integrals enter combined in such a complicated way that no simple relations between the coefficients exist.

To determine as many coefficients as possible in our final formulas we must again take into account the first approximation in A for large X . This means that though the multiplets are far apart, we do not neglect their own splitting up, which, by the way, we know exactly from multiplet separation theory. We take the doublet separation for a single d -electron equal to $5A$. The total separation for the 3F in the extreme Russell-Saunders coupling is then $7A$, and for the 3P it is $3A$. Remembering that the distances expressed in X are between the centers of gravity one finds the following energies in the extreme cases:

$$\begin{aligned}
 J = 3: & \quad E_3 = 0, \text{ reference level.} \\
 J = 0: X = 0: & \quad E_0 = 5A, -5A \\
 & \quad X \text{ large:} \quad (\alpha X - A), (\delta X + A) \\
 J = 1: & \quad E_1 = \alpha X \\
 J = 2: X = 0: & \quad E_2 = 0, +5A, -5A \\
 & \quad X \text{ large:} \quad -3A, (\alpha X + 2A), (\gamma X + A) \\
 J = 4: X = 0: & \quad E_4 = 0, +5A \\
 & \quad X \text{ large:} \quad +4A, (\beta X + A).
 \end{aligned}$$

The following expressions are the final results. One sees again that one coefficient in the cubic equation for $J=2$ could not be determined by our method.

$$\begin{aligned}
 J = 3: E_3 &= 0 \\
 J = 0: E_0^2 - (\alpha + \delta)XE_0 + \alpha\delta X^2 + (\alpha - \delta)XA - 25A^2 &= 0 \\
 J = 1: E_1 &= \alpha X \\
 J = 2: E_2^3 - (\alpha + \gamma)XE_2^2 + [\alpha\gamma X^2 - (2\alpha + \gamma)XA - 25A^2]E_2 \\
 &\quad + 3\alpha\gamma X^2A + hXA^2 = 0 \\
 J = 4: E_4^2 - (\beta X + 5A)E_4 + 4\beta XA &= 0
 \end{aligned} \tag{9}$$

THE ZEEMAN EFFECT

The application of an external magnetic field may be treated by the addition of a perturbation parameter to our formulas. We denote the field strength by H , expressed in the right units so as to obtain wave numbers in our equations.¹⁶ We then add terms with H to all our coefficients, but as we are only interested in the results for weak fields, we need consider the terms in the first power¹⁷ of H only. We shall discuss the simple case in which the energy is given by a quadratic equation. One can easily extend it to more

¹⁶ For this purpose the wave-number shift of the normal Zeeman effect must be chosen as the unit.

¹⁷ Taking into account all the powers of H would lead to the study of the Paschen-Back effect, which has been done in great detail by C. G. Darwin, Proc. Roy. Soc. A115, 1 (1927).

complicated cases but it is then in general impossible to determine all the necessary coefficients by our method. Equation (1) we will now write

$$E^2 + E(x + pH) + y_2 + qzH = 0. \quad (10)$$

In this equation x , y_2 and z stand symbolically for the linear and quadratic functions of the other perturbations, such as X and A . We assume that x and y_2 are completely known from the problem without field. The term in H^2 has been purposely omitted. We know that the field splits each level into a number of levels with different values of the magnetic quantum number M , but for our purpose we consider only an arbitrarily chosen value for this number. If E' and E'' were the energy levels without field, they become in the field

$$E = E' + Mg'H \text{ and } E'' + Mg''H.$$

Substituting these values in (10) leads at once to

$$g' = -\frac{pE' + qz}{2E' + x} \text{ and } g'' = -\frac{pE'' + qz}{2E'' + x}. \quad (11)$$

There originally stood Mg' and Mg'' , but just because M enters here merely as a proportionality factor we can put it equal to 1 irrespective of the fact whether this is in reality possible value for M or not. From the first part of this paper we have

$$x = -E' - E''.$$

Substituting this and adding the two g -values shows

$$g' + g'' = -p. \quad (12)$$

This is the well-known g -sum rule for this simple case and it tells us at once the value of the coefficient p . The coefficients q of the linear function z of the other perturbation parameters has not such a simple meaning but can always be found by means of the known g -values in extreme couplings.

In our example of the configuration p^4 we find for instance

$$\text{for } J = 2 \quad g = \frac{5/2E - 3X + 7/2A}{2E - 2X + 3A} = \frac{5/2E' - 3X + 7/2A}{E' - E''}. \quad (13)$$

For p^2 one obtains again the same formulas but with the sign of A reversed.

CONCLUSION

We have illustrated our method of deriving relations between multiplets by various examples. Needless to say it is possible to apply it to many more cases than have been mentioned here. For instance it is clear that the formulas derived by Houston can be easily obtained by our method.

In a following paper a few more cases will be treated and the formulas will be applied to the available spectroscopic material. It is actually surprising

that in many instances they are not so very bad after all and even the discrepancies may prove to be of interest.¹⁸

The intensities can be treated by a similar procedure as used in this paper especially since we now know the intensity formulas for the extreme (j, j) coupling from the recent paper by Bartlett.¹⁹

This and the following paper, I hope, will contribute a little bit to the understanding of spectra with intermediate coupling. The fact that so few of such spectra have been analysed at present is certainly only due to a lack of theoretical knowledge of their structure, for the classification of these spectra can not be so very much harder than for multiplet spectra. But one must not look for multiplets in spectra where there are not such structures and one perhaps ought to start by abolishing the use of multiplet notations in those cases, where they are, in the main, meaningless and misleading.

¹⁸ Compare a paper by Laporte and Inglis treating important examples of the d^2s and p^2s configurations, as was mentioned at the beginning of this article. This issue, p. 1337.

RESONANCE SEPARATIONS IN CONFIGURATIONS OF TYPE p^5s and d^9s

BY O. LAPORTE AND D. R. INGLIS

DEPARTMENT OF PHYSICS, UNIVERSITY OF MICHIGAN

(Received April 21, 1930)

ABSTRACT

Considerations concerning the invariance of the configurations p^5s and d^9s with changing coupling lead to application of Houston's formulas to the cases p^5s and d^9s with negative A and X values. The expressions thus obtained are tested on the separations and g values of numerous spectra. The agreement is satisfactory.

AS IS well known the separations of the levels within a configuration depend upon influences of two kinds: firstly those of relativistic origin obeying a $(Z-\sigma)^4$ law and secondly those depending upon the coupling between the electrons. Although through the researches of Goudsmit¹ and Slater² the niveau distances are known in the extreme cases of pure Russell-Saunders and of pure $\{jj\}$ coupling, the transition stage has heretofore been investigated only for simple configurations of two electrons one of which is in an s state. The formulas of this case were given by Houston.³

For pure $\{LS\}$ coupling such a configuration yields a triplet and a singlet term with inner quantum numbers $l-1, l, l+1$ and l ; the total separation of the triplet term which is given by the Sommerfeld formula

$$\frac{\Delta\nu}{R} = \frac{\alpha^2(Z-\sigma)^4}{n^3l(l+1)} \quad (1)$$

is small compared with the distance between the two terms. Here A denotes the so-called interval factor, n and l are the quantum numbers of that electron which is not in the s state; Z is the nuclear charge, σ the screening number and $R\alpha^2$ a universal constant with the value 5.82. The position of the middle triplet level is fixed by Landé's interval rule.

In the other extreme case of pure $\{jj\}$ coupling the four levels are arranged in two narrow doublets with the distance (1) from each other. All one knows from elementary considerations about the transition is that the change in coupling will not affect the distance between levels whose inner quantum numbers occur only once, like $l-1$ and $l+1$.

If we define the centroid of the triplet term in the well-known way by

$$\Gamma(J) = \frac{1}{2}A(J(J+1) - l(l+1) - 2),$$

then the general formulas of Houston for the transition from $\{LS\}$ to $\{jj\}$ coupling may be written:

¹ S. Goudsmit, Phys. Rev. 31, 946 (1928).

² J. C. Slater, Phys. Rev. 34, 1293 (1929).

³ W. V. Houston, Phys. Rev. 33, 297 (1929).

$$\left. \begin{aligned} \Gamma_1(l) &= A \left\{ \frac{X-1}{2} + \frac{1}{2}((X+1)^2 + 4l(l+1))^{1/2} \right\} \\ \Gamma(l+1) &= Al \\ \Gamma_2(l) &= A \left\{ \frac{X-1}{2} - \frac{1}{2}((X+1)^2 + 4l(l+1))^{1/2} \right\} \\ \Gamma(l-1) &= -A(l+1) \end{aligned} \right\} \quad (2)$$

X is the parameter which describes the transition; for $X = \infty$ we obtain pure $\{LS\}$, for $X=0$ pure $\{jj\}$ coupling.

MODIFICATION OF HOUSTON'S FORMULAS

The application of these formulas to configurations of type p^5s and d^9s suggested itself to the authors for two reasons: firstly the inner quantum numbers are the same as in the cases ps and ds , and secondly it follows from the above mentioned considerations of Goudsmit, that the configurations p^5 and d^9 yield regardless of coupling 3P and 3D terms the separation of which is given by (1). The only difference is that these terms possess a negative A value, *i.e.* they are inverted. In (2) a negative A value would mean that (for large X) the singlet lies below the triplet term—which is almost never the case. Upon changing the sign of X also, it is seen however that the singlet term and the middle triplet level change places. Thus a negative X as well as a negative A brings about the desired arrangement with an inverted triplet term and a singlet level above it. If then $-X=X'$ and $-A=A'$ with $X', A' > 0$ are introduced into (2) we obtain:

$$\left. \begin{aligned} \Gamma_2(l) &= A' \left\{ \frac{X'+1}{2} + \frac{1}{2}((X'-1)^2 + 4l(l+1))^{1/2} \right\} \\ \Gamma(l-1) &= A'(l+1) \\ \Gamma_1(l) &= A' \left\{ \frac{X'+1}{2} - \frac{1}{2}((X'-1)^2 + 4l(l+1))^{1/2} \right\} \\ \Gamma(l+1) &= A'l. \end{aligned} \right\} \quad (3)$$

For positive X' the magnitude of the four Γ values is in the order in which they are given above. It is readily seen that for large or small X' values, that is to say complete $\{LS\}$ or complete $\{jj\}$ coupling, the levels have indeed the position required.

All that has been said about the separations holds *mutatis mutandis* for the g values of the Zeeman effect. Due to the principle of the permanency of the g sums the g values of the outer triplet levels (with inner quantum numbers $l \pm 1$) are independent of the coupling. They remain unaltered and thus offer nothing new. The g values of the middle triplet level and the singlet level however are obtained from Houston's expressions by introducing $-X = X' > 0$. Thus the following formulas are arrived at:

$$\left. \begin{aligned} g_2(l) &= 1 + \frac{1}{2l(l+1)} + \frac{X' - 1}{2l(l+1)((X' - 1)^2 + 4l(l+1))^{1/2}} \\ g_1(l) &= 1 + \frac{1}{2l(l+1)} - \frac{X' - 1}{2l(l+1)((X' - 1)^2 + 4l(l+1))^{1/2}} \end{aligned} \right\} \quad (4)$$

COMPARISON WITH DATA

A vast amount of spectroscopic material can be interpreted by means of the equations (3), because levels of type p^5s and d^9s occur in a series of well investigated spectra of rare-gas type and of Ni, Pd and Pt type.⁴ Fortunately these spectra have lost their Russell-Saunders character almost completely. The comparison with the data was carried out in the following manner. First from the distance $\Gamma(l-1) - \Gamma(l+1) = A'(2l+1)$ the values of A' were obtained. Then by means of the second and fourth equation (3) the position of the centroid was determined. Finally two independent values of X' were calculated from Γ_2 and Γ_1 by means of the formula

$$X'_{1,2} = \frac{\Gamma_{1,2}}{A'} - \frac{l(l+1)}{(\Gamma_{1,2}/A') - 1} \quad (3')$$

in order to avoid giving preference to either level. The agreement of these two determinations is a measure for the degree of accuracy with which (3) represent the measured separations.

The following Tables I and II give the numerical values for the levels of type p^5s and d^9s respectively. The first and second columns contain symbols

give the two values of X' as calculated from (3'), and finally in the ninth and tenth columns the g values are listed which were computed from (4) using an average X' .

Fig. 1. Values of Γ/A' plotted against X' .

In Fig. 1 and 2 the values of Γ/A' are plotted against X' for the configurations p^5s and d^9s . Obviously by dividing with A' we free ourselves of the dependance upon the spin doublet of the preceding ion and are then in a position to study the dependence of the separations upon X' alone.

The bad agreement in the case of platinum is probably due to the fact that our equations (3) which are only the result of a first order calculation do not hold in the case of very large A' values which are comparable with the ionization potential $d^9s - d^9$. We thus understand the better agreement for the higher isoelectronic analogues of Pt I, namely Au II, Hg III, etc.

On the other hand the total lack of agreement for the higher series members $3p^56s$ to $3p^59s$ of A I renders doubtful the identifications of the combinations involved. The same might be said of $3p^54s$ of K II.

Fig. 2. Values of Γ/A' plotted against X' .

It is interesting to study the dependence of X' upon Z for a group of isoelectronic spectra. It seems that after some initial irregularities X' varies almost linearly with Z .

The only spectrum in which a comparison of the equations (4) with the experiment is possible, is Ne I. In this spectrum the g values of the singlet and the middle triplet level of $2p^53s$ were measured by Back.⁵ The following Table III gives the comparison of experimental and theoretical values.

TABLE III.

	observed (Back)	calculated Table II.	calculated {LS} coupling	calculated {jj} coupling
g_2	1.034	1.036	1.000	1.300
g_1	1.464	1.464	1.500	1.200

The agreement is excellent. Many attempts have been made in the past to compute the g values of these Ne levels, but naturally only the values in limiting cases were obtained.

SINGLET-TRIPLET INTERVAL RATIOS FOR sp , sd , sf , p^5s AND d^3s CONFIGURATIONS*

BY E. U. CONDON AND G. H. SHORTLEY

UNIVERSITY OF MINNESOTA

(Received April 29, 1930)

ABSTRACT

A systematic comparison of the known data on the singlets and triplets arising from sp , sd , sf , p^5s and d^3s configurations with the theory of Houston shows that the theory gives a good account of the deviations from the Landé interval rule which accompany departure from Russell-Saunders coupling. There are numerous significant discrepancies, however. Writing 1L_l and $^3L_{l+1}$, 3L_l , $^3L_{l-1}$ with $L=P, D, F$, when $l=1, 2, 3$ for the term values, we plot as abscissa $(^3L_{l-1}-^3L_{l+1})/|^3L_l-^1L_l|$ and $(^3L_{l-1}-^3L_l)/(^3L_l-^3L_{l+1})$ as ordinate if $(^3L_l-^1L_l)$ is positive, otherwise the reciprocal of this quantity. Houston's equations (12) give functional relations between these interval ratios which are compared with the experimental values.

HOUSTON¹ has worked out an approximate quantum mechanical theory of the relation of the triplet interval ratio to the singlet-triplet interval for two electron configurations in which one of the electrons is in an s state, but the comparison he makes with experimental data gives one very little idea as to just how accurate the theory is. The purpose of the present paper is therefore to make a systematic comparison of the available data with Houston's theory.

If we write the terms of a singlet-triplet system as 1L_l , $^3L_{l+1}$, 3L_l , $^3L_{l-1}$, with $L=P, D, F$, when $l=1, 2, 3$, Houston's equations (12) give the following relative term values in terms of the parameter X , which is the ratio of the exchange perturbation integral to the perturbation theory integral which measures the spin energy. (The first classification applies to $X > 0$, the second to $X < 0$):

$$\begin{aligned} ^1L_l, ^3L_l &= -\frac{1}{2}(X-1) - \frac{1}{2}\{(X+1)^2 + 4l(l+1)\}^{1/2} \\ ^3L_{l+1} &= -l \\ ^3L_l, ^1L_l &= -\frac{1}{2}(X-1) + \frac{1}{2}\{(X+1)^2 + 4l(l+1)\}^{1/2} \\ ^3L_{l-1} &= l+1. \end{aligned}$$

Fig. 1. illustrates the behavior of these intervals. With X large and positive the triplet has the Landé interval and the singlet is high above the triplet as at a . As X approaches zero the levels approach coincidence in pairs as at b ; and with X large and negative we again have the Landé interval with the singlet far below the triplet as at c .

* This paper was presented at the Washington meeting of the American Physical Society, April 24, 1930.

¹ W. V. Houston, Phys. Rev. 33, 297 (1929).

The theoretical curves of Figs. 2 and 3 are plotted as follows: For abscissa is used $(^3L_{l-1} - ^3L_{l+1}) / |^3L_l - ^1L_l|$. For the lower curve, $X > 0$, the ordinate is $(^3L_{l-1} - ^3L_l) / (^3L_l - ^3L_{l+1})$, which goes from $l/(l+1)$ with abscissa zero, to zero with abscissa one. For the upper curve, $X < 0$, the ordinate

Fig. 1. Diagram illustrating the behavior of the singlet-triplet intervals. (a) X large and positive. (b) X very small and positive. (c) X large and negative.

is the reciprocal of this, $(^3L_l - ^3L_{l+1}) / (^3L_{l-1} - ^3L_l)$, which goes from zero with abscissa one to $(l+1)/l$ with abscissa zero. The fact that the abscissa starts increasing (to $(l+\frac{1}{2})/(l(l+1))^{1/2}$ at $X = -1$) shows that $^1L_l - ^3L_l$ becomes less than the whole spread of the triplet until the ordinate equals $1/2l$ at $X = -2$.

* S. Smith, Phys. Rev. 34, 397 (1929) has a question as to which of two singlets belong to this configuration. These are both listed, one for $X > 0$, plotted with a question mark and one for $X < 0$, which tell off the graph.

† The singlet is within the triplet.

A fairly complete search of the literature was made and the points plotted on Figs. 2 and 3. The coordinates are tabulated in the accompanying tables together with a brief reference to the source of the data. No points were plotted for which any of the intervals were less than 2.5 cm^{-1} , since the accuracy of these points did not seem to be sufficient for a fair comparison with the theory. Such points are listed in the table with a dagger (†). Those points

Fig. 2. P and F curves showing sp and $p's$ points. (F curve is drawn lightly and no points plotted.)

Fig. 3. D curve showing sd and $d's$ points.

whose coordinates fell off the graph are listed with an asterisk (*). No sf points were plotted because there were just a few clustered near Russell-Saunders coupling.

It is found that the theory works well for p^5s and d^9s configurations, in which we are one p or d electron short of a closed shell, except that the whole system of lines is inverted. These points all fall on the upper curves.

Pb III² and Tl II³ have sf configurations in which 3F_3 and 1F_3 are on opposite sides and outside of the $^3F_2 - ^3F_4$ interval. A similar thing happens in the case of the $3p^5 8s$ configuration of A I⁴. These partially inverted triplets might have been plotted with negative ordinates on our graphs.

As to the accuracy with which the points fit the theory, it can be said that in general the d^9s and p^5s fit best, sp and sd for $X > 0$ next, and sp and sd for $X < 0$ poorest. Also in general, elements of high atomic number show especially pronounced disagreements. The disagreements are to be regarded provisionally as cases in which the second-order perturbations are not negligible rather than as essential defects in the basic theory.

INTENSITIES OF VIBRATION-ROTATION BANDS WITH
SPECIAL REFERENCE TO THOSE OF HClBY J. L. DUNHAM¹

RVERSON PHYSICAL LABORATORY, UNIVERSITY OF CHICAGO

(Received April 19, 1930)

ABSTRACT

Intensity formula for vibration bands. The intensities of vibration bands depend on certain matrix elements of the electric moment of the molecule. The electric moment of a diatomic molecule is a function of the nuclear separation and must be expanded in a power series about the equilibrium point. Matrix elements are calculated by perturbation methods for the fundamental and first two harmonic bands of the vibration spectrum, and it is found that, to a first approximation, for the n^{th} harmonic it is necessary to consider the $(n+1)^{\text{th}}$ power in the series expansion of the electric moment, and higher powers for better approximations. The formulas for the fundamental and first harmonic are given to a second approximation. The matrix elements are also calculated from wave functions due to Morse for a diatomic molecule, and it is shown that there is a negligible difference between the two methods of calculation for small quantum numbers. Formulas are also given for the ratio of the intensity of the first two harmonic bands to that of the fundamental.

Application to HCl. The formulas derived in the first part are applied to the case of HCl which is the only molecule for which the intensities of the vibration bands have been measured with any precision. New data from wave-length measurements of Meyer and Levin are used and the value of the coefficient of the quadratic term in the power series expansion of the electric moment is found. It is found that two values of this coefficient would give the same intensities and no satisfactory way of resolving the ambiguity is available. Numerically it is found that if the electric moment $p = p_e + p_e' \xi + p_e'' \xi^2/2$, then $p_e'' = 0.070 \times 10^{-18}$ or 4.56×10^{-18} e.s.u.

INTRODUCTION

I HAVE recently shown² that the ratio of the measured intensities of the fundamental and harmonic bands of HCl in the near infrared can be predicted quantitatively assuming Morse's³ vibrational wave function analysis and also that the electric moment of the molecule is a linear function of the nuclear separation. Morse's potential function is not as general as a simple power series expansion of the potential function about the equilibrium point and so there has been some question as to what effect the difference between these forms for the potential function would have on the predicted intensities. It is the purpose of the present paper to compare the intensity formulas obtained from both potential functions and also to consider the effect on the intensities of higher terms in the power series expansion of the electric moment. Briefly stated the results are that the intensity formulas derived by the two methods give numerical results which differ by less than the experi-

mental error of the measurements, and that the inclusion of higher terms in the electric moment is, in general, necessary. The numerical agreement obtained previously does not have a unique interpretation. Either it is an indication that for HCl the coefficient of the quadratic term is very small indeed, or it is due to a cancellation of terms. The first part of the paper will deal with the derivation of the intensity formulas based on the two potential functions and with a comparison of these formulas; the second part will consider their application to the numerical results for HCl.

PART I

The ratio of the intensities of two corresponding lines in different bands has been shown to be⁴

$$\frac{\alpha_{nm}}{\alpha_{jk}} = \frac{\nu_{nm} \left(\frac{P_{nm}}{P_{jk}} \right)^2}{\nu_{jk}} \quad (1)$$

where α_{nm} is the intensity of the line $n \rightarrow m$ and ν_{nm} is its frequency. P_{nm} is the matrix component of the electric moment associated with the line $n \rightarrow m$ and will hereafter be called the *intensity integral*. It is calculated from the expression

$$P_{nm} = \int p(r) R_n(r) R_m(r) dr \quad (2)$$

where $p(r)$ is the electric moment of the molecule and is a function of r , the nuclear separation, and $R(r)$ is the radial part of the wave function. If we expand $p(r)$ in a power series about the equilibrium point ($r=r_e$) and change to the dimensionless variable $\xi = (r-r_e)/r_e$, we have

$$p(\xi) = p_e + p_e' \xi + \frac{p_e''}{2} \xi^2 + \frac{p_e'''}{6} \xi^3 + \dots \quad (3)$$

where $p_e' = (dp/d\xi)_{\xi=0}$ etc., and, correspondingly

$$P_{nm} = p_e' \xi_{nm} + \frac{p_e''}{2} \xi_{nm}^2 + \frac{p_e'''}{6} \xi_{nm}^3 + \dots \quad (4)$$

where $\xi_{nm}^i = \int \xi^i R_n R_m r_e d\xi$, is the $(n\ m)^{\text{th}}$ component⁵ of the matrix ξ^i .

The expansion of the potential function about the equilibrium point can be written as

$$U = \frac{h\omega_e}{2\theta^2} (\xi^2 + a_1 \xi^3 + a_2 \xi^4 + a_3 \xi^5 + \dots) \quad (5)$$

where ω_e is the frequency of a classical oscillation for very small amplitudes, $\theta^2 = h/4\pi^2 \omega_e I_e \ll 1$, I_e is the moment of inertia of the molecule, and a_1 , a_2 and a_3 are arbitrary constants which can be determined from the frequencies of the

⁴ This formula was given in reference 2, p. 448. The material for its derivation is given very concisely by E. C. Kemble, Phys. Rev. 25, 1 (1925); where the only change to be made by the new quantum mechanics is that on p. 6. \bar{M}^2 is to be replaced by P_{nm}^2 .

⁵ This expansion of P_{nm} is not to be confused with the expansion of charge distribution into dipoles and multipoles. This entire analysis concerns only the dipole radiation.

lines.^{6,7} The first term gives the potential of a simple harmonic oscillator, for which the wave functions are known, but the wave functions of the more general case must be calculated by perturbation methods. Fues⁷ has calculated the energy levels by this method and has given a formula for evaluating all of the integrals required in the perturbation calculation so that the details of the analysis will not be reproduced here. Suffice it to say that the perturbed wave functions are calculated by straight forward application of perturbation methods and from them the intensity integrals are obtained by Eq. (4).

The intensity integrals for the fundamental and the first two harmonic bands are found to be

$$P_{01} = \frac{p_e' \theta}{(2)^{1/2}} \left[1 + \theta^2 \left(\frac{11}{16} a_1^2 - \frac{3}{4} a_2 - \frac{5\rho'' a_1}{4} \right) \right] \quad (6)$$

$$P_{02} = \frac{p_e' \theta^2}{2(2)^{1/2}} \left[(a_1 + \rho'') + \theta^2 \left(\frac{243}{32} a_1^3 - \frac{111}{8} a_1 a_2 + 5a_3 \right. \right. \\ \left. \left. + \rho'' \left(\frac{3}{32} a_1^2 - \frac{15}{8} a_2 \right) - \frac{3a_1 \rho'''}{2} \right) \right] \quad (7)$$

$$P_{03} = \frac{p_e' \theta^3 (3)^{1/2}}{4} \left[\frac{3a_1^2 + 4a_2}{8} + a_1 \rho'' + \frac{\rho'''}{3} \right] \quad (8)$$

where $\rho'' = p_e''/p_e'$ and $\rho''' = p_e'''/p_e'$. The formulas for P_{01} and P_{02} have been carried out to a second approximation, and the formula for P_{03} has been given to show how higher derivatives of p enter into the intensity integrals for higher harmonics. There are no reliable intensity measurements for any second harmonic bands so far as I am aware, and consequently P_{03} has been given only to a first approximation.

Mensing and Dennison⁸ have obtained by perturbation methods similar to those used here a formula for the intensity ratio of the harmonic to the fundamental band based on the first terms of Eqs. (6) and (7) but omitting the term in ρ'' , and Fues⁹ has given formulas for the intensity integrals to a first approximation, using Kratzer's potential function, which are closely related to the first terms in Eqs. (6), (7) and (8), but omitting ρ'' and ρ''' . However, the fact that ρ'' enters into the first term of P_{02} in Eq. (7), and that both ρ''' and ρ'' enter into P_{03} , shows that in general these terms cannot be neglected even to a first approximation. Generalizing from the above equations it seems that for the band $(0 \rightarrow n)$ it is necessary to consider at least the first n terms in Eq. (4).¹⁰

⁸ Note by D. M. Dennison at the end of a paper by Meyer and Levin, Phys. Rev. **34**, 44 (1929). L. Mensing, Zeits. f. Physik **36**, 814 (1926).

⁹ E. Fues, Ann. d. Physik **81**, 281 (1926).

¹⁰ The reason for this can be seen quite simply by considering the case of P_{02} in the following fashion. The wave functions are those of an harmonic oscillator made slightly asymmetrical by the anharmonicity of the potential function. The integrand of ξ_{02} is composed of

It turns out that because the expressions for P_{nm} are even or odd in θ , it is necessary to carry the perturbation process two steps farther for each new term in θ added to P_{nm} , a behavior very like that found by Fues for the energy levels.

The frequency ratios which are necessary to calculate the intensity ratios (see Eq. (1)) are given by $\nu_{02}/\nu_{01} \cong 2(1-x)$ and $\nu_{03}/\nu_{01} \cong 3$ and the formula for x (which is the coefficient of the quadratic term in the vibrational energy level formula) as given by Fues⁷ or Kemble⁸ is $x = 3h[5a_1^2/4 - a_2]/16\pi^2\omega_e I_e$ so that the intensity ratios are given by

$$\frac{\alpha_{02}}{\alpha_{01}} = \frac{\theta^2}{2} \left[(a_1 + \rho'')^2 + \theta^2 \left(\frac{103}{8} a_1^4 - \frac{51}{2} a_1^2 a_2 + 10 a_1 a_3 \right. \right. \\ \left. \left. + \rho'' \left(\frac{53}{4} a_1^3 - 27 a_1 a_2 + 10 a_3 \right) + \rho''^2 \left(\frac{23}{8} a_1^2 - \frac{3 a_2}{2} \right) \right. \right. \\ \left. \left. + \frac{5 a_1 \rho''^3}{2} - 3 a_1^2 \rho''' - 3 a_1 \rho'' \rho''' \right) \right] \quad (9)$$

$$\frac{\alpha_{03}}{\alpha_{01}} = \frac{9}{8} \theta^4 \left[\frac{3 a_1^2 + 4 a_2}{8} + a_1 \rho'' + \frac{\rho'''^2}{3} \right]. \quad (10)$$

The derivation of the formulas for P_{01} , P_{02} and P_{03} using the wave functions derived by Morse³ is similar to the calculation of P_{02} given in reference 2, with the exception that the terms in ρ'' and ρ''' require evaluation of integrals of the type $\int e^{-kx} x^{k-i-1} (\log x)^n dx$. This offers no difficulty as they can be obtained by $(n-1)$ -fold differentiation with respect to i of the formula for the integral with $n=1$. Since we are using only small quantum numbers and since $k=1/x \gg 1$ it is possible to expand the logarithms and radicals appearing in the expressions for P_{nm} ¹¹ in terms of $1/k=x$. This simplifies these expressions considerably.

$$P_{01} = \frac{p_e'(x)^{1/2}}{ar_e} \left[1 + x \left(\frac{1}{2} + \frac{5\rho''}{2ar_e} \right) \right] \quad (11)$$

$$P_{02} = \frac{p_e'x}{ar_e(2)^{1/2}} \left[\left(1 - \frac{\rho''}{ar_e} \right) + x \left(\frac{3}{2} + \frac{2\rho''}{ar_e} - \frac{3\rho'''}{a^2r_e^2} \right) \right] \quad (12)$$

$$P_{03} = \frac{p_e'x^{3/2}}{ar_e} \left(\frac{2}{3} \right)^{1/2} \left[1 - \frac{3\rho''}{2ar_e} + \frac{\rho'''}{2a^2r_e^2} \right]. \quad (13)$$

the product of two wave functions both of which are nearly even functions, and of ξ which is an odd function, so that the *integrand* as a whole is nearly odd. Consequently in the *integral* there is nearly complete cancellation, it being saved from vanishing only by the slight asymmetry of the wave functions. Now ξ is a first order small quantity to begin with, because for low quantum numbers the wave functions are appreciable only for a small range of ξ about $\xi=0$, so ξ_{02} is a second order small quantity. On the other hand the integrand of ξ_{02}^2 is nearly even, all three factors being nearly even, so that there is no cancellation, but, since ξ^2 is a second order small quantity, the value of ξ_{02}^2 is of the second order too, and therefore of the same order of magnitude as ξ_{02} .

¹¹ Unfortunately in reference 2, Eq. (13) was incorrectly printed. The factor $A_0 A_2 k^{k-3}$ should be replaced by $[(k-2)(k-5)/2a^2]^{1/2}$.

From these the intensity ratios can be calculated at once.

$$\frac{\alpha_{02}}{\alpha_{01}} = x \left[\left(1 - \frac{\rho''}{ar_e} \right)^2 + x \left(1 + \frac{4\rho''^2}{a^2r_e^2} - \frac{5\rho''^3}{a^3r_e^3} - \frac{6\rho'''}{a^2r_e^2} + \frac{6\rho''\rho'''}{a^3r_e^3} \right) \right] \quad (14)$$

$$\frac{\alpha_{03}}{\alpha_{01}} = 2x^2 \left[1 - \frac{3\rho''}{2ar_e} + \frac{\rho'''}{2a^2r_e^2} \right]. \quad (15)$$

We are now in a position to compare the intensity ratio formulas given by the perturbation method with those given by Morse. This is best done by expanding Morse's potential function in powers of ξ about $\xi=0$ giving

$$U = Da^2r_e^2 \left(\xi^2 - ar_e\xi^3 + \frac{7}{12}a^2r_e^2\xi^4 - \frac{1}{4}a^3r_e^3\xi^5 \right). \quad (16)$$

There are only two assignable constants in this expression, D and a , whereas in Eq. (5) all the terms have arbitrary coefficients. That is to say there are certain relations connecting the coefficients of all the higher terms in Morse's potential with that of the first term. Now if we impose these relations on the coefficients a_1 , a_2 and a_3 in Eqs. (9) and (10), we find that we get exactly Eqs. (14) and (15), so that any numerical differences in the values of intensities calculated by these two methods would be entirely due to slight differences between the potential functions assumed and not to any difference in the mathematical analysis. It has been pointed out by Fues^{7,8} that since the harmonic oscillator has no continuous spectrum and since the perturbing terms in the energy go to infinity for large values of ξ , intensity calculations based on this perturbation procedure are not to be relied upon. The identity of the two analyses shown here, however, proves that for low quantum numbers and to the approximations used, the absence of a continuous spectrum in the perturbation analysis has no effect upon the intensities.

A word should be said about the relative accuracy of the two methods. Although for accurate calculations the perturbation method is more precise than Morse's, because the potential function assumed can be fitted to any given molecule more accurately, nevertheless, for first approximations Morse's formulas are to be preferred. The reason is that the first term in Eq. (9) takes into account only the first perturbing term in the potential function, whereas the first term in Eq. (14) contains contributions from higher terms in the potential function as well. In other words Morse's intensity formula converges the more rapidly of the two, so that its *first term* is a better approximation than that of the perturbation formula.¹² For HCl, the numerical difference between the two second approximations is considerably less than the experimental error of the observed intensities. For gases like CO and NO where x is materially smaller than for HCl, the difference is very small even for the first order terms.

¹² Of course perturbation methods could be applied to Morse's wave functions to obtain a more accurate intensity formula, but there is no need of this here in view of the relatively large experimental error.

PART II

We are now ready to turn to a consideration of the numerical values for HCl. Unfortunately there are no accurate data on the intensities of vibration-rotation bands for any other diatomic molecule, as data from imperfectly resolved bands observed with only one tube length or only one pressure are not in the least reliable for intensity measurements.

I have measured the intensity of several lines in the harmonic band of HCl² and shown that the observed ratio of the intensity of that band to the intensity of the fundamental band as observed by Bourgin¹³ is 0.0161. The probable error of this ratio depends on the probable error of the measured intensities of both bands. The probable error of the harmonic is given (reference 2, p. 445) as 6 percent and Bourgin gives 25 percent as the "precision limits" of his measurements. Interpreting "precision limits" as a figure which the true error is unlikely to exceed, or that there is, say, but one chance in ten of the true error being greater than 25 percent, the probable error for the fundamental turns out to be 10 percent.¹⁴ The probable error of the ratio is given by the square-root of the sum of the squares of the separate errors,¹⁴ which is 12 percent. Thus we have for the observed value of the intensity ratio

$$\frac{\alpha_{02}}{\alpha_{01}} = 0.0161 \pm 0.0019. \quad (17)$$

Dennison,⁹ on the basis of observations of Meyer and Levin, has estimated the ratio of these intensities as 0.021 ± 0.004 , which agrees, within the limits of error, with the value just given. Dennison's estimate, however, is based on the measurements of one or at most two tube-lengths and so cannot be considered to be as accurate as the value given in Eq. (17).

To compare this value with the theoretical expressions for intensity it is necessary to substitute in Eqs. (9) or (14) the values of the measurable constants of HCl. Meyer and Levin⁹ have recently published the results of new measurements of the wave-lengths of the HCl bands under higher dispersion than had previously been obtained and Colby¹⁵ has derived the values of the various molecular constants from their data. These values differ appreciably from the constants used in reference 2. They are:¹⁶

$$\begin{aligned} I_e &= 2.613 \times 10^{-40} \text{ gm cm}^2 & a &= 1.710 \\ \omega_e &= 2988.7 \text{ cm}^{-1} & a_1 &= -2.34 \\ x &= 0.01725 & a_2 &= 3.62 \\ r_e &= 1.276 \times 10^{-8} \text{ cm} & a_3 &= -2.60 \\ \theta^2 &= 0.00709 \end{aligned}$$

¹³ D. C. Bourgin, *Phys. Rev.* **29**, 794 (1927).

¹⁴ R. T. Birge, *Phys. Rev. Supp.* **1**, 1 (1929), esp. p. 4.

¹⁵ W. F. Colby, *Phys. Rev.* **34**, 53 (1929).

¹⁶ The values given are obtained by averaging the results for the two isotope components which is sufficiently accurate for our purposes. The value of a_3 has been obtained by using the value of $a^3 r_e^3/4$ (i.e. the value of a_3 according to Morse's analysis, cf. Eq. (16)). a_3 is a small term occurring only in a second order correction so that a more precise evaluation is not necessary.

Substituting these values in Eqs. (9) and (14) we have:

$$\frac{\alpha_{02}}{\alpha_{01}} = (0.0194 - 0.0166\rho'' + 0.00355\rho''^2) \quad (\text{Pert}) \quad (18)$$

$$(-0.0015 + 0.0008\rho'' + 0.00026\rho''^2 - 0.000147\rho''^3 - 0.000414\rho''' + 0.000177\rho'''\rho'')$$

$$\frac{\alpha_{02}}{\alpha_{01}} = (0.0173 - 0.0159\rho'' + 0.00364\rho''^2) \quad (\text{Morse}) \quad (19)$$

$$(+0.0003 + 0.00025\rho''^2 - 0.000143\rho''^3 - 0.000376\rho''' + 0.000173\rho'''\rho'')$$

In Eqs. (18) and (19) the two terms in θ appearing in Eqs. (9) and (14) have been kept separate to show that the formula from Morse's analysis converges more rapidly than the other so that its first term may be considered a better approximation than that of Eq. (9). If the two terms are combined, it is easy to see that the difference between the two second approximations cannot be greater than 2 percent, as none of the major terms differ by more than that amount.

In these equations the only unknowns are ρ'' and ρ''' . Unfortunately we cannot evaluate both of these constants from one equation, as the method of successive approximations would not yield very significant results for ρ''' in view of the relatively large experimental error. Consequently we shall use only the first terms and solve only for ρ'' . Now, as we have seen, if we are going to use only the first term, Eq. (19) is more accurate than Eq. (18) so that we shall use the former in calculating ρ'' , which gives us:

$$\rho'' = \begin{matrix} 0.066 \pm 0.13 \\ 4.30 \pm 0.13 \end{matrix} \quad (20)$$

there being two values because the first term of Eq. (19) is quadratic in ρ'' . Now $p'' = p_e''/p_e'$ and, for a known value of p_e' determines p_e'' . Using the value of p_e' found by Bourgin¹³ ($p_e' = 1.06 \times 10^{-18}$ e.s.u.) we have for p_e''

$$p_e'' = \begin{matrix} 0.070 \times 10^{-18} \\ 4.56 \times 10^{-18} \end{matrix} \left. \vphantom{\begin{matrix} 0.070 \times 10^{-18} \\ 4.56 \times 10^{-18} \end{matrix}} \right\} \text{e.s.u.} \quad (21)$$

p_e'' is the coefficient of the quadratic term in the expansion of $p(\xi)$ about $\xi=0$ and consequently is a measure of the "curvature" of the electric moment at that point.

The fact that one of the values of p_e'' is zero (within experimental error) shows why in my previous paper on this subject² a calculation of the intensity ratio assuming a linear electric moment gave results in good agreement with the observed value. This correspondence, however, cannot be used to show that p_e'' is negligible because we have just seen that a value of p_e'' which is a good sized positive quantity (a negative quantity if p_e' is negative) also gives

the correct value for the intensity ratio, and there is no way, using only intensity data, to distinguish between these two values of p_e'' .

A similar ambiguity arises in the case of p_e' where, because of the quadratic dependence of the intensity on the electric moment, it is not possible to determine the sign of p_e' from intensity measurements alone. This ambiguity in the sign of p_e' leads to a sort of double ambiguity in p_e'' because a change of sign of p_e' changes the sign of p_e'' as determined from Eq. (20). This, of course, does not affect that value of p_e'' which is practically zero, but the other greater value may apparently have either sign depending on that of p_e' .

It has always been assumed that the electric moment of HCl is linear and that p_e' is positive in the region about the equilibrium point. These were natural assumptions when HCl was supposed to dissociate into ions, but in recent years, it has been shown that HCl probably dissociates adiabatically into neutral atoms,¹⁷ which means that at least for large values of r , the electric moment decreases with increasing nuclear separation. This surely means that the curvature of the electric moment is appreciable somewhere, and there is no reason why it should be negligible at the equilibrium point, so that we cannot rule out the larger value of p_e'' until there is more detailed information on the form of p as a function of r . As far as the sign of p_e' is concerned, it is probably positive. The position of the hydrogen nucleus when at equilibrium, is generally considered to be inside the M shell of the chlorine atom and so we may assume that its distorting influence on the chlorine atom, and consequently the electric moment of the molecule, is not at its greatest, and hence p is still increasing with r .¹⁸ This is a very rough sort of reasoning but owing to our complete ignorance about the detailed processes responsible for setting up electric moments in molecules with atomic binding, it is the only sort of reasoning that we can apply to the data at present.

¹⁷ V. Kondratjew, *Zeits. f. Physik* **48**, 583 (1928); R. Samuel, *Zeits. f. Physik* **49**, 95 (1928); F. London, *Zeits. f. Physik* **46**, 455 (1928) esp. p. 472 et seq.; Franck und Kuhn, *Zeits. f. Physik* **43**, 164 (1927) esp. p. 169.

¹⁸ Assuming that the electric moment at r_e is near its maximum and has a positive slope, the most probable value of p_e'' is the small one (nearly zero) because the other implies a large positive curvature which is impossible in the neighborhood of a maximum. However the assumption that r_e is near the maximum is too questionable to warrant definite predictions and the whole matter may be complicated by subsidiary maxima in the electric moment for values of r less than r_{max} .

THE RAMAN EFFECT IN HCl GAS

BY R. W. WOOD AND G. H. DIEKE
JOHNS HOPKINS UNIVERSITY, BALTIMORE

(Received April 23, 1930)

ABSTRACT

Improvements in the experimental conditions made it possible to get much better pictures of the Raman effect of HCl-gas than before. The results are in perfect agreement with what is predicted by the dispersion theory.

THE first report of the Raman effect in the case of a gas at atmospheric pressure was published by R. W. Wood in *Nature*, February 2, 1929, where it was shown that hydrochloric acid gas contained in a long glass tube mounted in contact with a Cooper-Hewitt glass mercury arc, the whole surrounded by a reflecting cylinder of highly polished sheet aluminum, gave a Raman line excited by the Hg 4046 line, the frequency difference corresponding to an infrared line in the position of the "missing line" of the absorption band at 3μ . In the following number of *Nature*, Rasetti announced the discovery of the Raman lines of CO and CO₂ also at atmospheric pressure.

The experiments in HCl were more fully described in the *Phil. Mag.* for April 1929 and it was shown that the 4358 Hg line was accompanied by a series of close companions, corresponding to rotations of the HCl molecule, and it was further shown that the infrared frequencies corresponding to these lines were of very nearly the same wave-length as the *alternate* lines observed by Czerny. An interpretation of these results was given by several investigators independently.² Rasetti¹ studied with great success the Raman effect of other diatomic gases at atmospheric or higher pressures.

With the same tube, and with a platinum diaphragm as was employed in the earlier experiment, but with a recently constructed spectrograph equipped with two interchangeable camera lenses, one a large Steinheil portrait objective (F2.5) and the other a Cooke objective of one meter focus, some superior spectrograms of the Raman effect in HCl have been obtained.

A better alignment of the tube was secured and greater precautions taken to exclude all parasitic light. Six, or possibly seven rotation bands appeared on the long wave-length side of Hg 4355 and three (anti-Stokes) on the other side. Rotation bands also appeared on both sides of the 4046 line, but the "Q branch" line excited by 3650–3655 and 3663 appeared in triplicate mixed in with these rotation bands.

¹ F. Rasetti, *Nature* **123**, 205, 757 (1929). *Proc. Nat. Acad. Sci.* **15**, 234, 515, (1929). *Phys. Rev.* **34**, 367 (1929).

An enlargement of the entire spectrum is reproduced in Fig. 1. and a highly enlarged portion of the part showing the *Q* branch excited by 4046 and the rotation bands to the right and left of the 4358 line in Fig. 2.

Fig. 1. Enlargement of entire spectrum.

Fig. 2. Highly enlarged portion of spectrum.

INTERPRETATION OF THE RESULTS

The Raman effect of HCl furnishes an excellent opportunity to compare the theoretical predictions with the experimental results, for the HCl molecule is very simple, and furthermore we know its entire infrared absorption spectrum. The situation is therefore much more favorable than for the organic molecules, the exact structure of which is generally not known, so that it is impossible to say what we ought to expect theoretically.

The experimental data are given in Table I.

* This line is excited by $\lambda 4047$. The corresponding line excited by $\lambda 4358$ would fall in a region where the plate is very insensitive. The infrared datum is the zero line of the absorption band at 3.4μ . The wave-length of the Raman *Q*-branch has been taken from the previous work because the dispersion was then greater. We find now a value about 3 cm^{-1} less, but think it less reliable.

The first column gives the observed wave-lengths of the Raman lines. The second column gives the frequency differences with the exciting line $\lambda 4358$.

In the third column we find the rotational transitions in the molecule to which the lines correspond, and the fourth column gives a comparison with the infrared data (see farther down).

The dispersion theory of Kramers and Heisenberg³ published in 1925 contains, as is well known now, a complete theory of the Raman effect. The more rigid radiation theory of Dirac leads essentially to the same formulae. The essential feature of this theory is, that the intensity of a Raman line which corresponds with a transition of the molecule from the level a to the level b , has no connection at all with the transition probability between these two levels, which would determine the intensity of the corresponding absorption line. In order to find the intensity of a Raman line we must consider virtual transitions with a certain third level c . If this level c can be reached in an ordinary transition from both the levels a and b , the Raman line is allowed. The Raman line can therefore be considered as the difference between two lines of the molecule, one of which must be an absorption line. The theory gives further the exact intensities of the lines expressed in terms of the transition probabilities between the different levels of the molecule, but we need not go here into details of the theory.

If we consider now a HCl molecule in its normal electronic and vibrational state and with a value j of the rotational quantum number, we have to consider first the possible absorption transitions in order to find which Raman lines we have to expect. In any transition the change of j can be only zero or ± 1 . From the theory of the spectra of diatomic molecules it is well known⁴ that those states to which the molecule can go if $\Delta j=0$ are of a different nature from those for which $\Delta j=\pm 1$.

Let us consider the latter ones first. The molecule would be either in a state with $j+1$ or with $j-1$ after the virtual absorption act. It has to fall back in a virtual emission act to the *normal* electronic level, and the change of j can only be ± 1 in this transition. After the emission of the Raman line the molecule can therefore only be in a state with the rotational quantum number j or $j\pm 2$. If we take into account also those virtual absorption acts for which $\Delta j=0$, (such transitions would occur when the upper electronic state is a Π -state), nothing will be changed in this result. For in the virtual reemission act j must remain likewise unchanged, so that in this particular kind of Raman transition no change of j can occur. As we have to take the sum over all possible third levels c , our result is that in any Raman transition j can change only zero or ± 2 . As for any infrared absorption line of HCl we must have $\Delta j=\pm 1$, we see that not a single Raman line can correspond to an absorption line.

As was shown by Van Vleck⁵ the possible changes of the vibrational quantum number are zero or ± 1 only, even if intermediate levels c with high

⁴ E. Hulthén, *Zeits. f. Physik* **46**, 349 (1927). R. de L. Kronig *Zeits. f. Physik* **46**, 814 (1928).

⁵ J. H. Van Vleck, *Proc. Nat. Acad. Sci.* **15**, 754 (1930).

values of the vibrational quantum number are taken into account. A higher electronic level of the HCl molecule than the normal one is as yet unknown. From the behavior of similar molecules we have reason to expect that an absorption act will result in such a case into dissociation. There seems to be no reason why these dissociated states cannot act in just the same way as the discrete levels as intermediate states in the Raman effect. The considerations which determine the selection rule for j hold just as well for this kind of transition. It may be expected that the probability for the ultraviolet absorption is much greater than that for the infrared absorption so that the transitions via the dissociated states play the most important part in the Raman effect of HCl. But other factors ought also to be considered, so that this point cannot be settled yet with the present material.

If the vibrational quantum number does not change, we can notice only a change ± 2 of the rotational quantum number for $\Delta j = 0$ gives the unmodified line. If j increases two units we have what is called the normal Raman

Fig. 3. Diagram showing the connection between the Raman and the infrared rotational spectrum of HCl.

effect,⁶ i.e., lines on the red side of the directly scattered line and as the table shows, the transitions up to $7 \rightarrow 9$ have been observed except the first one which would come too close to the strong unmodified line so that it cannot be detected. We can obtain the same rotational differences also from the infrared data of the vibrational rotational bands *nl*. as differences $R(j-1) - P(j+1)$ of lines of the *R*- and *P*-branch, and these differences are given in the fourth column of the table.⁷ The agreement is as good as it can be expected from measurements of such faint lines.

In the former communication and in the beginning of this paper it was mentioned that these lines correspond with alternate lines of the rotational absorption band in the far infrared observed by Czerny.⁸ But this correspondence is only accidental as can be seen immediately from Fig. 3 in which

⁶ A sequence for which in the Raman effect $j \rightarrow j+2$ is called an *O*-branch. It would be similar to an ordinary *P*-branch with double spacing. Similarly a sequence of lines for which $j \rightarrow j-2$ is called an *S*-branch.

⁷ Taken from C. F. Meyer and A. A. Levin, *Phys. Rev.* **34**, 44 (1929).

⁸ M. Czerny *Zeits. f. Physik* **34**, 227 (1925); **44**, 235 (1927).

both the Raman and the far infrared absorption spectrum of Czerny are plotted and the corresponding transitions indicated. The fact that the Raman lines coincide with alternate infrared lines is only due to the fact that the rotational energy can be represented with good approximation by $Bj(j+1)$, from which follows that the Raman lines due to the transitions $j+1 \rightarrow j-1$ coincide with the absorption lines $2j+1 \rightarrow 2j$. This agreement is not exact as one would find deviations if one takes into account also the higher terms in the rotational energy. These deviations are however too small to be noticeable with the accuracy of the present observations.

The conditions for the observation of the Raman lines corresponding to transitions $j \rightarrow j-2$ (anti-Stokes lines, *S*-branch) were much less favorable, as the first lines are covered by the companions of $\lambda 4358$. However, the three lines given in the table can clearly be recognized. Obviously the distance of a line $j \rightarrow j-2$ from the unmodified line must be the same as that for the line $j-2 \rightarrow j$. The intensity of the $j \rightarrow j-2$ transition seems to be less than that of the $j \rightarrow j+2$ transition. This asymmetry can also be accounted for theoretically. For a $\Sigma \rightarrow \Sigma$ transition the probability for a transition $j+1 \rightarrow j$ is equal to that for $j \rightarrow j+1$ and proportional to $j+1/2$. For a Raman transition the intensity is determined by expressions in which the product of the probabilities for the virtual absorption and emission act occur. Therefore for a transition $j \rightarrow j-2$ the intensity would be proportional to $(j-1/2)(j-3/2)$ whereas for the transition $j \rightarrow j+2$ the intensity would be proportional to $(j+1/2)(j+3/2)$. That means that a line of the *O*-branch must be stronger than the line of the *R*-branch which has the same initial state, and that is in agreement with the observed intensities.

If the vibrational quantum number increases one unit, we have to expect transitions $j \rightarrow j+2$ (*O*-branch) $j \rightarrow j-2$ (*P*-branch) and $j \rightarrow j$ (*Q*-branch). The *O* and *P* branches were too weak to be noticeable on the plates, which indicates that a Raman transition in which the vibrational quantum number increases one unit is *much* less probable than the transition in which it remains unchanged in accordance with Van Vleck's calculations. All the lines of the *Q*-branch fall so close together that they cannot be separated and are seen as one somewhat diffuse line. As the moment of inertia is larger in the final state of the Raman transition (on account of the stronger vibration) the *Q*-branch ought to be degraded towards the exciting line, i.e. towards the violet. It can clearly be seen on the plate that this is actually the case.

THE PHOTOELECTRIC AND THERMIONIC PROPERTIES
OF PLATINUM COATED GLASS FILAMENTS

BY A. KEITH BREWER

FERTILIZER AND FIXED NITROGEN INVESTIGATIONS BUREAU OF CHEMISTRY AND SOILS
WASHINGTON, D. C.

(Received April 21, 1930)

ABSTRACT

The photoelectric and thermionic properties of platinum sputtered glass filaments are discussed, special attention being given to the effect of temperature, and to electrolysis of potassium through the glass to or from the sputtered coating. When electrolysis is away from the surface, the photoelectric threshold is independent of the temperature up to 450° and is close to 2720Å. With electrolysis toward the surface the threshold remains at 2720Å up to 260°C above which it shifts toward the red with rising temperature, reaching a maximum value of about 4300Å at 410°C . Electrolysis produces identical effects on the photoelectric and thermionic emissivity for electrons; the effect on positive ion emission is similar, also, except that a peculiar maximum in the emissivity occurs for a specific electrolysis potential. Ultraviolet radiation has no effect on the thermionic emission of electrons or positive ions from this type of filament.

IN A recent article from this Laboratory by F. G. Cottrell, C. H. Kunsman and R. A. Nelson¹ a new method was presented for the production and control of positive ions. The present paper is a continuation of this study, and deals with the photoelectric and low temperature thermionic phases of the problem.

APPARATUS

The type of emitter chosen for this research consisted of a platinum filament over which a thin layer of potassium glass* was fused, the diameter being about 1.5 mm. A reserve supply of potassium was provided by immersing the filament in molten potassium nitrate and electrolyzing potassium through the glass onto the filament; the potassium formed a golden brown layer over the filament surface. The emitting surface was a thin layer of platinum deposited on the glass by cathode sputtering; short distances at the ends were kept free to insulate the platinum coating from the filament. Electrical contact to the platinum coating was made by twisting a fine platinum wire tightly around the filament. With this type of filament, potassium could be electrolyzed to or from the platinum coating as desired by placing a suitable potential (V_E) between the coating and the filament.

A schematic drawing of the apparatus is shown in Fig. 1. The temperature of the filament was given by a thermocouple twisted about the coating. The emission currents were read with a Compton electrometer shunted with a

¹ Cottrell, Kunsman and Nelson, J. O. S. A. 20, 152 (1930), and in press.

high resistance leak and potentiometer, which enabled currents to be read from 10^{-15} to 10^{-10} amps. The collecting electrode was made of copper, while the filament supports were made of nickel or tungsten. Ultraviolet light was admitted through a 1 inch quartz window with a graded glass seal.

A Hilger monochromatic illuminator was used to resolve the light of a hot mercury arc of the Uviarc type operating at 75 volts and 1.85 amps. The intensities of the various lines were measured with a Hilger thermopile, using the same slit width as that used in the photoelectric measurements, namely 0.5 mm.

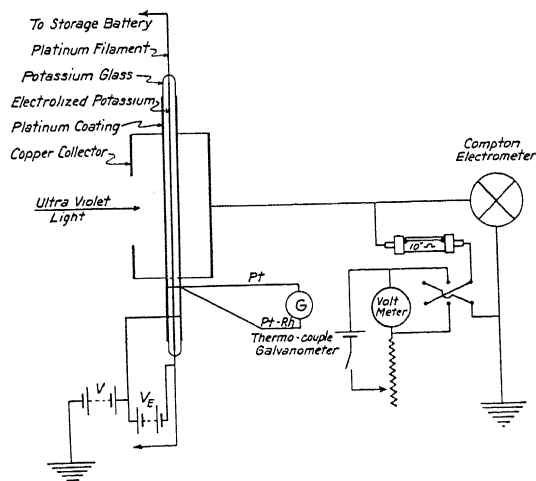

Fig. 1. Diagram of apparatus.

The nature of the filament did not permit of a systematic outgassing process. The pressure in all cases, however, was below the sticking point of mercury in the McLeod gauge (10^{-6} mm of Hg).

RESULTS

Photoelectric emissivity. In determining the photoelectric threshold the current per unit of light intensity method was used. Corning glass filters and direct radiation from the arc were used also where greater intensity was needed.

The factors investigated in this research were (1) the effect of the electrolysis potential between the coating and the filament on the threshold, and on the emissivity; (2) the effect of temperature on the threshold, and on the rate of electrolysis; (3) the effect of electrolysis on the characteristics of the wave-length—current intensity curve, and (4) the effect of ultraviolet light on the thermionic emissivity of both electrons and positive ions.

The effect of an electrolysis potential (V_E) on the photoelectric activity is shown by line A of Figure 2.

It will be noted that the emissivity for λ 2653 is changed by an order of 30 fold, when V_E is changed from 1.5 v. negative to 3.0 v. positive. These

voltages, however, are not corrected for the fall of potential along the filament which for this temperature was about 3.0 v., the filament drop being negative to the coating. The zero, therefore, should be moved 1.5 v. to the right in Fig. 2, to give the correct electrolysis potential.

Fig. 2. A. Photoelectric emission, $\lambda 2653$, temp. 337°C ; B. Thermionic emission of electrons, temp. 632°C ; C. Thermionic emission of positive ions, temp. 422°C .

In these experiments a constant difference of potential of 45 volts was maintained between the coating and the collector. Saturation was obtained at slightly less than 2 volts and showed no change up to 135 volts.

The effect of temperature on the rate of electrolysis is shown in Figure 3.

Fig. 3. Effect of temperature on the rate of electrolysis.

It will be noted that at 295°C one hour is required for a steady state to be reached when the electrolysis potential is changed from 9 v. positive to 9 v. negative, or vice versa. At 415°C steady conditions are reached in about 4 minutes, while at higher temperatures the change is too rapid to be measured. At 260° no effect could be observed from changing the electrolysis potential, as is illustrated by line C of Figure 4.

A lag exists between the time when V_E is made positive and when an increase in photoelectric activity is observable, the duration of the lag decreasing with rising temperature. On the other hand, the emissivity falls off rapidly the instant a negative electrolyzing potential is applied.

The effects of temperature and electrolysis potential on the threshold and on the specific activity for various wave-lengths are illustrated in Fig. 4.

Line *C*, as has just been stated, represents the current per unit intensity at 260°C for $V_E = +9$ v. and $V_E = -9$ v. This is the lowest temperature at which an electrolysis effect could be observed. These results were obtained with a fresh filament. After the filament had been worked in at temperatures up to 400°C the threshold shifted to a position represented by line *D*.

The long wave-length limit for a worked-in filament with $V_E = -9$ volts was very close to 2720 Å, as is shown by line *D*. After the filament was

Fig. 4. Effects of temperature and electrolysis potential on the threshold and on the specific activity for various wave-lengths.

once worked in, the temperature coefficient became zero for all temperatures up to 425°C. At temperatures above 425°C the threshold shifted downward as is shown by line *E*, the shift increasing with the temperature.

The electrolysis of potassium to the surface (V_E positive) at temperatures above 260°C results in an enhanced photoelectric activity increasing with V_E as is shown by line *A* of Fig. 2, and with temperature, as is shown by comparing lines *A* and *B* of Fig. 3. The increase in emissivity is accompanied by a nearly corresponding shift in the threshold toward the red.

The conditions for maximum threshold are shown by line *A* of Fig. 4, in which case it was just possible to detect a photoelectric current with $\lambda 4350\text{Å}$. As the temperature was raised above 260°C, the threshold moved from about 3130 Å to 4350 Å, at 425°C. The exact value depended on the previous treatment of the filament, being higher when the filament had been cooled down with a strong positive electrolyzing potential applied. At temperatures above 425°C the threshold again shifted toward shorter wave-lengths, and the shape of the line became more regular as is shown by

line *B* of Fig. 4. At visibility the threshold shifted to about 3050Å. The shift in the neighborhood of redness is due to the combined effect of temperature and fatigue, for the total emissivity cannot be restored by lowering the temperature.

The specific photoelectric activity is apparently abnormally high in the region around 2700Å and 2400Å as is shown by the breaks in curves *A* and *B*. These irregularities are more pronounced for fresh filaments and when electrolysis to the surface has just been increased by raising the temperature or by increasing the electrolysis potential.

The long wave-length limits, as determined above, were checked with Corning filters using the direct radiation from the arc. At 280° the photoelectric current was about 10^{-10} amp. when the light direct from the arc was passed through 12 mm of Pyrex, which should cut out $\lambda 3022\text{Å}$, and fell to 1.1×10^{-13} amps. for a 3.5 mm Noviol O filter, and to about 10^{-15} for 7 mm, which should exclude most of $\lambda 3650\text{Å}$; the threshold is, therefore, very close to 3600Å. When the temperature was raised to 310°, the photoelectric current increased 4-fold.

The effect of fatigue is especially noticeable at high temperatures; the total activity can be reduced to a third of its initial value by holding the filament at redness for a period of minutes. The activities can usually be restored by reversing the sign of V_E and electrolyzing potassium ions away from the coating. Filaments have also been restored by washing in water and alcohol, and then lightly annealing with a small blue flame.

The thermionic emission of electrons. The thermionic emission of electrons from a fresh surface was detectable at temperatures above 425°C for positive electrolyzing potentials. The effect of V_E on the current is shown by line *B* of Fig. 2. The fall of potential along the filament is not corrected for in the graph; making this correction would shift the entire line 2 volts to the left.

The work function curves obeyed the Richardson equation fairly well, yielding a value for b of about 4×10^4 . No significance can be applied to this value, however, since the character of the surface definitely changed with temperature.

Special tests were made to detect an enhancement of the thermionic emission in the presence of ultraviolet light. These tests were carried out by balancing out the photoelectric current with the leak potentiometer, while the thermionic current was observed, and then by balancing out the thermionic current and measuring the photo-electric emissivity. Both general and monochromatic radiation were used. No effect of the ultraviolet light could be observed either in the temperature at which thermionic emission became detectable or in the magnitude of the thermionic currents.

The thermionic emission of positive ions. The emission of positive ions became detectable at 270°C. This is very close to the temperature where the photoelectric measurements showed the electrolysis potential to become operative.

The effect of V_E on the positive ion emission at 422°C is shown by line *C* in Fig. 2. The fall of potential along the filament is such that the entire

line should be shifted 1.5 volts to the left, bringing the peak of the curve at approximately $V_E = 0$.

Curve *C* is distinctly different from curves *A* and *B* in that it shows a critical value of V_E at which the maximum ion current is obtained.

The positive ion currents between 270°C and 450°C agree very well with those reported by Cottrell, Kunsman and Nelson, except that the value of ϕ computed from the Richardson equation is higher by about 0.5 volts. The high work function at the low temperature is to be expected from the fact that the rate of electrolysis also increases with temperature, thus increasing the available supply of possible ions at the surface.

A test for the photoelectric emission of positive ions was made, using direct radiation from the arc in which light of wave-lengths below the threshold of the copper collector was screened out by Corex A Blue Purple filters. No photoelectric emission of positive ions could be detected.

DISCUSSION OF RESULTS

The fact that the emission of electrons thermally and by ultraviolet light are both affected by electrolysis to and from the surface becomes doubly interesting when the characteristics of curves *A* and *B* of Fig. 2 are considered. By making the necessary corrections for zero potential, it will be seen that the two curves are identical in form and position. This is a further proof for the contention that the same group of electrons in the metal contribute to photoelectric and thermionic emission,² and is in line with the results of DuBridge³ and of Warner⁴ who have shown that the work functions for the two types of emission are identical.

Line *C* for positive ion emission is also very similar to lines *A* and *B* for electron emission, except for the fact that it contains an optimum value of V_E . It will be noted that the photoelectric activity increases rapidly at the value of V_E where positive ion emission becomes detectable.

The similarity between the positive ion and electron curves as well as the presence of an optimum electrolysis voltage for positive ions is readily explained by applying to the Richardson equation the intrinsic force concept previously outlined by the writer.^{5, 6, 7}

In the equation $i = ne(kT/2\pi M)^{1/2}e^{-b/T}$, n is the number of possible positive ions per unit volume at the surface of the emitter, while b is a measure of the work done in bringing such an ion through the surface region. From this it follows that any process which decreases n or raises b will decrease the positive ion current.

The electrolysis of positive ions away from the surface ($-V_E$) decreases the value of n ; line *C* of Fig. 2 shows that the positive ion emission is not de-

tectable for large negative values of V_E . The increase in the positive ion current as shown on the graph from $V_E = -1.75$ to $V_E = +1.5$, is without doubt due to an increase in the value of n .

The accumulation of an element of large atomic diameter such as potassium on the surface should, according to the intrinsic force concept, increase the value of b for positive ion emission just as it decreases b for negative emission. The decrease in emissivity beyond the critical value of V_E is due, therefore, to an increase in the thermionic work function for positive ions occasioned by the accumulation of potassium at the surface. Thus the electrolysis of potassium to the surface increases both n and b for positive ion emission, the observed emission curve being a resultant of these two effects.

The fact that an electrolysis potential larger than 3 volts positive has only a small effect on the emissivity, as may be seen from Fig. 2, raises the question as to the nature of the potassium on platinum surface. A condition such as this may result either from the surface being completely covered with potassium at this point, or from a state of polarization being reached in the surface layer which prevents a further accumulation of potassium.

Two facts may be mentioned which indicate that a state of polarization exists and that the surface does not become covered with free potassium. First, in Fig. 3 it will be seen that the emissivity drops markedly the instant a negative electrolyzing potential is applied. Had the surface been covered with a layer of potassium, lines A' and B' should have shown a time lag. The second fact is that it was never possible to obtain the threshold for pure potassium, the values found always lying between that for potassium and platinum. It would seem, therefore, that the surface can best be considered as a surface solution of potassium in platinum rather than a deposit of potassium on platinum.

The writer's best thanks are due Dr. C. H. Kunsman for his interest and advice, and Mr. R. A. Nelson for constructing the filament and rendering other valuable assistance.

THE ROLE OF THE CORE METAL IN
OXIDE COATED FILAMENTS

By E. F. LOWRY

WESTINGHOUSE RESEARCH LABORATORIES, EAST PITTSBURGH

(Received March 14, 1930)

ABSTRACT

Temperature-power relations have been determined for numbers of oxide coated filaments. Part of these filaments had cores of platinum-10% iridium and others had cores of "Konel," an alloy of nickel, cobalt, iron and titanium. Oxide coated Konel is a much better radiator than oxide coated platinum-iridium which causes a considerable difference in their temperature-input power characteristics. Nevertheless, emission measurements show that oxide coated Konel filaments yield higher electron emissions than oxide coated platinum-iridium under the same conditions of filament power. Experimental proof is also given that these filaments need no activation other than the decomposition of the alkaline earth carbonates to oxides in vacuo. The enormous difference shown between the emission characteristics of these two types of oxide filament necessitates the conclusion that the core metal has a definite function other than simply a mechanical support for the alkaline earth oxides.

Suggested mechanism of thermionic emission from oxide coated filaments. In order to account for this difference, a modification is suggested in existing ideas concerning the mechanism of emission from this type of cathode. This modification consists in assuming that the source of emission is the composite layer formed by occlusion of alkaline earth metal on the surface of the core and that the electrons emitted diffuse through the interstices in the oxide coating into the vacuum space. Argument is presented to show that this explanation will also account for other peculiarities in the behavior of oxide cathodes. (1) The decay of emission during life may be explained by a slow sintering of the coating and a consequent closing of these pores. (2) De-activation of the filament by over-heating may be attributed to the same cause. (3) Non-saturation may be due to a pseudo-space charge formed by occlusion of electrons on the surface of the coating particles.

INTRODUCTION

SINCE the discovery by Wehnelt¹ in 1904 of the exceedingly large electron emissions obtainable from glowing calcium oxide, this type of hot cathode has steadily become of greater and greater importance both for use in various thermionic devices and as a copious source of electrons in work of purely scientific interest. This popularity has followed closely upon necessary improvements in technique, resulting in a much greater degree of uniformity from filament to filament as well as in a constant improvement in their efficiency. An inspection of the values of the work function for the alkaline earth oxides obtained by various investigators in the chronological order in which their results were obtained is an excellent proof of this improvement. A table of this sort is appended for which we are indebted to Espe.²

As a result of the composite nature of this type of cathode the phenomena attendant upon its use are quite complicated and of a somewhat different nature than those found upon examination of pure metallic cathodes. This complexity has given rise to several schools of thought in regard to the mechanics of electron emission from this class of material. It has been held:

1. That the emission is derived from the oxide *per se*,
2. That it is the result of a chemical reaction within the coating, and
3. That the emission comes from a layer of metallic barium on the surface of the oxide coat.

To the best of the author's knowledge the effect of the base or core metal has always been held to be negligible or has been entirely ignored. This is, perhaps, a natural consequence of the various ideas concerning the nature of the oxide emission which have been held up to the present and to the fact that nearly all students of this subject have used platinum as the core metal to the exclusion of everything else. Schottky and Rothe in Vol. 13, chapter IX page 227 of the Wein-Harms Handbuch der Experimental Physik (1928) have summed up the situation very nicely as follows: "Aus einer der ersten Untersuchungen der Oxydemission durch F. Deiningen geht hervor, dass diese (i.e., the work functions for various oxides) unabhängig von dem Material des Glühdrahtes und eine charakteristische Eigenschaft des betreffenden Oxyds ist, wie es auch allen unseren Anschauungen über die Wirkung von Oberflächenschichten entspricht."

Results which have been obtained in this laboratory indicate that the core metal does play a very important rôle in the behavior of this type of hot cathode and therefore that the explanations stated above are misleading as to the true nature of this emission, or at best, are inadequate. It is the purpose of this paper to set forth proofs that the core metal has a vital function in the phenomena of oxide emission. It is also our purpose to suggest an explanation of the mechanics of emission which will take into account this newly discovered factor as well as conform to the demands of their better known but equally important characteristics.

With the advent of the oxide coated filament into common use in radio receiving tubes, it became an economic necessity to find a satisfactory substitute for platinum-iridium as the core metal. Dr. Dayton Ulrey of this laboratory suggested that nickel was the logical metal to begin with. Experiment showed that quite as good emissions could be obtained from oxide coated nickel filaments as had ever been gotten from the oxide coated platinum filaments then in use. The subsequent almost universal adoption of this material for commercial use has entirely corroborated the results obtained by the author at that time.

The search for a satisfactory platinum substitute was not abandoned with the proof that nickel could be used with equally good results. A metal having a higher tensile strength at red heat and above was desirable to insure longer life before burn out as well as less danger of breakage.

An alloy of nickel, cobalt, iron and titanium was found to meet these requirements and also to give excellent thermionic results when coated with oxides of the alkaline earths in the usual way. This alloy has received some publicity of late under the name "Konel."

During the course of investigation of oxide coated Konel filaments in commercial tubes of the UX-112 type it was noted that the brightness temperature of these filaments appeared to be considerably lower than that of similar oxide coated platinum filaments operating at the same power per unit area. This observation seemed to call for a careful study of the relative operating temperatures of these two types of filaments, since neither theory nor experience could account for the effect noticed. This investigation was carried out in the manner described in the succeeding paragraphs.

EXPERIMENTAL METHOD AND RESULTS

The filaments used during the course of this investigation have all been of the type used in UX-281 Radiotrons. Both the platinum-10% iridium (referred to hereafter in this paper simply as platinum) and the Konel filaments were coated in the same fashion. Several applications of a water paste consisting of equal parts of BaCO_3 and SrCO_3 were baked on the ribbon in an atmosphere of CO_2 . This carbonate coating was subsequently decomposed to oxide in vacuo during the outgassing process of the tube to be examined. Since all data given are averages obtained from a rather large number of filaments made from different spools of ribbon and coated at different times, their exact dimensions are irrelevant. Their approximate dimensions were

27 cm length by 0.06 cm width. Both the platinum and the Konel filaments had practically the same areas and resistance characteristics. This equality of area insures equal space charge limitations when mounted in tubes whose anodes are all of the same size. The filaments were mounted *M* fashion in standard UX-281 tubes save that for the temperature investigation no anodes were included. No corrections for cooling effects of the leads and hooks have been applied since a careful test showed that this effect was negligible when plotting the temperature of the center of the filament against the power input to the filament.

This test was carried out on a tube in which were mounted two filaments as shown in Fig. 1. These filaments were taken from the same spool of coated ribbon but were of different lengths. They were connected in series

Fig. 1. Diagram of tube.

so that by subtracting the voltage drop through the shorter filament from that through the longer one the power loss in the uniformly heated central portion of the longer filament could be calculated. Further calculation showed that the end cooling on a filament of this length was responsible for an error in the curves of about 3 degrees in the lower range of temperature and about 1 degree in the upper range. The target for optical pyrometer observations on the base metal was formed by carefully scraping the coating from one side of the ribbon at the center of one of the middle legs of each filament for a space about equal to the width of the filament. Brightness temperature observations were made on this spot as well as on the surface of the coating at a point immediately adjacent to this bare area. Two Leeds & Northrup optical pyrometers calibrated against standard lamps furnished by Dr. Forsythe of Nela Park were used for this work, the results of

which are shown in Fig. 2. It may be well to call attention to the fact that each point plotted is an average of five separate observations and each point of a group was found for a different filament. A check test was run recently on two of the filaments previously studied using a different pyrometer. The results of this check are indicated by crosses. It seems entirely safe to conclude from the results shown that the brightness temperature curves given here are not in error by more than $\pm 5^\circ\text{C}$.

Obviously, we are interested in the true temperature of the core metal and not particularly in that of the surface of the coating. In order to calculate the true temperature of the Konel filaments it became necessary to find the value of its spectral emissivity at $\lambda = 0.65\mu$ in the temperature region under investigation. This was accomplished by the spiral filament

Fig. 2.

method described by Shackelford³ with the result that a value of 83% was found for this factor. Foote and Fairchild⁴ give this correction factor for platinum as 33% and for iridium as 30%. A rough calculation of the spectral emissivity of the coatings yields a value of the order of 25%. This value is of course only approximate since the difference in temperature between the surface of the coating and that of the base metal is not precisely known, although it can at the most be a matter of only 10 to 15 degrees C. Furthermore, these coatings, although appearing pure white by reflected light are quite porous as well as translucent, with the result that the above value is probably high.

By applying the proper correction factors to the curves of Fig. 2 we arrive at the values shown in Fig. 3 which refer of course to the true temperature

³ Shackelford, Phys. Rev. 8, 470-478 (1916).

⁴ Foote & Fairchild, Symposium on Pyrometry, Am. Inst. Mining & Met. Eng. 338, (1920).

of the metal cores as a function of the power supplied to the filaments in watts per cm^2 .

The difference in temperature between oxide coated platinum and Konel filaments operating under like conditions of power input is readily explained. Konel becomes considerably oxidized during the coating process described above and hence is a much better radiator than platinum. The oxide coating, although a poor radiator, allows an appreciable amount of the radiation from the core to escape owing to its porosity and translucence. As a result the energy radiated is dependent upon the nature of the core

Fig. 3.

to a considerable extent and is not limited entirely by conduction through and radiation from the surface of the coating.

In Fig. 4 are shown some space current measurements made with UX-281 Radiotrons using similar filaments to those used in the tests described above save that these filaments have a length of approximately 17 cm. In fact, some of them were taken from the same spools of coated ribbon. These curves are also averages for numbers of tubes and show that when the currents are limited by emission rather than by space charge the values for oxide coated Konel are higher than for oxide coated platinum operating at the same power per unit area. It must be borne in mind that the results given here are to be considered as typical of this particular kind of coating. It is possible that different results might be obtained with, for example,

the barium azide method of coating. The whole process of making oxide filaments, coating them with oxides and their subsequent treatment on the pumps is of the nature of an art only to be acquired through long practice. The author would, therefore, hesitate to comment on the results to be obtained by some distinctly different process of coating. The filaments used

Fig. 4.

throughout this work were good representative samples of commercial oxide coated filament. The tubes used were also representative in every way, their only difference from commercial tubes being that the most extreme care was used in getting the highest obtainable vacuum in each one to obviate the possibility that any appreciable part of the space currents obtained was due

Fig. 5.

to the presence of gas. The normal value of emission for UX-281 Radiotrons is 0.170 amperes at $E_p=100$ volts and a power input of approximately 4 watts per cm².

The results of the previous curves have been combined to obtain the results shown in Fig. 5. Here are shown the space current values obtained

at various anode voltages plotted against the temperature of the filaments in degrees C. It here becomes obvious that the core metal has an enormous effect on the thermionic activity of the coating. It is readily seen from these curves that the same anode current may be obtained from oxide coated Konel at 775°C. as can be obtained from platinum coated with the same oxides at 950°C. This is the phenomenon which we believe is new and for which we offer a possible explanation in the succeeding pages.

THE MECHANICS OF EMISSION

As mentioned in the introductory matter of this paper, at least three distinctly different explanations of the mechanics of emission from oxide coated filaments have been set forth in the past. None of them take into account any function of the core metal other than as a mechanical support for the thermionically active oxides and as a means of furnishing the necessary thermal energy to them in a convenient manner. The experimental facts stated in the foregoing pages make it imperative that the role of the core metal be recognized and its effect explained. It is obvious that such an explanation must also be in accord with other phenomena peculiar to this type of cathode. Some of these phenomena are:

1. The formation process.
2. Destruction of activity by overheating.
3. Decay of activity with life.
4. Non-saturation.

The explanation most in favor during recent years has been that offered by Koller,⁵ Espe,⁶ Rothe⁷ and others in which it is assumed that the source of activity is a layer of metallic barium on the surface of the oxide coating. Espe argues that this barium is formed by electrolytic decomposition of the oxide coating and that the barium diffuses to the surface of this coating where it serves as emission centers. The explanation submitted herein is a modification of this idea in that it is believed that the emission arises from a layer of metallic barium occluded on the surface of the core metal or alloyed with it. This modification seems necessary in that if the emission arises from the oxide itself or from barium "emission centers" on the surface of the coating, the thermionic activity of such filaments should be unaffected by the nature of the core. In such case both platinum and Konel oxide filaments should be equally active at like temperatures. This obviously is far from the fact.

In a way, it is immaterial to the argument at hand as to just the method by which the barium is produced. If it is formed by electrolytic decomposition according to Espe,⁶ the barium ions would be positively charged and have a natural tendency to migrate toward the core. As a matter of fact this is probably the method by which a constant supply of barium on the core is maintained after the initial "activation."

⁵ Koller, Phys. Rev. 25, 671, (1925).

⁶ Espe, reference 2.

⁷ Rothe, Zeits. f. Physik 36, 737-758 (1926).

It is also possible that metallic barium is formed by positive ion bombardment under certain conditions of activation. This explanation does not, however, account satisfactorily for a maintenance of a barium supply under high vacuum conditions.

With the type of coating used by the author in the course of this work it is, however, entirely probable that the barium is formed either by thermal decomposition of the carbonates in vacuo or by the reducing action of the metallic core. Figure 6 shows a curve of the behavior of a typical filament during the course of an experiment to prove this point. Tube #X2410 containing Konel filament #125-386 was baked at 400°C in the usual way, after which the metal parts of the tube were thoroughly outgassed in a high

Fig. 6.

frequency furnace. The only heating received by the filament up to this time was that due to radiation from the hot anode. An instantaneous measurement of emission was then made and yielded a value of 5×10^{-6} amp. at a filament power input of 4 watts per cm^2 and an anode voltage of 100 volts. The filament was then heated at 8.5 watts per cm^2 for several minutes and then at 5-6 watts per cm^2 until the gas pressure in the tube had been reduced to less than 1×10^{-5} mm of mercury. During this treating out of the filament no anode voltage was applied and the plate was cold except for radiation absorbed from the filament. Another instantaneous determination of the emission now gave 0.186 amperes under the same test conditions as before. Subsequent treatment of various kinds gave no improvement as is indicated by the curve, which is self explanatory. This behavior is typical of this type of filament when properly handled. Similar results have been obtained with oxide coated platinum filaments, so the results described can-

not be ascribed to the kind of base metal used. Since a certain amount of vaporization of the barium from the core is to be expected at operating temperature especially in the case of platinum filaments, it is quite likely that the supply of barium is replenished by some such process as the electrolytic decomposition of the oxide coating. It certainly is not essential however to their initial activation. Again we must insist that this applies only to coatings of the type used in this work. If the carbonates are converted to oxide by long continued heating in the air and not converted in vacuo as in this case, an activation process of some length does have to be followed to bring the filaments up to normal activity.

Evidence of this and also of the fact that the emission is due to metallic barium was obtained in an experiment similar to the one just described in which the filament was burned in air at low pressure for a short time after it had been tested as above with identical results. The burning in air had the result of enormously reducing its activity (to about 5×10^{-6} amp.) and it was only by heating it for some hours in high vacuum with a constant application of 200 volts on the anode that its activity was restored to the same order of magnitude that it had originally.

A necessary consequence of our hypothesis is that the electrons leaving the emitting layer must diffuse through the interstices in the oxide coating. This consequence presents no serious difficulties. Indeed, it offers a solution to some of the perplexing problems connected with the behavior of this type of cathode. At best, the electrical resistivity of these oxide coatings is very high even at glowing temperatures. In fact, Dr. C. T. Ulrey of the Research Laboratory of the Westinghouse Lamp Company during the course of some yet unpublished work has not been able to obtain a discontinuity in the space current curve for such filaments when the anode was made to approach the filament until it actually touched the surface. Furthermore, these coatings are very porous. When viewed through a microscope they have the appearance of a light fluffy fall of snow. It seems reasonable to suppose therefore that the escaping electrons may diffuse through this oxide layer which, however, does offer some impedance to their progress. Suppose now that this coating should become more compact so that its pores are partially closed. The natural consequence would be that the apparent activity of the filament would be measurably impaired. This is precisely the type of phenomenon that does occur. It is well known that glowing the filament for a comparatively short interval of time at a considerable overvoltage will practically ruin its emission. It has been the author's experience at least that a filament which has been so mistreated cannot, in general, be reactivated to anything like its original characteristics. It is also true that such filaments will, after such reactivation as is possible, yield large emissions if very high anode voltages are applied. The net result of such an overheating of a filament is essentially to increase the impedance of the tube by an appreciable amount. This we believe to be caused by a partial closing of the pores of the coating. Preliminary microscopic examination of some such filaments actually showed a sintering or glazing of the coating until it had the appearance of a crackled enamel.

Exactly similar behavior is shown by filaments whose activity has gradually decreased during a long period of use. Such worn out filaments always retain an appreciable amount of coating. In fact, a fairly close inspection shows that they still possess nearly as thick a layer of oxide as they had initially. In this case also large emissions may be drawn if sufficiently high anode voltages are applied.

If the loss of activity in these cases were due solely to a loss of metallic barium due to vaporization it should be possible to cause these filaments to regain all their initial activity by electrolysis or by positive ion bombardment. As stated above it is rarely if ever that it is possible to do this.

The process of electron diffusion through a porous, poorly conductive coating may also explain the phenomenon of non-saturation which is commonly met with in this type of cathode. It follows logically that large numbers of electrons will become enmeshed in the pores of the coating or occluded on the surface of the particles of poorly conducting material composing it. It is quite possible also that the numbers of electrons so entrapped will vary somewhat with the anode voltage applied. This process will give rise to an effect similar to a negative space charge within the confines of the coating itself. The space currents obtainable then at any given anode voltage and filament temperature represent the number of electrons per second it is possible to drag out of or through this negative charge built up within the coating layer. The result will be that much higher anode voltages will be required to approach a saturation than if this pseudo space charge did not exist. At temperatures in the neighborhood of 1000°C the electron emission from these filaments is so enormous that it is next to impossible to obtain anything approaching saturation owing to the very considerable heating effects of the emission itself. At these temperatures also the conductivity of the coatings will be increased appreciably affording a better opportunity for the electron charge to leak off.

CONCLUSIONS

In view of the experimental results presented in the foregoing pages, we are forced to accept the fact that the base or core metal does affect appreciably the electron emission from the alkaline earth oxides. This situation in turn demands a modification of existing ideas concerning the mechanism of emission from oxide cathodes.

An hypothesis is offered concerning this mechanism in which:

1. The source of emission is assumed to be a layer of metallic barium (or other alkaline earth metal) occluded on the surface of the base metal or alloyed with it. In this case the constants of the well-known Richardson equation must be characteristic of the composite surface.
2. The electrons emitted from this composite surface must diffuse through the pores of the coating.
3. The coating in turn, as a function of its porosity, offers considerable impedance to the progress of the electrons.

4. The occlusion of electrons on the particles of the coating sets up a pseudo space charge effect which serves to explain the phenomena of non-saturation as well as the fading of emission during short periods of operation.

5. The gradual decay in activity of coated filaments during life is due to a slow sintering of the coating resulting in a closing of its pores and a consequent increase in the impedance offered to the passage of electrons. A similar process occurs if the filament is strongly glowed for a comparatively short interval of time with or without anode voltage.

It is admitted that no crucial tests of this explanation have been offered with the exception of that showing the pronounced influence of the core metal; which, of course, is the effect which makes the above modification in existing ideas necessary. Numerous experimental investigations are now under way in this laboratory which have been designed as tests of the various assumptions made herein. It is hoped that these tests will be far enough along to permit of their publication in this magazine in the near future.

In conclusion, the author wishes to express his gratitude to Dr. C. T. Ulrey of the Westinghouse Lamp Company Research Dept. and to Drs. D. L. Ulrey and N. Rashevsky of this laboratory for their interest and for the helpful suggestions received from them during the progress of this work.

ON THE THEORY OF THE SOLAR CORONA*

BY E. O. HULBURT

NAVAL RESEARCH LABORATORY

(Received April 17, 1930)

ABSTRACT

The outer atmosphere of the sun is assumed to be composed mainly of ions and electrons which are actuated by gravitation, radiation pressure and the magnetic field of the sun. By distillation along the lines of magnetic force the particles collect in the lower latitudes of the solar outer atmosphere and by their diamagnetism reduce the magnetic field approximately to zero in this region, leaving a stray field at the poles. Thus the polar plumes, prominent during sun-spot minima, are regarded as owing their form to the magnetic field of the sun. Whereas the wide spreading structureless coronal luminosity extending out from the lower latitudes is due to an accumulation of ionization which reduces the magnetic field to a low value and permits the radiation to blow the particles out to great distances. During maximum solar activity there is sufficient ionization of the outer atmosphere to reduce the magnetic field to a low value even at the poles, and hence the outer atmospheric spray extends roughly equally in all directions, in accord with the appearance of the corona.

DURING minimum solar activity the corona spreads out from the sun between latitudes about 50° north and south as shown in Fig. 1.¹ In this region the luminosity is mainly structureless, with of course irregularities such as clouds and prominences. The polar plumes are short and well defined. During maximum solar activity the corona extends more or less equally in all directions, as in Fig. 2,² with no marked polar plumes. At times the luminous streams ejected from the active latitudes around 40° give the corona roughly the outline of a square. The material of the corona is considered to be very attenuated, for comets have been observed to pass through it without being damaged.² The coronal particles were found, from Doppler effects, to be moving outward from the sun³ with velocities around 20 km sec^{-1} . In the present paper the assumption is made that the outer atmosphere of the sun is composed of ions and electrons, and it is shown that the particles, due to the influence of gravitation, radiation pressure, and the magnetic field of the sun, form an atmosphere which has approximately the observed shape of the corona.

From measurements of the Zeeman effect of spectrum lines in the chromosphere Hale⁴ has shown that the magnetic field of the sun is similar to that of a uniformly magnetized sphere. The magnetic field around a uniformly

magnetized sphere is drawn in Fig. 3. The magnetic field of the sun was found to decrease along the radius, falling from 55 gauss to less than 10 gauss in a distance of a few hundred kilometers measured radially outward.⁴ Gunn⁵ explained the radial degradation of the magnetic field by means of the diamagnetism of the long free path ions and electrons in the chromosphere; various drift currents may add to or subtract from the diamagnetic effect but perhaps not to a great extent.

Fig. 3. Magnetic field of a uniformly magnetized sphere.

If a region contains γ long free path ions or electrons per cm^3 and if H is the impressed magnetic field in the region, the ions and electrons by their diamagnetism cause a reduction in H . The condition that H be reduced to a small value is expressed by⁵

$$\gamma \geq H^2/4\pi kT, \quad (1)$$

where T is the absolute temperature of the ions and k is the Boltzmann constant 1.371×10^{-16} erg deg⁻¹. Although accurate enough for the present discussion (1) is an approximation, for it neglects the possible warping of the field H by the diamagnetic cloud.

In order for diamagnetism to exist we must have

$$\gamma \geq \rho, \quad (2)$$

where γ is the free path of the ion and ρ is the radius of gyration of the ion about H . Assuming that all the particles are ions of mass m , diameter $\sigma = 3 \times 10^{-8}$ cm and velocity v ,

$$\rho = mv/He, \quad (3)$$

⁵ Gunn, Phys. Rev. 33, 614 (1929), 35, 635 (1930).

and

$$\gamma = 1/(2)^{1/2} \pi y \sigma^2. \quad (4)$$

From (1) with T of order 10^4 °K and with H of order 10^{-3} , 10^{-4} and 10^{-5} gauss at various regions of the corona y can not be greater than 10^6 , 10^4 and 10^2 , respectively. From (2) it follows that the ions can not reduce the field to zero, for if H is very small ρ from (3) is so large that (2) is not satisfied. For example, with m of order 10^{-23} grams and v of order 10^5 cm sec $^{-1}$ H can not be reduced by the diamagnetism of the ions to less than 10^{-7} , 10^{-9} and 10^{-11} gauss for $y = 10^6$, 10^4 and 10^2 , respectively. However, this slight remnant of the magnetic field is of no interest here, for it does not influence the motion of the coronal ions appreciably.

It is assumed that the outer regions of the chromosphere are composed mainly of ions and electrons, each cm 3 containing approximately an equal number of positively and negatively charged particles, and that the particles are forced outward by radiation pressure with velocities around 20 km sec $^{-1}$. A mechanism of radiation pressure has been discussed by Milne⁶ and need not be described here. The diamagnetism of the ions reduces the solar magnetic field to small values in the outer chromosphere. Let us suppose that the magnetic field outside of the chromosphere were that of a uniformly magnetized sphere, as Fig. 3, with a value of, say, 1 gauss at chromospheric levels at the equator. The positive and negative ions and electrons, forced out by radiation pressure, follow along the lines of magnetic force in tight spirals; with $m = 10^{-23}$ grams, $v = 2 \times 10^6$ cm sec $^{-1}$ and $H = 1$ gauss ρ from (3) is 12.6 meters, which is very small compared to distances in the corona. In general, wherever the magnetic field is more or less normal to the radiation pressure the ions accumulate sufficiently to break down the field. Thus the charged particles ejected between the latitudes 50° north and south are constrained to move in the space between the 50° magnetic line, Fig. 3, and the sun. They accumulate in this space until by their diamagnetic action they reduce the magnetic field to very small value, practically to zero. From (1) with T of order 10^4 °K and $H = 1$ gauss y is 10^{11} . Therefore, when y reaches 10^{11} the guiding action of H is destroyed. The ions thereupon steam out from the sun in the lower latitudes to form a structureless luminosity similar to that of Fig. 1.

In polar latitudes the lines of magnetic force are nearly parallel to the force of radiation pressure. The ions slide out along the lines of force without hindrance and large ion densities in the polar regions of the corona are not built up. Therefore the corona in the polar zones does not extend to such great distances from the sun as it does in the lower latitudes. The polar magnetic field is not destroyed; it guides and is outlined by the flying ions. Thus the short polar coronal plumes are formed, as are observed during solar quiescence, Fig. 1. During maximum solar activity we may suppose that sufficient numbers of ions are ejected to wipe out the magnetic field in the coronal regions at all latitudes, thereby permitting the coronal ions to move out more or less uniformly in all directions, as in Fig. 2.

⁶ Milne, Monthly Notices, Roy. Ast. Soc. **87**, 697 (1926-27).

The solar latitudes around 40° are the regions of greatest activity, the eruptions being in general more frequent there than in other areas of the solar surface. It is possible that enough ions may be emitted to reduce H to zero above the 40° line, Fig. 3, and yet because of a less rapid supply of ions in latitudes below 40° , H may be appreciable in the lower latitudes within the coronal regions bounded by the 40° line. Thus the present view is not incompatible with Deslandres' hypothesis⁷ that H is of the order 10^{-7} gauss. The hypothesis was advanced to explain the curvature of certain solar protuberances, on the idea that the material of the eruption carried an excess charge, either positive or negative, and therefore in its progress across the magnetic field would move in a curved path. The hypothesis may, however, not be necessary, for in certain cases, at least, asymmetrical radiation pressure, as suggested by Pike,⁸ may cause the curvature of the prominences. The curious twining and curvature occasionally observed in the long coronal streamers and filaments may be evidence of remnants of the distorted magnetic field.

The total brightness of the corona is about 10^{-6} of that of the sun, and the luminosity falls off roughly with the inverse fourth to sixth power of the distance from the center of the sun². The ions and electrons of the coronal atmosphere are pushed out from the chromosphere by radiation pressure, the pressure acting mainly on the ions which, by their electrostatic attraction, drag the electrons along with them. The ions absorb the sunlight, thereby being subjected to radiation pressure, and reemit a portion of the absorbed energy as coronal light. The radiation pressure acceleration⁹ p is given by

$$p = I\beta/mc, \quad (5)$$

where I is the energy flux of the sunlight which is absorbed by the ion with ionic absorption coefficient β , m is the mass of the ion and c is the velocity of light. If a fraction f of the absorbed energy is reemitted as coronal radiation I_c , then

$$I_c = f\beta I\gamma_c, \quad (6)$$

where γ_c is the total number of ions in the corona.

The total energy flux in all wave-lengths from the solar surface is 6.2×10^{10} erg cm^{-2} sec^{-1} . Assuming that 10^{-3} of this, corresponding to the energy in the ultraviolet region from about 1500 to 1800A, is absorbed by ions of mass $m = 10^{-23}$ grams and absorption coefficient $\beta = 5 \times 10^{-16}$, I is 6.2×10^7 and p from (5) is 10^4 cm sec^{-2} . This is somewhat greater than the solar gravitational attraction acceleration 2.75×10^4 cm sec^{-2} , which is as it should be if the coronal ions are forced out from the sun by radiation pressure. If the ion density y is 10^6 ions cm^{-3} in the outer chromosphere and falls off with the inverse fifth power of the distance from the center of the sun, γ_c is about 10^{40} ions. With these values and with $f = 10^{-5}$ in (6) I_c is 3×10^{27} erg sec^{-1} . The total

⁷ Deslandres, *Comptes Rendus* 189, 413 (1929).

⁸ Pike, *Monthly Notices, Roy. Ast. Soc.* 88, 3 (1927).

⁹ Cf. Hulburt, *Phys. Rev.* 35, 1098 (1930), section 8.

radiation I_s emitted by the sun amounts to 3.7×10^{33} erg sec⁻¹. Thus the coronal energy I_c is 10^{-6} of I_s in accord with observation.

Equations (5) and (6) are valid no matter what processes of light absorption and emission are assumed, i. e. whether the processes are those of fluorescence, Raman radiation, resonance scattering,¹⁰ etc. On the other hand, Anderson's¹¹ very startling theory of the corona makes quite a different set of hypotheses and therefore uses equations different from (5) and (6). The theory assumes that positive electricity is continually annihilated in the sun leaving the sun negatively charged, that the excess negative electrons are driven out mainly by electrostatic forces to form a pure electron atmosphere around the sun and that the coronal light is the solar radiation scattered from this atmosphere. As far as can be seen the considerations advanced in the foregoing paragraphs in explanation of the geometrical form of the corona will hold equally well on Anderson's theory as on a radiation pressure theory. Probably a final decision about the constitution of the coronal atmosphere can not be reached as long as the origin of the lines in the spectrum of the corona remains unknown.

In conclusion the present paper can hardly be regarded as offering a quantitative theory of the corona. It presents a few quantitative ideas about the processes which may be important in the corona and thus furnishes a framework on which to build a quantitative theory. To work out the ideas in more exact detail promises to be a difficult problem, entirely apart from the fact that the development will have to deal as best it can with many unknown quantities and uncertainties of assumption.

DISTRIBUTION OF NON-REACTING FLUIDS IN THE GRAVITATIONAL FIELD

BY MORRIS MUSKAT

RESEARCH DEPARTMENT, THE GULF COMPANIES

(Received March 28, 1930)

ABSTRACT

The paper consists essentially of an analysis of the equations given by Lewis and Randall for the distribution of non-reacting ideal fluids in a gravitational field. When the fluids are incompressible a formal solution is obtained, for a mixture of any number of constituents. But it has not been possible to put it into a form convenient for numerical application. The ratios of the concentrations of any constituent at the top to that at the bottom of a vertical column of the mixture are given explicitly, both for incompressible and compressible fluids. When all the molar volumes of the various fluids are equal the equations are solved completely and lead to a *relative* barometric distribution, and in the particular case of ideal gases, to individual barometric distributions. The physical meaning of this is briefly discussed. The case of binary mixtures is treated in detail, and numerical examples are given, first for a mixture of two paraffins, and secondly for a dilute solution of NaCl in water which is equivalent to an ideal solution of liquids. As is to be expected, the effect is extremely small, and in the first case only one tenth as large as is given by a simple barometric formula.

I. INTRODUCTION

ALTHOUGH we might predict, *a priori*, that the effect of gravity in causing a variation with height in the composition of a mixture of non-reacting fluids is but a slight one, it is of interest to have explicit theoretical expressions for this effect. As yet, this has not been attained in the general case of a mixture of any number of constituents: however, the problem of a binary mixture of two ideal fluids has been completely solved and some results of interest have been obtained for the general case. These results and the general problem will be discussed in the following.

Gouy and Chaperon¹ first, and later Duhem² and van der Waals³ considered binary mixtures thermodynamically, but they do not present explicit formulae for the results. Even earlier, however, Gibbs⁴ derived the general conditions of equilibrium for a mixture of any number of fluids, but he applied them only to the ideal gas mixture. The conditions of Gibbs are:

- (a) The temperature, T , be uniform throughout the mixture;
- (b) $\mu_i + gz = \text{constant}$ (1)

where μ_i is the intrinsic potential of the i^{th} constituent, and z is the height above a fixed horizontal plane.

- (c) $d\phi = -g\rho dz$ (2)

where $p = p(z)$ is the pressure at z , and $\rho = \rho(z)$ is the density of the mixture at z .

II. THE DIFFERENTIAL EQUATIONS FOR THE EFFECT

The general differential equations for the effect were then set up by Lewis and Randall.⁵ Their method is the following:

Considering any constituent separately, the i^{th} for example, the second law of thermodynamics requires that under equilibrium conditions throughout the mixture

$$dF_i = \frac{\partial F_i}{\partial z} dz + \frac{\partial F_i}{\partial p} dp + \frac{\partial F_i}{\partial \bar{n}_i} d\bar{n}_i + \sum_j \frac{\partial F_i}{\partial \bar{n}_j} d\bar{n}_j = 0, \quad (3)$$

where $F_i = F_i(p, z, T, \bar{n}_i, \bar{n}_j)$ is the partial molal free energy of this constituent and $\bar{n}_i = \bar{n}_i(z)$ is its mol fraction. This is obviously equivalent to Gibb's condition (1).

Clearly, if w_i is the i^{th} molar mass,

$$\frac{\partial F_i}{\partial z} = w_i g, \quad (4)$$

and by the second law of thermodynamics,

$$\frac{\partial F_i}{\partial p} = \bar{V}_i \quad (5)$$

where $\bar{V}_i = \bar{V}_i(p)$ is the partial molal volume for the i^{th} constituent.

Now for ideal solutions, to which the present considerations will be restricted, \bar{V}_i is by definition equal to the i^{th} molar volume, V_i , at the pressure p and temperature T . This is a consequence of the criterion that an ideal solution must obey the law of additivity of volumes. Also, in this case,

$$\frac{\partial F_i}{\partial \bar{n}_j} = 0, \quad j \neq i \quad \frac{\partial F_i}{\partial \bar{n}_i} = \frac{RT}{\bar{n}_i} \quad (6)$$

where R is the gas constant, per mol. Combining (2), (4), (5) and (6) with (3):

$$\frac{d\bar{n}_i}{dz} = \frac{\bar{n}_i g}{RT} [\rho v_i - w_i] \quad i = 1, 2, \dots, r \quad (7)$$

if there are r constituents. This is the final form given by Lewis and Randall.

To get the explicit solution to the problem under consideration, the system of simultaneous equations (7) must be integrated, since the composition is essentially given by the \bar{n}_i . In principle, (7) would be immediately integrable in the case of incompressible fluids, except for the term $\rho = \rho(z)$ which must be determined from the equations together with the \bar{n}_i . This difficulty is not serious in itself, since $\rho(z)$ may be expressed in terms of the \bar{n}_i , and in this way eliminated; for, by definition,

$$\rho = \sum_i w_i \bar{n}_i \quad (8)$$

⁵ Lewis and Randall, Thermodynamics, p. 242.

where n_j is the number of mols of the j^{th} constituent per cc of mixture. Also, the definition of the ideal mixtures implies that

$$\sum_i v_j n_j = 1. \quad (9)$$

Hence

$$\rho = \frac{\sum_i w_j n_j}{\sum_i v_j n_j} = \frac{\sum_i w_j \bar{n}_j}{\sum_i v_j \bar{n}_j}. \quad (10)$$

Alternatively, (10) may be derived from the equations (7) themselves: by adding the equations (7) and noting that by definition

$$\sum_i \bar{n}_j = 1 \quad (11)$$

$$\sum_i \frac{d\bar{n}_j}{dz} = \frac{d}{dz} \sum_i \bar{n}_j = 0 = \frac{g}{RT} \left[\rho \sum_i v_j \bar{n}_j - \sum_i w_j \bar{n}_j \right]$$

which is identical with (10).

Putting (10) into (7), the latter becomes a system of non-linear coupled equations:

$$\frac{d\bar{n}_i}{dz} \sum_j v_j \bar{n}_j = k \bar{n}_i \sum_j \bar{n}_j (v_i w_j - v_j w_i) \quad (12)$$

where $k = g/RT$; $\rho_i = w_i/v_i$.

III. INTEGRATION OF THE EQUATIONS

The general system (12) has not been integrated completely, except in the case of a binary mixture. However, when all the v_i are equal, (12) or (7) can be solved exactly for a mixture containing any number of constituents.

Returning to (7), its integral is, clearly:

$$\bar{n}_i = c_i e^{-k w_i z + k \int v_i \rho dz} \quad (13)$$

and hence

$$\frac{\bar{n}_i}{\bar{n}_j} = \frac{n_i}{n_j} = \frac{c_i}{c_j} e^{kz(w_j - w_i) + k \int \rho (v_i - v_j) dz}. \quad (14)$$

However, as $\rho(z)$ is unknown until the \bar{n}_i themselves are known, (13) or (14) do not give the solution to the problem in a form which can be applied to any specific case. If the v_i are taken to be constant, ρ can be eliminated from (12), giving

$$\frac{(\bar{n}_i)^{1/v_i}}{(\bar{n}_j)^{1/v_j}} = \frac{(c_i)^{1/v_i}}{(c_j)^{1/v_j}} e^{kz(\rho_j - \rho_i)}. \quad (15)$$

But, although there is yet the relation (11) to be imposed on the \bar{n}_i , the system (15) cannot in general be solved for the \bar{n}_i .

On the other hand, for the special case where

$$v_i = v_j = \dots = v, \text{ for all values of } z, \quad (16)$$

(14) gives

$$\frac{\bar{n}_i}{\bar{n}_j} = \frac{n_i}{n_j} = \frac{c_i}{c_j} e^{kz(w_j - w_i)}. \quad (17)$$

This equation clearly implies that

$$\bar{n}_i = c_i e^{-kzw_i + \phi(z)}, \quad (18)$$

$$n_i = c_i e^{-kzw_i + \psi(z)}. \quad (19)$$

Applying (11) to (18)

$$\bar{n}_i = \frac{c_i e^{-kzw_i}}{\sum_j c_j e^{-kzw_j}} \quad (20)$$

and applying (9) to (19)

$$n_i = \frac{c_i e^{-kzw_i}}{v \sum_j c_j e^{-kzw_j}}. \quad (21)$$

From (2), (8), and (21) it now follows that

$$\int v dp = RT \log \sum_j c_j e^{-kzw_j}. \quad (22)$$

If v is known as a function of p , (22) will give p , and hence v as a function of z . This, when put into (21), gives n_i explicitly as a function of z . The constants c_i may then be determined, in principle, by applying the conditions that:

$$\int_0^h n_i dz = N_i \quad (23)$$

where z is measured from the bottom of the vessel containing the mixture and h is the height of the free surface above $z=0$; N_i is the total number of mols of the i th constituent in the mixture.

If v is not a function of p , (21) itself gives the final solution to the problem, after the determination of the c_i by (23).

It may seem that (16) is a very strong restriction upon the mixture constituents. Nevertheless, the important case where these constituents are perfect gases satisfies (16). For the molar volume is the same for all perfect gases at a given temperature and pressure, and they obviously form "ideal mixtures." In fact, for perfect gases

$$v_i = v_j = \dots = v = \frac{RT}{p}. \quad (24)$$

When this is put in (22), it gives

$$p = \text{const.} \sum_j c_j e^{-kzw_j}. \quad (25)$$

Thus, by applying again (24), (21) becomes:

$$n_i = n_0 e^{-kzw_i}. \quad (26)$$

This is the ordinary barometric formula derived quite differently by Gibbs, though usually tacitly assumed without explicit justification. Here, it results from a very special case of the general equations.

In addition to the case of perfect gases, (16) would be satisfied by a set of non-reacting liquids whose molar volumes happen to be the same, or nearly the same, since the liquids may be taken as incompressible. (21) is the complete solution under these circumstances.

Finally, the fact that we get the barometric formula (17) under the assumption that all the v_i are equal, whereas, when this assumption is not made the distribution law is quite different, is of added interest in that it suggests the physical basis of the effect under consideration. If we mix a number of substances whose molecules interact in no way with each other, it is clear that a barometric distribution of the type given by (17) will result, since before mixing each had a barometric distribution. Hence, variations from barometric distributions must be related to the interactions between the molecules. For the present purposes, we may consider a molecule and its field of force to be characterized by its "effective volume," i.e., the volume per molecule in the ensemble, and we note that the assumption of ideal mixtures means that, on mixing at constant pressure and temperature, these effective volumes are not changed.

If, then, to a homogeneous substance is added another with molecules of the same effective volumes, it is apparent that to the original molecular type the added ones will be indistinguishable, in the matters of collisions and perturbing forces, from molecules of their own kind, and vice versa. The effect will be essentially that of increasing the total number of molecules of either kind. Thus, we should expect the *relative* distribution to be barometric, as it was before mixing. Only for ideal gases will the individual distributions be barometric, but the relative distributions in all such cases will be of the type given by (17).

On the other hand, when the effective volumes of the added molecules are different from that of the original kind, the added molecules will exert different forces upon those originally present from those which the latter exert between themselves. Under these circumstances, we cannot expect even the relative distributions to remain as they were before mixing. Hence, in this general case we may get a distribution quite different from that given by (17). In fact, for the example given below of a binary mixture in which the effective volumes differ by a factor of about 2, we find that the distributions given by (15) and that given by a barometric formula may differ by a factor of 10.

Thus, in this qualitative way we can understand the physical basis for the analytical simplicity involved in the assumption of equal molecular volumes for all the molecular species.

Before discussing in detail the binary liquid mixture, it may be of interest to examine (15) further. If (15) be written as

$$\frac{(\bar{n}_1)^{1/v_1}}{(\bar{n}_i)^{1/v_i}} = c_j e^{kz(\rho_j - \rho_1)} \quad c_1 = 1 \quad (15')$$

and if $s \equiv (\bar{n}_1)^{1/v_1}$, then

$$\frac{s^{v_j}}{\bar{n}_j} = c_j^{v_j} e^{kz v_j (\rho_j - \rho_1)}$$

and

$$\bar{n}_j = 1 - \bar{n}_1 - \sum_l \bar{n}_l = 1 - s^{v_1} - \sum_l \frac{s^{v_l}}{c_l^{v_l} e^{kz v_l (\rho_l - \rho_1)}}$$

so that

$$\sum_j \frac{s^{v_j}}{c_j^{v_j} e^{kz v_j (\rho_j - \rho_1)}} = 1 \quad (27)$$

This is an equation for s as a function of z . Provided the c_j were known, it could be readily solved numerically for any value of z . But as the c_j are implicitly determined by (23), it is very difficult to express them directly in terms of the N_i . However, if, in the particular problem under consideration, the object is to study the variation in composition from an assumed composition at a given height, (27) will suffice. As

$$c_j = \frac{[\bar{n}_1(h)]^{1/v_1}}{[\bar{n}_j(h)]^{1/v_j}} e^{-kh(\rho_j - \rho_1)}, \quad (28)$$

the composition assumed at the height h , will give the c_j , and (27) will then give the composition at any other height.

Finally, it should be pointed out that, both for incompressible and compressible fluids, the ratio of the concentrations f_i , defined as the mol-fraction, of any constituent at the top to that at the bottom of the vessel containing the mixture, can be found in the general case. Considering first the incompressible fluids, if h be the height of the vessel and M the total mass of the mixture for the volume of unit section of height h , then (13) taken between the limits 0, h , gives

$$\frac{\bar{n}_i(h)}{\bar{n}_i(0)} = \frac{f_i(h)}{f_i(0)} = e^{-kw_i h + kv_i M} \equiv A_i. \quad (29)$$

If an average density be defined by $\bar{\rho} = M/h$, then

$$\frac{f_i(h)}{f_i(0)} = A_i = e^{kv_i h (\bar{\rho} - \rho_i)}. \quad (30)$$

Thus, if $\rho_i < \bar{\rho}$, the composition of the i th constituent at the top is greater than that at the bottom and, conversely, if $\rho_i > \bar{\rho}$. This of course, would be expected.

If the fluids are compressible, we may consider their molar volumes, v_i , to be given as a function of the pressure. In this case, applying (2) to (13), we get

$$\bar{n}_i = c_i e^{-kz w_i - k/a \int v_i(p) dp}. \quad (13')$$

We may consider $\int v_i(p) dp = b_i(p)$ as known. Then, taking (13') between the limits 0 and h , we get:

$$\frac{\bar{n}_i(h)}{\bar{n}_i(0)} = \frac{f_i(h)}{f_i(0)} = e^{-k w_i h - k/g [b_i(p_0) - b_i(p_0 + M_0)]} f(h) \equiv f_0. \quad (30a)$$

For any particular case, the expressions for $b_i(p)$ may be put into (30a) and the actual ratios of the concentrations may then be determined numerically.

IV. THE BINARY MIXTURE

We shall first treat the binary mixtures of incompressible fluids. In this case, (15) does permit of an explicit solution. Letting

$$\left. \begin{aligned} t &= \frac{\bar{n}_1}{\bar{n}_2} = \frac{n_1}{n_2} \\ \bar{n}_1 &= \frac{t}{1+t}; \quad \bar{n}_2 = \frac{1}{1+t} \end{aligned} \right\} \quad (31)$$

then

Hence, by (15)

$$\frac{1}{v_1} \log t + \left(\frac{1}{v_2} - \frac{1}{v_1} \right) \log (1+t) = \text{const} + k z (\rho_2 - \rho_1). \quad (32)$$

Now from (29) and (11)

$$A_1 \bar{n}_1(0) + A_2 \bar{n}_2(0) = 1$$

which, combined again with (11), gives

$$\left. \begin{aligned} t(0) &= \frac{1 - A_2}{A_1 - 1} \equiv t_0 \\ \bar{n}_1(0) &= \frac{1 - A_2}{A_1 - A_2}; \quad \bar{n}_2(0) = \frac{A_1 - 1}{A_1 - A_2} \end{aligned} \right\} \quad (33)$$

so that

$$\frac{1}{v_1} \log \frac{t}{t_0} + \left(\frac{1}{v_2} - \frac{1}{v_1} \right) \log \frac{1+t}{1+t_0} = k z (\rho_2 - \rho_1). \quad (34)$$

As t_0 is known, (34) gives explicitly the variations of the composition t with z . The density of the mixture is then

$$\rho = \frac{w_1 t + w_2}{v_1 t + v_2}. \quad (35)$$

The actual magnitude of the effect may be more directly inferred from the extreme values of the concentrations $\bar{n}_1(0)$ and $\bar{n}_2(0)$, given by (33) and (29), or by the extreme values of the density. These latter are easily found to be by (35), (33), and (29)

$$\left. \begin{aligned} \rho(0) &= \frac{w_1 - w_2 + w_2 A_1 - w_1 A_2}{v_1 - v_2 + v_2 A_1 - v_1 A_2} \\ \rho(h) &= \frac{A_1 A_2 (w_2 - w_1) + A_1 w_1 - A_2 w_2}{A_1 A_2 (v_2 - v_1) + A_1 v_1 - A_2 v_2} \end{aligned} \right\} \quad (36)$$

Referring to (23), we let $N_1/N_2 = c$, and noting that $N_1 w_1 + N_2 w_2 = M$, $N_1 v_1 + N_2 v_2 = h$, A_1 and A_2 take the values

$$A_1 = e^{k v_1 v_2 (\rho_2 - \rho_1) h / v_1 c + v_2}; \quad A_2 = A_1^{-c}. \quad (37)$$

Thus, $\rho(0)$ and $\rho(h)$ can be expressed directly in terms of c and h . For comparison with these formulae, we may note the expression for the composition which would be given by a barometric distribution. This latter is

$$t^1 = \frac{n_1}{n_2} = \frac{N_1 w_1 (1 - e^{-k w_2 h})}{N_2 w_2 (1 - e^{-k w_1 h})} e^{k (w_2 - w_1) z}. \quad (38)$$

We see that here the molar volumes V do not enter at all. Yet, this is in complete agreement with our physical picture of the phenomenon, according to which a barometric distribution implies that all the molar volumes are equal and hence do not explicitly affect the distribution. The fact that c does not enter in the expressions as $\rho(h)/\rho(0)$ is simply a corollary of the same reasoning.

The forms of (36) and (37) indicate that the effects of gravity, which we have been considering, should be entirely beyond experimental observations for any reasonable values of h . The following computation will give an example of the actual magnitude of the effect. We consider a mixture of two members of the paraffin series, heptane and octodecane, mixtures of which are very nearly "ideal." Let the temperature be 293°K. The data are

$$\begin{aligned} w_1(\text{heptane}) &= 100.12; \quad \rho_1 = 0.684; & v_1 &= 146.374 \\ w_2(\text{octodecane}) &= 254.30; \quad \rho_2 = 0.777; & v_2 &= 327.284 \end{aligned}$$

Let $c=1$. The computation gives for

$$\begin{aligned} h=100 \text{ meters: } \rho(0) &= 0.74834 \\ &\rho(h) = 0.74818 \\ h=1000 \text{ meters: } \rho(0) &= 0.74901 \\ &\rho(h) = 0.74750. \end{aligned}$$

The composition variation according to (34) is plotted in Fig. 1 and, for comparison, is added the composition curve which would be given by the barometric formula (38).

It is of interest to observe that, for this case at least, the incorrect barometric formula would indicate a rather appreciable variation of composition, whereas the equation (34) gives a quite negligible variation.

As a final example, it may be mentioned that, since a dilute solution is equivalent to an "ideal" mixture, the present formulae may be applied to such a case as a dilute solution of NaCl in water. Thus, if $c = 100$, $T = 300^\circ\text{K}$.

FIG. 1.

$$w_2(\text{NaCl}) = 58.457; \quad \rho_2 = 2.17; \quad v_2 = 26.939$$

$$w_1(\text{H}_2\text{O}) = 18.016; \quad \rho_1 = 1.00; \quad v_1 = 18.016$$

the extreme values for $\rho(0)$ and $\rho(h)$ are, for a depth of 1000 meters,

$$\rho(0) = 1.01809$$

$$\rho(h) = 1.01571$$

again with a difference clearly insignificant.

Hence, it may be generally concluded that, except at very low temperatures or on a planet or star with a considerably higher gravitational constant, gravity cannot produce any appreciable variation with depth in the composition of a fluid mixture. It is possible, however, that in a centrifuge *effective* gravity constants may be obtained such as to make the effect observable.*

Finally, we shall outline the method of treating binary mixtures of compressible fluids. We note that equation (13') implicitly gives the distribution function, in the general case, except for the constants c_i . For the binary case, these constants may be determined as follows:

We know that at $z=0$, $p = Mg + p_0$ where M is the total mass of the liquid in the column of height, h , and unit cross section; also, at $z=h$, $p = p_0$. We therefore have

* This possibility was kindly suggested to us by Dr. A. G. Loomis of this laboratory.

$$\left. \begin{aligned} \bar{n}_1(0) &= c_1 e^{-k/gb_1(Mg+p_0)}; & \bar{n}_2(0) &= c_2 e^{-k/gb_2(Mg+p_0)} \\ \bar{n}_1(h) &= c_1 e^{-k[b_1(p_0)/g+w_1h]}; & \bar{n}_2(h) &= c_2 e^{-k[b_2(p_0)/g+w_2h]}. \end{aligned} \right\} \quad (39)$$

As $\bar{n}_1(0) + \bar{n}_2(0) = 1$ and $\bar{n}_1(h) + \bar{n}_2(h) = 1$, c_1 and c_2 can be expressed directly in terms of the known constants of the mixture, if we put into the above expressions the proper forms of the functions $b_1(p)$ and $b_2(p)$.

We next determine the pressure, p , by the relation;

$$c_1 e^{-w_1 z + b_1(p)} + c_2 e^{-w_2 z + b_2(p)} = 1. \quad (40)$$

When it is difficult to obtain an algebraic solution of this equation, for $p = p(z)$, a graphical solution will always be possible. When $p(z)$ is known, it may be put back into (13'), and we shall then have the desired solution to the problem, namely, the mol-fractions \bar{n}_i as a function of z . The individual molar concentrations, n_i , are then given by the general relation, already used in Eq. (20):

$$n_i = \frac{\bar{n}_i}{\sum_j \bar{n}_j v_j}. \quad (41)$$

With the aid of these formulae, $\bar{n}_i(z)$ and $n_i(z)$ may be determined for any particular case of a binary mixture of compressible fluids. Of course, the mixture of incompressible fluids is a special case of these, but the previous development has been given as it illustrates more clearly the general problem of the incompressible fluids.

The writer is indebted to Dr. P. D. Foote and Mr. W. O. Smith for suggesting this problem and to Drs. A. E. Ruark and L. Shereshefskey for the opportunity of discussing the problem with them.

THE RECOMBINATION OF IONS IN AIR AND OXYGEN
IN RELATION TO THE NATURE OF GASEOUS IONS

BY OVERTON LUHR

PHYSICAL LABORATORY, UNIVERSITY OF CALIFORNIA

(Received April 14, 1930)

ABSTRACT

Coefficient of recombination of ions produced by x-rays as a function of the age and initial concentration of the ions. Measurement of the coefficient of recombination of ions in air and oxygen has been continued, with an improved form of the apparatus previously described by L. C. Marshall. Marshall's results in air have been checked, showing a sharp initial drop in the coefficient α for short time intervals ascribed to initial non-random distribution of the ions. Further measurements at longer time intervals have been made, using a new system of calculation whereby α is found as a function of τ , the age of the ions, rather than t , the total time of recombination. In this case α does not drop to a constant value of about 0.8 to 0.9×10^{-6} as indicated by Marshall's results, but continues to drop off to values of 0.5 to 0.6×10^{-6} after the ions have aged for one second, and 0.3 to 0.4×10^{-6} after two seconds. This is for a high initial concentration of ions of about 3.5×10^8 ions per cm^3 . With an initial concentration of 1.55×10^8 ions per cm^3 , α drops only to 1.15×10^{-6} after a time of one second. In pure oxygen the values of α are in general higher than the corresponding ones for air, although they become equal at low initial concentrations.

Interpretation of results and the absolute value of the coefficient in air. The results may be explained by assuming that heavy slow-moving ions are formed in increasing amounts as time goes on by reaction with impurities present. The faster ions are constantly being removed at a high rate by recombination, leaving the slow ions behind with a resulting increasingly low coefficient of recombination. It is possible that the ionizing agent produces nitric oxides, O_3 or H_2O_2 , which load up the ions. It is impossible to set accurately an absolute value of α in air, due to two disturbing factors: initial non-random distribution producing abnormally high values of α at short time intervals, and the loading up of the ions with impurities producing abnormally low values of α at long time intervals. At a time where these two factors have a minimum effect α has the value $1.4 \pm 0.1 \times 10^{-6}$, which is set as the closest approximation to an absolute value.

INTRODUCTION

RECENTLY in this laboratory L. C. Marshall¹ measured the coefficient of recombination of ions in air and argon using a new direct method with x-rays as a source of ionization. His results showed that the coefficient α given by the equation $dn/dt = -\alpha n^2$ is not a constant as has generally been supposed with a value about 1.6×10^{-6} for air but is a function of three factors: (1) the time of x-ray exposure t' ; (2) the initial ion concentration n_0 ; (3) the time of recombination t . He found that α dropped from a value of 4.0×10^{-6} at short times of recombination to an apparent nearly constant value of about 0.8 or 0.9×10^{-6} at time intervals of about one second. Also, the value of α was in general higher for short times of x-ray exposure and small

¹ L. C. Marshall, Phys. Rev. **34**, 618 (1929).

initial concentrations of ions. The high values at short time intervals were shown by experiment and also by the theory of Loeb and Marshall^{2,3} to be due to the initial non-random distribution of the ions which results from their formation in pairs along a β -ray track. The theory indicates that after a time interval of about 2.25×10^{-8} seconds, the value of α should become constant since by that time the ions would attain random distribution due to their heat motions.

The work has been continued by the writer in air and oxygen with essentially the same apparatus as that used by Marshall, although with important improvements in some details and particularly using a new method of measurement and calculation. These results show that the value of α does not become constant after a short time as indicated by Marshall's results but continues to fall off quite rapidly as the ions become older. This leads to important conclusions concerning the nature of gaseous ions.

Fig. 1. Diagram of apparatus.

METHOD OF MEASUREMENT

The apparatus and system of measurement has previously been described by Marshall.¹ The essential features are shown in Fig. 1. D.C. potential is applied to the Coolidge x-ray tube by means of a transformer, kenotrons and filter system not shown in the diagram. The x-rays pass through a solid brass rotating disk which has a variable sector from 0° to 90° cut in it, thus producing a flash in the metal ionization chamber. The beam of x-rays is defined by three lead slits and passes through almost two meters of air and an aluminum window before reaching the chamber. The beam is thus sharply defined and nearly homogeneous. The shaft carrying the sector also carries an adjustable commutator by which potentials of 1000 to 10,000 volts may

² L. B. Loeb and L. C. Marshall, Jour. Franklin Inst. 207, 371 (1929).

³ L. B. Loeb, Trans. Am. Electrochem Soc. LV, 131 (1929).

be applied to the lower plate of the chamber. The high field almost instantly sweeps all the ions of one sign to the upper plate at any desired time after the x-ray beam has been cut off by the brass disk. The lower plate is also connected to ground through a one-half megohm resistance so that its potential becomes zero immediately after the brush breaks contact with the commutator segment.

Since the upper plate must also be kept at zero potential during the flash time and time of recombination, a neutralizing mechanism is used to prevent a charge from building up on the plate and electrometer system as a result of the repeated flashes of x-rays. For this the alternate system described by Marshall is used. A current of opposite sign to that collected on the upper plate of the chamber is forced through the high resistance leak R by means of a voltage applied from a potentiometer. Thus, when the electrometer deflection is zero, the two currents are neutralizing each other and the voltage

Fig. 2. Ionization chamber.

read directly from the potentiometer will be proportional to the ionic current.

It may be noted that difficulty was encountered in constructing a high resistance leak of the order of 10^{10} ohms which would remain constant over a period of several hours. Experiment showed that an India ink line drawn on typing paper and enclosed in an airtight vessel containing a small amount of P_2O_5 to remove the moisture, was satisfactory. Such a leak exhibits no polarization and stays constant well within 0.5 percent.

The only major change made in the apparatus used by Marshall was the substitution of a new ionization chamber allowing much greater volume of ionization (See Fig. 2). It consists of rectangular brass plates in a heavy brass box fitted with aluminum windows through which the x-ray beam passes. An important feature of the chamber is the plate glass cover to which the upper plate and guard ring are attached by means of amber insulators. The cover is sealed on by means of stopcock grease, a double seal with a groove between being employed to prevent the diffusion of stopcock grease vapor

into the chamber. The stopcock grease is employed only in the outer seal, all excess grease being forced either outside or into the groove. The total volume of ionization is 1520 cm³ compared to 63 cm³ in Marshall's apparatus. The advantages of this large volume are: (1) the ionic currents are much larger and can be measured more accurately; (2) the volume can be determined more accurately and diffusion plays a smaller though still appreciable role. In this connection it may be noted that the x-ray beam extends well beyond the sides of the plates; so that only diffusion toward the plates must be considered; not that toward the sides or ends.

The air and oxygen used in the ionization chamber were purified according to standard technique, all dust, moisture, CO₂ and organic vapors being removed by passage through glass wool, CaCl₂, sodium calcium hydrate, P₂O₅, and two liquid air traps. Special care was taken to remove organic substances by cleaning the metal chamber thoroughly with cleaning solution.

In calculating α the integrated form of the well-known equation,

$$\frac{dn}{dt} = -\alpha n^2 \quad (1)$$

is used, where n is the number of ions of either sign per cm³. Integration gives:

$$\alpha = \frac{1}{t} \left(\frac{1}{n} - \frac{1}{n_0} \right) \quad (2)$$

where t is the time of recombination, n_0 is the number of ions per cm³ at $t=0$ and n is the number of ions left after time t . Inserting the experimental constants Eq. (2) becomes:

$$\alpha = \frac{1.59 \times 10^{-19} RNV}{\epsilon} \frac{1}{t} \left(\frac{1}{r} - \frac{1}{r_0} \right) \quad (3)$$

where R is the value of the high resistance leak in ohms, N is the number of revolutions per second of the commutator, V is the volume of ionization, ϵ is the e.m.f. of the neutralizing potentiometer battery in volts, and r and r_0 are the direct potentiometer readings at the time $t=t$ and $t=0$ respectively.

In the method of calculation one important change is made from that used by Marshall who measured n_0 the number of ions at the instant the x-ray flash was cut off, then n the number left after varying time intervals t . α was calculated between these two limits thus giving an average value over the whole time of recombination. In the present work values of n_0, n_1, n_2, \dots are measured at short intervals of time 0, t_1, t_2, \dots . Then α may be calculated between any two of these intervals. That is, Eq. (2) becomes of the form:

$$\alpha = \frac{1}{t_p - t_q} \left(\frac{1}{n_p} - \frac{1}{n_q} \right). \quad (4)$$

This allows α to be studied as a function of the age of the ions rather than as a function of the time of recombination after the x-rays are cut off. Setting τ as the average age of the ions over any period of recombination $t_p - t_q$ and assuming $\tau = 0$ at $t = 0$ we have:

$$\tau = t_q + \frac{t_p - t_q}{2}. \quad (5)$$

If $t_p - t_q$ is a short time interval compared to the maximum time allowable at any particular commutator speed, τ is a fairly accurate measure of the age of the ions and the variation of α with τ can be studied.

RESULTS

The first series of runs were taken as a check on Marshall's work and show results similar to his, α being plotted as a function of t the time of recombination (see Fig. 3). Each succeeding run was taken with the commutator speed one-half that of the previous run. These show the sharp initial drop due to the non random distribution of the ions with the apparent flattening out of

Fig. 3. First six runs corrected for diffusion.

the curves at longer time intervals. The final value at one second is about 1.03×10^{-6} compared to Marshall's value of 0.9×10^{-6} . This is due to a very short time of exposure (0.01562 seconds which was kept constant throughout the series of runs by narrowing the sector) and a resulting low initial concentration of the ions. The matter of initial concentration is important even at long time intervals as will be seen later.

All later runs were taken by measuring n at short intervals of time thus making it possible to calculate α as a function of τ the age of the ions, as well as a function of t the time of recombination. All the curves (Fig. 5) show without exception a continued drop in α up to a time of two seconds, the maximum time which could be studied. At the end of these long time intervals α still shows no indication of becoming constant although the slope of the curves gradually decreases.

Fig. 4 shows a comparison for one particular run of the two methods of calculating α . In the upper curve, α is plotted as a function of the time of recombination, in the lower curve as a function of τ the age of the ions. In the lower curve α drops more sharply than in the upper. In other words, Marshall's results gave an average high value of α rather than the true value at any particular time. However, on the magnified scale of Fig. 4, α still drops quite sharply even with Marshall's method of calculating, while it appeared to be nearly constant on the scale used in Fig. 3.

Values of α calculated as a function of τ do not lie as close to a smooth curve as those calculated as a function of t . (See Fig. 4). This is because α is obtained for comparatively small differences in the potentiometer readings, especially at the later time intervals when the concentration of ions

Fig. 4. Comparison of two methods of calculating α .

has become small and very little recombination takes place. Thus small errors in the potentiometer readings may result in large errors in the calculated values of α . However, the points show a definite trend in every case. This is more important than the absolute values since a final definite value of α does not seem to exist.

Fig. 5 shows the complete results for all the runs taken over the longer time intervals in air and oxygen. α is plotted against τ , the age of the ions, and the curves are all averages of values taken from two or more runs which may vary by considerable amounts due to an overcorrection for diffusion at the longer time intervals which will be discussed later. The dotted lines show the results in oxygen and the full lines those for air.

Curve I is a run taken with the commutator revolving at the rate of two revolutions per second; curve II, one revolution per second; curve III 0.5 revolutions per second; curve IV 0.25 revolutions per second; all at rather

high initial ion concentrations varying from 2.5 to 3.5×10^6 ions per cm^3 . Curve V is taken in air at 0.5 revolutions per second corresponding to curve III, only in this case the initial concentration was reduced to 1.55×10^6 ions per cm^3 compared to 3.5×10^6 for curve III. As can be seen, the values of α for the low concentration are much higher than those for high concentration although the slope of the curve is approximately the same in each case.

Curves VI, VII and VIII are those for pure oxygen; VI corresponding to III for air, VII corresponding to V and VIII corresponding to IV. Curve VI is much higher than the corresponding curve III for air at the same initial concentration. For low concentrations the oxygen and air curves (V and VII) are approximately the same although the points do not fall on a smooth curve due to the extreme difficulty of measuring the coefficient accurately at these low concentrations. The trend is very definite however,

Fig. 5. Complete results for all runs taken over the longer time interval in air and oxygen.

and shows the slope to be about the same as for the curves taken at higher concentrations. Curve VIII for the longest time intervals in oxygen is only slightly higher than the corresponding curve IV for air although there is a distinct difference.

One question which must be considered in connection with these results is the correction for diffusion. Two types of runs were made: one with the beam of x-rays grazing though not touching the plates; so that the whole volume between the plates was ionized; and another with the beam about one centimeter from the plates. In general if no diffusion correction is made, the values of α obtained in each case are nearly the same. If, however, correction is made for diffusion, the values are higher when the beam is one centimeter from the plates, especially at the longer time intervals. This results from the fact that the correction is in the opposite direction in the two cases.

For the case when the beam grazes the plates, a certain number of ions diffuse to the plates during the time of recombination and are thereby lost. This loss is in addition to the loss due to recombination. The number lost by diffusion may be calculated, and this number then added to the measured value n_p at the time t_p to give the true value due to recombination alone. The number diffusing to the plates in time $t_p - t_q$ is given by

$$2n_p A [(\overline{\Delta x})_p - (\overline{\Delta x})_q] \text{ where } (\overline{\Delta x})_p = \left(\frac{4Dt_p}{\pi} \right)^{1/2} \text{ and } (\overline{\Delta x})_q = \left(\frac{4Dt_q}{\pi} \right)^{1/2}$$

n is the number of ions per cm^3 of either sign, A is the area of each plate, $\overline{\Delta x}$ is the average distance an ion diffuses in the time t derived from the Brownian movement equation,² and D is the coefficient of diffusion having a value about 0.047. The number

$$2n_p A \left[\left(\frac{4Dt_p}{\pi} \right)^{1/2} - \left(\frac{4Dt_q}{\pi} \right)^{1/2} \right]$$

being added to the measured value of n_p serves to reduce the uncorrected value of α by as much as ten percent.

Marshall has derived a rather complicated equation for the case when the beam is some distance from the plates but this is not readily applicable when α is calculated as a function of τ rather than t . In this paper therefore, a correction is made assuming a swelling of the volume of ionization due to diffusion which gives approximately the same results as Marshall's equation. In calculating α at any time τ the volume is assumed to be:

$$V = V_0 + 2A(\overline{\Delta x})_\tau = V_0 + 4A \left(\frac{D\tau}{\pi} \right)^{1/2}.$$

Since V occurs in the numerator of Eq. (3) this increases the value of α over that calculated without the diffusion correction.

From the fact that the diffusion correction throws the values of α as much as twenty percent apart at the longest time intervals there is apparently an overcorrection for this effect in the equations and values used. This would follow if the coefficient of diffusion becomes less for the ions remaining after long time intervals. Other factors may further reduce the actual rate of diffusion, but from a kinetic theory standpoint a correction like that indicated is necessary. As it does not seem justifiable to omit the correction, all the results are calculated in this manner and the average of the two types of runs is taken in plotting the curves in Fig. 5. The absolute value of α in the curves may be too high or too low by several percent especially for large values of τ since the correction for the case when the beam is one centimeter from the plates is greater than for the case when the beam is grazing the plates. However, the important fact remains that in every case, no matter whether a diffusion correction is made or not, the value of α still drops off continuously with the aging of the ions.

SUMMARY OF RESULTS AND CONCLUSIONS

From the curves in Fig. 5 the behavior of α may be summed up as follows:

(1) α is not a constant as has always been supposed, but beyond the sharp initial drop due to the non-random distribution of the ions, the curves continue to drop indefinitely as the ions age. At the end of one second the value of α is 0.5 to 0.6×10^{-6} ; at the end of two seconds, 0.3 to 0.4×10^{-6} .

(2) The lower the initial concentration of ions, the higher the value of α after random distribution has been attained. The value for an initial concentration of 1.55×10^6 ions per cm^3 drops to about 1.15×10^{-6} at the end of a second compared to about 0.6×10^{-6} when the initial concentration is 3.5×10^6 ions per cm^3 . However, the slope of the curves is about the same in each case.

(3) The values of α in pure oxygen are in general higher than the corresponding ones in air although they become equal when the initial concentration of the ions is small. The slope of the curves is still the same indicating that the same type of aging effect is taking place.

At first glance it would seem impossible to explain these results by any reasonable assumption. *However, the whole situation becomes clear at once if it is supposed that as time goes on some of the ions form clusters with the impurities present.*

Although special care was taken to remove organic vapors such as ether, alcohol, stopcock grease, etc., which are known to affect the nature of the ion, the number of these heavy molecules present was probably comparable to the number of ions. In addition, water vapor may be present coming from the walls of the metal chamber and there is the possibility that the intense hard x-rays form small quantities of nitric oxides, O_3 or H_2O_2 . Any of these impurities might form large ion clusters in increasing quantity during the time of measurement. The method is particularly sensitive to impurities as the small, fast moving ions are removed first by recombination leaving the heavier ions as time goes on. Hence α drops continuously.

The supposition that impurities formed by the x-rays form clusters is in agreement with the work of Tyndall, Grindley and Sheppard,⁴ also that of Erikson.⁵ Erikson showed definitely that the presence of β -rays from radium emanation tubes formed impurities which hastened the aging of the ions so that clusters formed in about 0.001 second. Passage of the gas through a metal ionization chamber which had not been thoroughly cleaned also hastened the aging although to a lesser degree. If neither the β -rays or metal ionization chamber were present there was no appreciable aging effect up to 0.1 second.

Since measurements of the coefficient of recombination in pure oxygen give in general higher values than in air, it would seem that the extremely low values in air are due in part to nitric oxides. The fact that low initial ion concentrations give higher values of α than high initial concentrations is

⁴ Tyndall, Grindley and Sheppard, Proc. Roy. Soc. A121, 125 (1928).

⁵ H. A. Erikson, Phys. Rev. 34, 635 (1929).

further evidence that clusters of some sort are forming and that the more intense the ionizing agent the more impurities there are present to retard recombination.

It has always been a moot question as to the true nature of ions in gases of normal purity such as are used in this experiment. Practically the only evidence on this subject is from mobility measurements. Erikson's well-known aging of the positive ions gives an indication of clustering and Loeb's measurements in mixtures show definitely that clustering occurs in some gases. Apparently in other gases the ions may consist of single molecules or at any rate small aggregates. However, the evidence from mobility measurements is incomplete in two respects: first because the measurements are generally made within a time interval of less than one tenth of a second after the ions are formed, and second because the mass factor is an unimportant one in mobility; i.e., the mobility is decreased very little by a considerable increase of mass.

The coefficient of recombination measurements are more reliable since in this case the ions can be studied up to time intervals of two seconds after they have had a chance to collide with all kinds of impurities and the faster ions have been weeded out by recombination. In addition, the mass factor is much more important than in mobility or diffusion. On J. J. Thomson's⁶ theory of recombination which Loeb and Marshall² have shown to be a correct approach to the problem, α is proportional to the velocity of thermal agitation of the ions. The velocity of thermal agitation is in turn inversely proportional to the square root of the mass. The better of two equations as given by Loeb and Marshall after inserting the various constants turns out to be:

$$\alpha = 1.9 \times 10^{-5} \left(\frac{273}{T} \right)^{3/2} \left(\frac{1}{M} \right)^{1/2} \epsilon$$

where T is the absolute temperature, M is the molecular weight of the ions, and ϵ is the probability that recombination will occur if the ions approach each other within a defined distance d . For the case of air or oxygen at room temperature and 760 mm pressure the theory gives ϵ a value of about 0.9 which, however, may be too high. T is about 295° so that the equation reduces to:

$$\alpha = 1.51 \times 10^{-5} \left(\frac{1}{M} \right)^{1/2}.$$

If α has a value of 0.4×10^{-6} which is the lowest observed in this work, it turns out that M the molecular weight of the ions is about 1400. This seems unreasonably high but is not inconceivable if there were a large cluster of heavy molecules. The equation, however, is correct only to the roughest approximation and probably gives high values of α . As a result, the mass, which varies inversely as the square of α may be much less than 1400.

⁶ J. J. Thomson, *Conduction of Electricity through Gases*, III Edition, Cambridge 1928.

The only conclusion which can safely be drawn is that little is actually known concerning the nature of gaseous ions, but that in gases of normal purity that are ordinarily used in gas ion work, clusters of large mass are formed, due probably to the effect of the ionizing agent. The process of cluster formation and weeding out of the faster ions by recombination continues for at least two seconds after the ions are formed. The exact nature and true mass of these clusters cannot be accurately determined owing to the lack of a completely satisfactory theory.

The absolute value of α in air. It appears to be of considerable interest to know the absolute value of α in air for use in numerous calculations. It is evident from the results in this paper that there are two factors which make it impossible to set an accurate absolute value. The first factor is the initial non-random distribution of the ions which produces very high apparent values of α at short time intervals and the second is the loading up of the ions with impurities and selective recombination which produces abnormally low values of α at long time intervals. Probably the closest approach to an absolute value is at a time when the ions have nearly attained random distribution but clustering and elimination of the faster ions has not yet played a major role. In other words, a point must be chosen on the curves in Fig. 3 where the sharp drop in α ends and the more gradual steady drop due to clustering begins. Such a point appears to lie between 0.05 and 0.1 seconds where the value of α is $1.4 \pm 0.1 \times 10^{-6}$. This is not much different from the commonly accepted value of 1.5 or 1.6×10^{-6} which has been determined by earlier investigators under conditions where, in general, these important disturbing factors have not been detected, or at any rate not clearly differentiated. The value of 1.4×10^{-6} for air may then be used with some degree of confidence under conditions where the ions have attained random distribution but have not aged more than one-tenth of a second.

In conclusion, the writer wishes to express his appreciation to Dr. Marshall who designed and constructed the fundamental parts of the apparatus; to Mr. G. P. Kraus of the shop who accomplished a difficult piece of work in building the ionization chamber; and to Mr. N. E. Bradbury who assisted in taking some of the later readings. Particularly, the writer wishes to thank Professor Loeb for his unfailing interest in the work and for his suggested explanation of the experimental results.

At present, the measurements are being continued in other gases, particularly argon and hydrogen.

LETTERS TO THE EDITOR

Prompt publication of brief reports of important discoveries in physics may be secured by addressing them to this department. Closing dates for this department are, for the first issue of the month, the twenty-eighth of the preceding month; for the second issue, the thirteenth of the month. The Board of Editors does not hold itself responsible for the opinions expressed by the correspondents.

Reflection of Positive Ions by Crystals

Further experiments on the reflection of hydrogen positive rays from crystals similar to those described in The Physical Review for December 1, 1929 have shown that the phenomenon is more complex than might have been expected. More than a hundred photographs showing reflected rays have been obtained under various conditions, and show several features of interest. Great differences have been found in the reflecting powers of different samples of calcite. Two were found that gave strong reflected rays when the glancing angle was less than two degrees. The images obtained on Schumann plates placed at right angles to the beam may be properly termed reflection patterns, as they show considerable complexity, vary in a regular manner with the angle of incidence, and can be reproduced at will with the same setting of the crystal and speed of the rays. Six other calcite crystals gave reflection patterns containing fewer lines or lines on a fogged background. Reflected rays were also observed with a diamond which was kindly loaned by Dr. D. Cooksey. A natural cleavage face of this diamond had been used in experiments on the reflection of gamma-rays. A highly polished face gave indistinct patterns on a fogged background. Clear lines were obtained from two other faces, one of which was the natural cleavage face, and the other a face that had been cut and appeared rough due to the saw marks. No reflected rays were found in a few trials with rock-salt galena and magnetite.

The strongest parts of the patterns are produced by rays that have energies corresponding to more than six thousand volts. Slower rays may be present in the original bundle, as shown by a positive ray analysis, but they are not reflected as strongly as the

faster rays. With a low potential on the discharge tube, the reflection pattern lacks certain of the parts that appear with high potentials. A positive-ray analysis of the ions reflected from one of the calcite crystals showed that in addition to the hydrogen atoms previously reported, all the positive ions in the original bundle are present in the reflection patterns, viz.: hydrogen molecules, triatomic hydrogen molecules and heavier ions that are probably oxygen atoms. With the present resolution the various ions are superimposed in the streaks or lines formed by the reflected rays of various velocities.

The dependence of the angle of deviation by the crystal on the energy of an ion rules out the possibility of ascribing the reflection to the deviation of particles by electrostatic forces which would require the reflected rays of various velocities to lie in a plane and to have angles of deviation inversely proportional to the energies of the particles. In most cases the reflected rays of different velocities do not lie in planes as they give curved images on the plate and in the cases where a straight line is formed the deviation is not inversely proportional to the energy but is a linear function of the reciprocal of the velocity. Charges would not be expected to accumulate on the crystal because of the secondary electrons liberated by the bombardment of metal parts near it and its uncharged condition is shown by the fact that those rays which just pass over the crystal without hitting it are undeflected. The small penetration of ions into matter as compared with electrons of the same equivalent wave-length suggests that energy changes at the surface or inside the crystal will have to be taken into account in a complete theory. The important factor in determining the angles may be a quantity

analogous to a refractive index which would depend on the energy of the ion and its alterations.

Small changes in the angle at which the incident rays hit the crystal produce a regular series of changes in the directions of the deflected rays. At nearly grazing incidence on one of the calcite crystals with the rays parallel to an edge of the cleavage rhomb there was a fan-shaped arrangement of the reflected rays in eight or more radial lines of different intensities. As the angle was made steeper the lines formed by the reflected rays of various velocities shifted towards the normal to the crystal surface and became curved the intensities altered and new curved lines appeared at the sides making the patterns more complex and more symmetrical. This change was produced by an increase of

only one degree. With a second calcite crystal which was turned so that at grazing incidence the rays made an angle of about fifteen degrees with an edge of the cleavage rhomb clear patterns were obtained which had an unsymmetrical character. These patterns as well as those from the diamond also changed in a regular manner with small increases in the angle of incidence. The dependence of the angles of reflection on the angle of incidence and on the velocity of the rays suggests very strongly that a theory of the phenomenon will have to contain other elements besides particles and the forces exerted on them by electric and magnetic fields.

High-Voltage Tubes

We have found that the internal shattering and puncturing of Pyrex high voltage tubes of the cascade type described in the Physical Review of January 1 is entirely eliminated if the glass is "heat-worked" throughout. Since last autumn we have been using tubes made by blowing a series of "bubbles" which comprise the cascade sections at proper intervals along a piece of Pyrex tubing using a glass lathe for holding the work. In other respects the tube construction and shielding have been similar to that previously described except that tungsten instead of wax seals were used and the electrodes were shorter. Shattering and puncture finally occurred with most of our tubes in the necks between bulbs ("bubbles") although such tubes were operated to over 1600 kilovolts by careful "seasoning" and by short-circuiting sections which shattered before these had progressed to actual puncture. It was then found that if the glass tubing was first worked at all points (by heating and alternately blowing and contracting as in working a glass seal or joint) and then formed into bubbles and necks and the electrodes assembled no shattering took place when the tube was used. In two months of very severe tests on a series of such "heat-worked" tubes we have not been able to produce any shattering or puncturing with our Tesla coil voltages. One such tube of 14 sections, 135 cm overall, was operated up to 1950 kolovolts (at about one spark per second) where gassing set in due to slightly contaminated electrodes. This

type of limitation by gas is the only one we experience with these tubes and our vacuum technique can be improved considerably when higher voltages are desired. An ionization-gauge near the pumps usually reads about 10^{-6} mm Hg equivalent air-pressure. We find that every tube which is assembled using reasonable precautions against contamination especially by water-vapor, can be relied on to go to voltages of 1,000 to 2,000 kilovolts, depending on the number of sections, the ground-point, and the success in avoiding contamination, which usually shows up as a discoloration of the out-gassed electrodes.

These tubes have been operated as high as 1500 kilovolts without a potentiometer, that is, with all except the end-electrodes electrically floating. We made the accidental discovery on several occasions that some of our potentiometer units had been broken while we were running a tube, without our knowing of their failure until afterwards, no trouble having been noted with the tube. When all of the potentiometer units were removed, the tube still operated without severe flashing, although the voltage-distribution was obviously very non-uniform. Brasch and Lange (Naturwiss. January 3, 1930) have already reported the successful operation of a somewhat similar "floating-electrode" tube. Whether or not a filament is used in a tube makes no detectable difference in its behavior or flashing, at least up to 1500 kilovolts at one spark per second, nor has any effect of the filament

been noted with 120 sparks per second up to 800 kilovolts, which voltage has happened to be the maximum available with 60-cycle excitation of the condenser at the time of these tests, due to temporary power-limitations.

We are now using tubes of 12 sections placed inside of a Tesla coil 6 inches in diameter and 38 inches long, each electrode being connected to a tap on the winding of the coil. The coil itself shields the tube from ground, and distributes the voltage. A tube of this type, *with one end grounded*, has been operated to 1900 kilovolts at one spark per second, and to 1600 kilovolts at 120 sparks per second, at which voltage the tube oper-

ated perfectly; primary power was again the limitation. Insulation difficulties are also serious at these voltages above ground. Experiments are in progress on direct measurements of the output from these tubes of the expected radiations and "rays" of radioactive energy-equivalents, the results of which we hope to report shortly.

Photoelectric Effect and the *J* Phenomenon

In the issue of the Physical Review for May 1, 1930, appears a paper by E. Marx describing "A new photoelectric effect in alkali cells" wherein that author investigates changes produced in the limiting potential acquired by an insulated alkali electrode, by varying the composition of the incident radiation. Although these experiments constitute the first systematic study of the phenomenon in the optical region, an analogous investigation was carried out with x-rays some years ago by C. G. Barkla. I quote from one of the latter's notices (Nature, March 27, 1926, p. 448)—"The ionization produced by a heterogeneous beam of x-rays in a gas, or the electronic emission from a metal plate, (measured by ionization outside the plate) may be abruptly and enormously increased either by (a) superposing on that beam a very feeble radiation of slightly shorter wave-lengths, or (b) by taking away from the complex radiation a very small amount of the radiation of longer wave-lengths, as by filtering; that is, either by adding higher frequency radiations to or eliminating lower frequency radiations from the beam, the same effect is produced; namely, a sudden large increase in the ionization. The magnitude of a sudden increase may be from 100 to 150 percent of the original magnitude. This is the *J* ionization produced by the *J* photoelectric emission accompanying the *J* absorption."

Since the independent variable (composition of the incident radiation) is the same for both cases, they deal presumably with the same effect, and it should be legitimate to compare the results, although an extrapolation from the optical to the x-ray region must be made with caution. This comparison is

difficult, since it is unlikely that the experimental arrangements were the same for both. In Marx's work, the alkali electrode was insulated, and the removal of some of the red from an incident beam of white light caused an increase in the limiting potential acquired. On the other hand, in Barkla's experiment, the photoelectric plate was probably kept at a constant potential, and he observed that the removal of some of the long wave-length radiations from the beam of x-rays caused an increase in the ionization due to photoelectrons. Barkla interprets his result as a manifestation of some unexplained interaction between the component radiations in the incident beam, which causes a fundamental change in the amount or in the nature of the photoelectric emission. This is not necessarily inconsistent with the experiments of Marx, but it is not one of the assumptions of the tentative theory which he offers. Other possible suppositions as to Barkla's experimental arrangement lead also to conclusions which are at variance with the theory of Marx. At present all that can be deduced is that the four items (a) the experiments, (b) the theory of Marx, (c) the experiments, (d) the theory of Barkla, are not consistent.

I am not aware that Barkla's observation has ever been verified. It is possible that a series of varied experiments of this nature might throw some light on the elusive *J* phenomenon.

The Origin of O^{17}

In the Physical Review of April 1 Harkins and Schuh have considered the possibility of all the O^{17} atoms in the earth's crust and atmosphere having been formed by close collisions of alpha-particles with the nuclei of nitrogen atoms as revealed by the cloud tracks. Assuming that the ratio $O^{17}:O^{16}$ atoms is the same in the crust as in the atmosphere and that the known nitrogen and radium contents are uniformly distributed in the crust they estimate that the necessary lapse of time would have been about 10^{18} years which is an impossibly great age for the earth.

At about the same time the writer made (Minnesota Technol. 10, 240 (1930)) a similar calculation for the atmosphere alone by using its known radon content of 10^{-10} curie per cubic meter. The result is about 10^{14} years required. Since this also represents an apparently excessive age one is inclined to seek auxiliary means of production. A former content of U-Ra-Rn higher than at present suggests itself but seems improbable as one would then expect to find higher Pb:U ratios than those actually found in nature.

From Harkins and Schuh's calculation it is evident that oxygen liberated from the crust would diminish the relative content of O^{17} in the atmosphere. However if instead of a uniform distribution of uranium and nitrogen in the crust we consider concentration in the form of high grade uranium ore and an enhanced concentration of nitrogen in the ore the rate of O^{17} production would be increased. Hillebrand (W. F. Hillebrand U. S. Geol. Survey Bull. 78, 43 (1891); Am. J. Sci. 40, 384 (1890)) did find a striking association of nitrogen and uranium. Whether this could be a large source of O^{17} would of course depend on the size of such deposits. This would be difficult to estimate and it appears unnecessary to consider it further in this connection since the following simple considerations show it to be highly improbable that any important fraction of O^{17} in the atmosphere can have been

generated on the earth either in the crust or in the atmosphere itself by alpha-ray bombardment.

About 100,000 alpha-particles are required for each nuclear encounter with nitrogen. Therefore the ratio of He to O^{17} generated would be 100,000 He:1 O^{17} . In the atmosphere the actual ratio is about 1 He:5 O^{17} . We can hardly conceive any natural process that would have achieved a change of 500,000 fold in the ratio of the two gases.

If we reverse the calculation and assume with Jeans (Jeans' Dynamic Theory of Gases, 1921, p. 345-6) no diffusion of helium away from the upper atmosphere then for 100,000 He atoms there would be only one O^{17} atom of the assumed origin, or only about two millionths of the O^{17} atoms actually found by the band spectrum method.

As a matter of fact there are good reasons for believing that at least several fold as much helium has diffused "out at the top" as now remains, since that many fold have been liberated into the atmosphere by erosion, etc. The writer would point out that Jeans' denial of loss by diffusion is based wholly on thermal diffusion; whereas light gases like hydrogen and helium in the upper atmosphere can absorb radiation which upon conversion into translational energy would give them a velocity quite beyond that corresponding to thermal equilibrium with the surroundings and thus allow their escape. This process would therefore raise the O^{17} ratio by lowering the helium. While it may have taken place to an extent several times the present helium content of the atmosphere, it would be difficult to believe that it might have occurred to an extent of 500,000 fold, which would be necessary to have established the present He: O^{17} ratio.

Paschen-Back Effect on the Line Spectra of Solids

In a work which we shall publish soon,¹ we have been able to assign a number of the lines of the spectrum of Gd^{+++} in the crystal $GdCl_3 \cdot 6H_2O$ to definite energy levels. These levels have been fixed by studying the spectrum under various conditions, namely, observing how the lines shift their position with the

temperature, observing their polarization, the corresponding lines of the crystal $GdBr_3$.

¹ Freed and Spedding, Nature 123, 525 (1929).

Freed and Spedding, Phys. Rev. 34, 945 (1929).

$6\text{H}_2\text{O}$, and the behavior of the spectrum in a magnetic field.

The lines that are decomposed by a relatively weak magnetic field invariably break up in two components which are equal in intensity and are symmetrically displaced from the position of the original line. However, dissymmetries occur with stronger fields when the levels produced by the magnetic field approach each other. The dissymmetry in the intensities is especially pronounced. Some of the lines become much stronger while others become weaker, practically vanishing in some cases. A number of the lines coalesce and it has been found impossible to force any crossing with the maximum field at our disposal.

This work was done with a crystal of

$\text{GdCl}_3 \cdot 6\text{H}_2\text{O}$ at room temperature. The dissymmetries would undoubtedly have been different at other temperatures as the intervals between the energy levels are then different² and consequently the intervals and the interactions between the magnetic levels would no longer be the same.

BOOK REVIEWS

Einführung in die Geophysik, II, Erdmagnetismus und Polarlicht, Wärme—und Temperaturverhältnisse der Obersten Bodenschichten, Luftelektrizität, von A. NIPPOLDT, J. KERRANEN, E. SCHWEIDLER. Pp. 388, figs. 130. Julius Springer, Berlin, 1929. Price RM 35. (bound).

The first part on the earth's magnetism and aurorae and the third part on the electricity of the lower atmosphere treat the subjects in pretty much the same way as most other handbooks have done. Brief and adequate discussions are given of what is known about the permanent magnetic field of the earth and its variations, of magnetic storms, of aurorae, of the earth's electric charge, of the potential gradient, ionization and electric current in the lower atmosphere, and of thunderstorms and their electrical effects. The older theories of the phenomena are well presented with, in some cases, an appraisal of the successes and the shortcomings of the theories. The high atmosphere is hardly touched upon, there is almost no mention of wireless wave phenomena. The second part deals in detail with the temperature of the upper few feet of the surface of the land. Temperatures of the soil and of snow are given at various latitudes, on mountains, etc., for various hours of the day and seasons of the year. Some of the results are interpreted with the aid of the mathematics of heat conduction theory.

E. O. HULBURT.

Einführung in die Geophysik, III, Dynamische Ozeanographie, von A. DEFANT. Pp. 222, figs. 87. Julius Springer, Berlin, 1929. Price RM 19.80 (bound).

"Distilled by the sun, kneaded by the moon," swept by the winds, the sea swirls, upwells and drifts in great streams and small eddies. The investigation, both experimental and theoretical, of these movements and of the causes which produce them, that is dynamical oceanography. Hydrodynamics as developed by Lamb dealt for the most part with homogeneous fluids. It was V. Bjerkness, perhaps, who laid the theoretical foundation of dynamical oceanography in his papers on the dynamics of heterogeneous fluids.

In the volume under review are chapters on the statics and kinematics of the sea, the general dynamics of ocean currents, stationary currents in a stratified ocean, convection currents, ocean circulation, waves and tides. A satisfying glimpse is given of the facts gathered by many expeditions on the sea. The mathematics are simple and are applied directly to the analysis of the water movements. Original references are given throughout. One could wish for an English translation of the treatise, for the subject deserves a wider attention in this country than it has received.

E. O. HULBURT

Traité de Polarimétrie. GEORGES BRUHAT. Pp. xvi+448, 250 figs. Editions de la Revue d'Optique théorique et Instrumentale, Paris, 1930. Price, 65 francs.

The volume is limited to the study of the phenomena of rotatory polarization and the apparatus which serves to measure it. The first part of the book contains detailed discussion of apparatus and technique. The second part is on the phenomena of natural rotation, magnetic rotation, and dispersion of rotation, including circular dichroism in the regions of absorption. This is a very useful handbook for all who have occasion to use the polariscope, whether for chemical analysis, or for the study of the phenomena of rotatory dispersion, circular dichroism, or magneto-optic rotation. The literature is made readily referable by the 882 references. The printing is good, but the binding is poor.

J. VALASEK

The Use of the Microscope. JOHN BELLING. Pp. xi+315, 28 figs. McGraw-Hill Book Company, New York, 1930. Price \$4.00.

The many common imperfections of microscope images are described, their causes are given, and the adjustment for optimum high-power microscopy are discussed. The intro-

ductory chapter is planned so that it summarizes the entire text in a form convenient for reference. At the end of the text is a list of 200 review questions and a glossary of microscope terms. Users of microscopes will find many useful suggestions in this volume.

J. VALASEK

Wien-Harms Handbuch der Experimental Physik. Vol. X. G. HOFFMAN—Das Elektrostatische Feld. W. O. SCHUMANN—**Hochspannungstechnik.** Akademische Verlagsgesellschaft m.b.H. Leipzig 1930. Price RM 55 (bound).

G. HOFFMANN. *Das Elektrostatische Feld.* Pp. 345.

Standard texts on electricity and magnetism consider electrostatics as an excuse for the introduction of some of the methods of mathematical physics. As a result little space is ordinarily devoted to the experimental side of the subject. It is very refreshing to see in the present volume a detailed and adequate presentation of the many interesting phenomena connected with static electric fields and of the experimental methods employed in their study. A concise introduction including historical references, definitions of quantities and units, and the most important formulae for capacities constitutes the first section. This is followed by a description and by the theory of instruments. Among these the electrometer is treated in particular detail with definite information concerning the sensitivity and performance of various types. A chapter is devoted to methods of measurement. A general survey of the data on properties of dielectrics is accompanied by a brief description of the current theories and a discussion of the experimental methods used. The experimental facts about the temperature dependence of the dielectric constant and the results of the theory, phenomena of dielectric absorption, volta effect, pyro- and piezo-electricity, conduction through dielectrics are brought up to date.

W. O. SCHUMANN. *Hochspannungstechnik.* Pp. 199.

Essentially a survey of the main points in high voltage engineering. Few books on this subject being available at present this is a very welcome section of the Handbuch. It is of particular interest to see the methods of German engineering practice. On account of the rapid development which took place since the completion of the manuscript much of the recent work has been referred to only in bibliographical addenda, and the volume is therefore already somewhat out of date. The presentation of the older developments is however very clear and contains the essential features of high voltage high power engineering. It is especially pleasing to see a discussion of the theory of dielectric breakdown both from the point of view of physics and of practical electrical engineering.

Both sections are very well illustrated with photographs and diagrams. The index is good and even the spelling of American names is almost correct.

G. BREIT

The Physics and Chemistry of Surfaces. NEIL KENSINGTON ADAM. Pp. 332+x. Figs. 45 Oxford University Press, 114 5th Ave., New York, 1930. Price, bound, \$6.00.

For some time, surface tension has been considered as one of the most classical, and accordingly for many most uninteresting parts of physics. Now this field has, thanks mainly to the author of the above book, to Harkins and Langmuir, and to the investigations of heterogeneous catalysis, developed into a flourishing branch which gives us many new results, up to now mostly concerning the properties of organic molecules and of crystal surfaces. This book is a very good account of this development, written with an eye on the chemist—even the industrial chemist.

Starting with a short chapter on definitions, it deals in the second chapter with films of insoluble substances. Adam distinguishes four types corresponding to two-dimensional crystals, liquids, compressed gases (the latter two are not sharply separated) and rarefied gases. In the solid films, long chain compounds have their active groups immersed in water while the long chains stand out, closely packed, similar to the arrangement in bulk crystals (Chapter III). In the gaseous films, the molecules seem to lie flat.

The next chapter deals with films of soluble substances and contains an interesting account of the nature of soap films.

Then follows a chapter (V) on the result of surface tension measurements, while a critical survey of the experimental methods is given in chapter IX with sufficient detail for the actual

performance of the experiments and their evaluation. This detailed description occurs also in other chapters and should be very valuable to non-specialists who want to use surface tension measurements. An attempt of a kinetic explanation of Eötvös' rule seems to be at least incomplete because it does not consider the fact that surface tension is only due to the *deviations* from the conditions in the interior.

The sixth chapter describes the behavior of an interface liquid-solid ("wetting"), followed by a chapter on lubrication. Both of these chapters show interestingly, how very practical questions can be better understood with increasing knowledge of molecular properties. Besides the technical problems mentioned above, Adam touches cleaning and dyeing, flotation of ores and (as already in chapter IV) emulsification and the influence of films thereon.

The eighth chapter, on adsorption on solids and its connection with chemical reactions and catalysis, can of necessity contain only a selection of topics. It starts out with the "sensitive patches" of Langmuir and Taylor, the marked increase in activity by mixing catalysts, and the methods for measuring the "microscopic surface" of a solid. Next the work of Langmuir on the theory of absorption and the behavior of gas films, which has already become classical in the good sense, is discussed, followed by selected organic reactions catalysed by metals. Then comes the discussion of charcoal and a little later some very interesting work on the catalytic properties of bacteria. The importance of adsorbed anions on the photosensitivity of silver bromide is then discussed. One wonders at the absence of a reference to the pioneer work of Fajans and his school. Finally, the theoretical calculation of surface tension in salts is discussed.

K. F. HERZFELD

Dipolmoment und Chemische Struktur. Edited by P. P. DEBYE. Leipziger Vorträge 1929. Pp. 134 + viii, 35 figs. S. Hirzel, Leipzig, 1929. Price Rm 9.

Elektrische Dipolmomente von Molekülen. I. ESTERMANN. Pp. 49, 20 figures, 7 tables. Part of Band VIII, *Ergebnisse der exakten Naturwissenschaften*, Julius Springer, Berlin, 1929.

Dipolmoment und Molekularstruktur. H. SACK. Pp. 60, 8 figures, 19 tables. Part of Band VIII, *Ergebnisse der exakten Naturwissenschaften*, Julius Springer, Berlin, 1929.

The first of the three titles reviewed contains lectures given at a Symposium on the connection between the dipolemoment and the chemical structure of molecules, held at the University of Leipzig in the summer of 1929, the two others are articles on the same subject from Volume 8 of *Ergebnisse der exakten Naturwissenschaften* and can not be purchased separately.

The determination of dipolemoments can be carried out in different ways: (a) By determining the temperature change of the dielectric constant ϵ in the gaseous state, which follows rigorously Debye's formula, if the exact equation of state is used in evaluating (R. Sängner, Zurich), (b) By investigating the deflection of a molecular ray, which is broadened if dipoles are present (I. Estermann, Hamburg).

In this way it is proved that pentaerythrite $C(CH_2OH)_4$ as gas has a moment and therefore the groups CH_2OH are not arranged in a regular tetraeder. (c) By investigating dilute solutions, where all associated molecules are broken up. Following ϵ to higher concentrations and at different temperatures, one can draw conclusions concerning the degree of association and compare them with vapor pressure and viscosity (I. Errera, Brussels).

(d) By subtracting the effects of electronic and ionic (or atomic) polarization from the total polarization (L. Ebert, Würzburg). The former can be determined from measurements of solids sufficiently far from the melting point, the electronic contribution also from the refractive index. To see how large the ionic polarization (displacement of the ions as a whole) is, Errera investigates salt crystals, while K. Hojendahl (Kopenhagen) uses the theory of Born-Landé concerning the forces in the crystal.

The results (Estermann, Errera, Sack, Ebert) show that one can with fair accuracy ascribe definite dipole moments to certain groups in organic compounds and that the resultant moment of a molecule with more than one of these groups can approximately be calculated as a result of a vectorial addition of the moments of each group as predicted by J. J. Thomson. It seems very probable from the results that the benzene ring is flat. The situation is more complicated in the case of groups like C-O-H where the valence bonds form an angle. Here the possibility of rotation of the dipole (lying along OH) around the C-O bond arises. Ebert dis-

cusses in much detail the transition between oscillation and free rotation as well as the question of an influence of the temperature on the apparent value of the dipole.

F. Hund (Leipzig) explains the results of the new quantum mechanics concerning the shapes of simple inorganic molecules.

K. L. Wolf (Karlsruhe) treats two auxiliary methods for solving doubts, which might occur in the interpretation of dipole measurements. These methods are first an observation of the Kerr effect and the depolarisation of scattered light, which are both connected with the unsymmetry of the molecule, and secondly the measurement of the shift of absorption bands for different compounds.

Finally W. Hückel (Freiburg) discusses the influence of the dipole on reaction velocities, especially in so far as there is a connection between the dipole moment and the heat of dissociation or activation of one of the parts of the dipole itself or a neighboring dipole.

K. F. HERZFELD

ERRATUM

AMERICAN PHYSICAL SOCIETY

PROCEEDINGS OF THE NEW YORK MEETING

Through an oversight the titles of the invited papers presented at the Symposium on photoelectric and thermionic phenomena were omitted from the program of the meeting as printed in the March 15, 1930 issue (Phys. Rev. 35, 656, 1930). On page 668 the following should be inserted after abstract 45:

SYMPOSIUM ON PHOTOELECTRIC AND THERMIONIC PHENOMENA

46. Photoelectric ionization of gases. F. L. MOHLER, *Bureau of Standards*.
47. Photoelectric multiple ionization by x-rays. F. K. RICHTMYER, *Cornell University*.
48. The quantum theory of the photoelectric and thermionic effects in metals. WILLIAM V. HOUSTON, *California Institute of Technology*.
49. The influence of surface conditions on the photoelectric effect. C. E. MENDENHALL, *University of Wisconsin*.
50. The velocity distribution of x-ray photoelectrons. DR. G. WENTZEL, *University of Zürich*.

PROCEEDINGS
OF THE
AMERICAN PHYSICAL SOCIETY

MINUTES OF THE WASHINGTON MEETING, APRIL 24-26, 1930

The 163rd regular meeting of the American Physical Society was held in Washington, D. C., On Thursday, Friday and Saturday, April 24-26, 1930. The Thursday and Friday sessions were held at the Bureau of Standards in the East Building and the Industrial Building. The Saturday sessions were held at the National Academy of Sciences. The presiding officers were Professor Henry G. Gale, President of the Society, Dr. W. F. G. Swann, Vice-President of the Society, and Professors John T. Tate, Harold W. Webb, and L. P. Sieg. On Thursday afternoon and Friday morning there were sessions devoted to papers on "Applied Physics."

On Friday evening there was a dinner for the members of the Society and their friends in the Gold Room of the Washington Hotel. President Gale presided and the speakers were Professors R. A. Millikan, G. F. Hull, Gregor Wentzel, Karl T. Compton and Doctors W. F. G. Swann and L. W. Nordheim. There were 257 guests at the dinner.

At the regular meeting of the Council held on Friday, April 25, 1930, thirty-five candidates were elected to membership. *Elected to Membership:* William Alter, John C. Batchelor, Ralph D. Bennett, John F. Blackburn, George W. Bloemendal, R. M. Buffington, H. R. Byerlay, Stuart Campbell, Shih-Chang Chen, Frank Coleman, T. C. Hardy, R. C. Hartsough, Curtiss R. Haupt, James A. Hootman, Frederick L. Hunter Jr., Franklin S. Irby, Hubert M. James, Carl Kaplan, Horace H. Lagerpusch, S. Lehrman, Leon B. Linford, Ellice McDonald, R. F. Morris, S. M. Naudé, Mr. Parker, John R. Patty, Herbert B. Roese, Oscar Siedman, Caspar V. Shapiro, Johannes A. Van den Akker, Claude C. Van Nuys, Bertram E. Warren, Carl J. Wiggers, Hugh C. Wolfe and Henry H. zur Burg.

The regular program of the American Physical Society consisted of 114 papers, numbers 1, 9, 15, 47, 48, 64, 65, 66, 74, 84, 105, 106, 107, 110 and 113 being read by title. The abstracts of the papers are given in the following pages, An Author Index will be found at the end.

W. L. SEVERINGHAUS, *Secretary*

ABSTRACTS

1. Distribution of non-reacting fluids in the gravitational field. MORRIS MUSKAT, *Gulf Research Laboratory Pittsburgh*.—The paper consists essentially of an analysis of the equation given by Lewis and Randall for the distribution of non-reacting ideal fluids in a gravitational field. When the fluids are incompressible a formal solution is obtained, for a mixture of any number of constituents. But it has not been possible to put it into a form convenient for numerical computation. The ratios of the concentrations of any constituent at the top to that

at the bottom of a vertical column of the mixture are given explicitly, both for incompressible and compressible fluids. When all the molar volumes of the various fluids are equal, the equations are solved completely and lead to a *relative* barometric distribution, and in the particular case of ideal gases, to individual barometric distributions. The physical meaning of this is briefly discussed. The case of binary mixtures is treated in detail, and numerical examples are given, first for a mixture of two paraffins, and secondly for a dilute solution of NaCl in water, which is equivalent to an ideal solution of liquids. As is to be expected, the effect is extremely small, and in the first case it is only one tenth as large as is given by a simple barometric formula.

2. **Capillary retention of liquids in assemblages of homogeneous spheres.** W. O. SMITH, PAUL D. FOOTE, P. F. BUSANG. *Gulf Research Laboratory, Pittsburgh.*—The pore space is an assemblage of uniform spheres was initially filled with liquid. After very slow drainage the amount of liquid retained by the spheres was experimentally measured. The liquid is retained in the form of rings at the contacts of adjacent spheres. The radii of curvature of the ring surfaces are computed in terms of surface tension, grain radius and pressure drop across the liquid-vapor interface, permitting calculation of the volume retained per sphere contact. The number of contacts per unit volume of spheres is obtained from porosity measurements using the theory developed earlier. (Phys. Rev. **34**, 1271 (1929).) Computed and observed data on the total volume of retained liquid are in agreement.

3. **The mechanism of "atomization."** R. A. CASTLEMAN, JR., *Bureau of Standards.*—The process of liquid "atomization" is in wide and important commercial use; yet, so far as the writer knows, no adequate explanation of its mechanism has been offered. The fact, however, that the phenomenon can be used with confidence in the design of machine and other details seems to be sufficient indication of a recognized definite physical background. If we assume that a necessary step in "atomization" is the drawing off, from the unatomized liquid, of ligaments of such size that they will eventually draw up into drops of the size observed in the spray, it appears that a satisfactory explanation of the phenomenon can be obtained by combining Rayleigh's theory of jet disintegration with some recent drop size measurements. For analysis shows that the degree of instability of ligaments of the necessary size is so great that direct observation of either the initial disturbances or even of the ligaments themselves seems improbable. The above assumption appears to be reasonable, necessary and sufficient.

4. **Wind pressure on cylindrical stacks.** H. L. DRYDEN AND G. C. HILL, *Bureau of Standards, Washington, D. C.*—A summary is given of the published model experiments on the wind pressure on cylinders and of some additional experiments (a) on model cylinders in the wind tunnel, (b) on a large cylinder in the natural wind, and (c) on the power plant stack in the natural wind. The object is to provide a basis for estimating the average wind pressure on stacks and other cylindrical structures at known wind speeds. The conclusions are as follows: 1. The wind pressure on a stack at a given wind speed is a function of the ratio of the height of the stack to its diameter and possibly of the roughness of the surface. 2. Model experiments can not be directly utilized because of a large scale effect. 3. Provision for a wind load equivalent to 20 pounds per square foot of projected area at a wind speed of 100 miles per hour is a safe procedure for stacks whose exposed height does not exceed ten times the diameter. 4. The local values of the pressure may require consideration in the design of thin-walled stacks of large diameter.

5. **Airfoils of circular-arc section for use at high speeds.** L. J. BRIGGS AND H. L. DRYDEN, *Bureau of Standards, Washington, D. C.*—Experiment has shown that the airfoil sections used in the design of airplane propellers change their aerodynamical properties as the relative air speed approaches the speed of sound. The component of the force in the direction of the airstream (the drag) increases more rapidly than the square of the airspeed, and the component normal to the airstream (the lift) less rapidly. In some earlier measurements, an airfoil which was a segment of a circular cylinder was found to give good results. The present measurements were undertaken to survey the field more thoroughly and to investigate the effect of

rounding the sharp edges. The effect of a moderate rounding was found to be small. At speeds above 0.95 of the speed of sound the circular-arc sections are more efficient than the usual types. At low speeds, (0.5 of the speed of sound), the thick circular-arc sections are much less efficient, but the thin circular-arc sections compare more favorably with the usual types. For propellers operating at high tip-speeds it would be advantageous to use circular-arc sections in the outer parts of the blade.

6. Absorption and velocity of high frequency sound in oxygen. W. H. PIELEMEIER, *Pennsylvania State College*.—Deviations of the experimentally determined absorption and velocity values from their theoretical values in air suggest their determination in oxygen and nitrogen at the same frequencies. The acoustic interferometer and torsion vane methods are used. The torsion vane method is the more reliable but the interferometer makes it possible to make simultaneous measurements of absorption and velocity. The theoretical value of K , the absorption constant, is given by the equation, $K = A/\lambda^2$, where A has the value 0.000365 for oxygen at 20°C. The experimental K is defined by the equation, $I = I_0 e^{-Kx}$. The frequency variation of the above deviations can readily be shown by comparing the theoretical value of A , 0.000365, with the observed values. At 1215 kilocycles the radiometer method gave 0.00039. With the interferometer 0.00031 was obtained. At 655.5 kilocycles the radiometer and interferometer both gave 0.00055. Dulong's value for V_0 , the velocity at 0°C, of audible sound in oxygen, is 317.2 m/sec. At 1215 and at 655.5 kilocycles the values are 317.1 and 317.4 m/sec respectively. The value given by Laplace's formula is 315.0 m/sec.

7. Influence of the walls enclosing a sounding air column upon the tone quality. DAYTON C. MILLER AND JOHN R. MARTIN. *Case School of Applied Science*.—Three organ pipes are provided, the first made of wood which sounds the tone of $G_2 = 192$. Two other pipes having the same internal dimensions are made of zinc about 0.5 millimeters thick. One of the zinc pipes is surrounded by a zinc case to form a double walled pipe, with spaces two centimeters wide between the walls. These two pipes have the same pitch, giving a tone a little flatter than $F_2 = 173$. When the single walled zinc pipe is blown in the ordinary manner, its sound has the usual tone quality. By touching this pipe on the outside, extraordinary changes in tone quality can be produced with the formation of inharmonic partial tones, the ratios of which are 1:2.06:2.66. When the double walled pipe has the space between the walls filled with a liquid the pitch is $E_2 = 153$. If the liquid is allowed to flow out gradually, the tone quality changes conspicuously during the process with the formation of inharmonic partials having the ratios 1:2:2.9. These experiments indicate that the material of which a musical wind instrument is made may have an important effect upon the tone quality.

8. The excitation of overtones of shear vibrations in Y cut quartz plates. J. R. HARRISON, *University of Pittsburgh*.—It is well known that Y cut quartz plates will function as resonators and oscillators with shear vibrations giving rise to transverse waves in the direction of the Y axis. (W. G. Cady, *Phys. Rev.* 29, 617, (1927).) Also it is not difficult to excite the odd overtones, i.e., those frequencies which are approximately odd multiples of the fundamental frequency. With a new type of crystal mounting it has been found possible to excite the even overtones also. To excite the second overtone, a three electrode crystal mounting is used. This mounting consists of two flat electrodes covering the two XZ plane surfaces of the plate and also a frame shaped electrode about one-third as thick as the crystal plate. This third electrode fits around the crystal plate like a frame and is symmetrically disposed with respect to the flat electrodes in the XZ planes. The frame shaped electrode allows fields to be applied between it and the electrodes in the XZ planes in opposite directions. To accomplish this, the flat electrodes are connected together serving as one terminal and the frame shaped electrode as the second terminal. By using two flat electrodes and three frame shaped electrodes, the fourth overtone can also be excited. Similarly, mountings can be constructed for exciting the higher overtones.

9. Torsion of rhombic prisms and of cylinders in the elastic and plastic state. JAKOB KUNZ, *University of Illinois*.—The corresponding problems for isotropic bodies are at first

solved by means of the stress function. The new problems are then reduced to the older ones by means of linear transformations of the variables. The plastic flow is then determined for the elliptic cylinder in a closed form, which however could not be found for the plastic rectangular prism.

10. Some applications of the theory of plastic deformations of ductile metals. A. NADAI, *Westinghouse Elect. Mfg. Co. East Pittsburgh*. (Introduced by S. M. Kintner).—A brief account will be given of the principal conditions which are available to express the equilibrium of stress in the plastic state of ductile metals. These conditions will be discussed for the case of rotational symmetry in a plastic body. As an example several cases of plastic flow in a thick walled cylinder subjected to high internal pressure with and without longitudinal expansion will be treated. The distribution of stress during yielding is given for a long cylinder and for a flat ring both subjected to radial pressure. How yielding and the plastic deformation spread through the walls of the cylinder will be shown.

11. The flarimeter: a clinical instrument for testing circulatory fitness. P. V. WELLS, *Medical Department, The Prudential Insurance Company of America*.—Forced expiration at constant lung pressure of 20 mm provides the most convenient means of placing the circulatory system under standard load. The response in systolic blood pressure is maximum at rates about 36 cc/sec. Among normals, the blow should exceed 50 seconds; its decrease measures shortness of breath, the leading symptom of an impaired heart muscle. The blood pressure normally rises 20 mm in 45 sec, 40 mm before the impulse to breathe stops the blow. The Flarimeter is a simple durable, reproducible, inexpensive, portable instrument designed to enable an individual to perform such a standard test. A 200 cc/sec orifice is also provided, its length of blow giving an accurate measure of vital capacity (the volume of a maximum single expiration). Some investigators have believed the vital capacity to be a measure of shortness of breath because it is so reduced in heart disease. But after exercise the vital capacity is not reduced, while the small orifice blow is shortened to a third of normal length, showing that it is a much better measure of shortness of breath.

12. Suggested explanation of Michelson-Morley-Miller experiment. N. GALLI-SHOHAT, *Mount Holyoke College*.—The complete theory of Michelson-Morley-Miller experiment leads to two effects: one due to the phase difference, another to the "rotation" of the waves produced by reflections from the moving mirrors. P. Epstein has given an estimation of this last effect and has found it too small to be discovered. However, his estimation was based on the orbital velocity of the earth, 30 km/sec, while the velocity of the solar system in space is much greater. Thus if one makes an estimation of the "rotational" effect for $v=300$ km/sec. one gets a displacement about 0.2 fringes in agreement with what Professor Miller has observed under the conditions of his experiment. This suggests the following assumptions: *Phase effect is fully compensated (Lorentz contraction); effect actually discovered by Miller is a rotational effect due to the aberration X' observed by Esclangon and discussed in the previous paper.* Rotational effect is assumed to be proportional to the horizontal component of X' , being $\beta l \cos \theta$ ($\sin^2 \theta - \cos^2(\theta - z)$)^{1/2} = $[\theta = (\theta_1 l), Z\text{-zenith}]$. The curves, representing the variation of the azimuth of the maximum effect and its magnitude, computed for Mt. Wilson, using the apex-declination 68° agrees with the curves given by Miller; the agreement being most striking for the data 1925.

13. The magnetic moment of the lithium nucleus. S. GOUDSMIT AND L. A. YOUNG, *University of Michigan*.—The hyperfine structure observed by Schüler in ionized lithium is of the same order of magnitude as the multiplets in that spectrum. This has led to the belief that the magnetic moment of the nucleus must be of the same order of magnitude as that of an electron. However, the hyperfine structure is produced by the deeply penetrating 1s electron whereas the multiplet separation is due to the outside 2p electron. These two should thus not be compared and indeed rough calculations show that a nuclear magnetic moment of only a few proton units is sufficient to account for the hyperfine structure. The considerations of H. E. White on lithium as well as other hyperfine structures (Phys. Rev. 35, 441 (1930)) are

incorrect since he erroneously compares them with singlet-triplet and other "Austausch" separations. His error is caused by a misinterpretation and a too literal application of the vector model.

14. Possibility of bringing mean life directly into Schroedinger equation for the hydrogen atom. A. BRAMLEY AND ALLEN C. G. MITCHELL, *Bartol Research Foundation*.—The possibility of bringing an expression for the mean life of an atom in a given state directly into the wave equation for the hydrogen atom with relative motion of the nucleus, has been investigated. A solution for the electron and proton in their mutual coulomb field has been found which contains a damping term β occurring in the time factor of the equation for

$$\Psi_m^t = \Psi_m \exp (2\pi i/h)(E_m + i\beta)t.$$

The value of the constant β is determined from the condition, that if the atom is in the state designated by eigenwert E_m for the electron at time $t=0$, then the probability of making a transition to any other state in all time is unity; or expressed analytically

$$\sum_n \alpha_{mn} \int M_{mn} dt = 1$$

where M_{mn} is the matrix moment of the transition. This leads to a value of β_m (reciprocal of mean life) which is proportional to $[\sum_n \{ \int x u_m u_n^* dx dy dz \}]^2$. This expression is similar to the expression derived by Sagiura from the Correspondence Principle for the value of the mean life.

15. Life and radius of the metastable mercury atom. M. L. POOL, *Ohio State University*.—The experimental arrangement described by the writer (Phys. Rev. 33, 22, (1929)) has been altered in order to lend itself more easily to mathematical treatment. A quartz resonance cell containing mercury vapor at 25°C is placed between two high speed disks which interrupt the total radiation from two symmetrically placed water-cooled and magnetically controlled quartz mercury arcs. A few millimeters of purified nitrogen and a trace of water vapor is admitted into the resonance cell and slowly moved over hot copper and copper oxide. The life of the 2^3P_0 state is measured by the rate of decrease of the absorption of 4047 with increasing time-wait after optical excitation of the mercury vapor. Extrapolation to zero nitrogen pressure gives a natural life of about 2×10^{-8} sec. Admixtures of argon at low nitrogen pressures prevented rapid diffusion of the metastable atoms to the walls of the tube. A treatment of the life-time similar to that outlined by Zemansky (Phys. Rev. 34, 213 (1929)) gives the radius of the metastable atom to be 2.4 to 3.0×10^{-8} cm depending on the pressure of the admixed nitrogen.

16. Interval rule for sp, sd, sf configurations. E. U. CONDON AND G. H. SHORTLEY, *University of Minnesota*.—A systematic comparison of the known data on the singlets and triplets arising from sp, sd, sf configurations with the theory of Houston (Phys. Rev. 33, 297 (1929)) shows that the theory gives a good account of the deviations from the Landé interval rule which accompany departure from Russell-Saunders coupling. There are numerous significant discrepancies, however. Writing 1L_l and $^3L_{l+1}$, 3L_l $^3L_{l-1}$ with $L=P, D, F$, when $l=1, 2, 3$ for the term values, we plot as abscissas $(^3L_{l-1} - ^3L_{l+1}) / |^3L_l - ^1L_l|$ and $(^3L_{l-1} - ^3L_l) / (^3L_l - ^3L_{l+1})$ as ordinate if $(^3L_l - ^1L_l)$ is positive, otherwise the reciprocal of this quantity. Houston's equations (12) give functional relations between these interval ratios which are compared with the experimental values.

17. The resonance of (B-A) bands of the hydrogen molecule. HUGH H. HYMAN, *Union College*.—Photographs of the extreme ultraviolet spectrum (λ 1100A to 11640A) have been taken, using a vacuum spectrograph made available to the author at the University of California. A three inch grating, 15000 lines per inch with a three meter focal length, was used, giving a resolving power of 0.1A and a dispersion of 2.76A per millimeter in the second order. The fine structure of sixty eight bands of the first resonance (B-A) system has been studied. The moment of inertia of the normal (A) state is found to be 0.4673×10^{-40} g.cm², the nuclear

separation, 0.7500×10^{-8} cm. In the first excited (*B*) state the moment of inertia is given as 1.4225 g.cm² and the nuclear separation as $1.308_4 \times 10^{-8}$ cm. Resulting constants leave no doubt but that the *B* state is also the lower state of bands found in the visible and studied by Richardson and Davidson. The proof of the connection between the ultraviolet system and the visible system leads to the conclusion reached by Birge that the ionization potential of the hydrogen molecule is 15.34 volts to within a few hundredths of a volt.

18. Regularities in the spectra of lutecium. WILLIAM F. MEGGERS AND BOURDON F. SCRIBNER, *Bureau of Standards*.—A study of the arc and spark spectra of lutecium (71 Lu) resulted in the separation of the lines into 3 distinct classes: (1) those characterizing neutral atoms, constituting the Lu_I spectrum; (2) those due to singly ionized atoms, the Lu_{II} spectrum and (3) a small number of lines ascribable to doubly ionized atoms, the Lu_{III} spectrum. Regularities have been discovered in each of these spectra. The normal state of neutral Lu atoms is represented by a 2D spectral term arising from the electron configuration (s^2d); its levels are separated by 1993.9 wave-numbers. The normal state of Lu⁺ atoms is described by $^1S(ss)$, and metastable terms 1D , $^3D(ds)$, $^3F'(dd)$ have also been established. The relative values are as follows:

$$\begin{aligned} ^1S &= 0.0, & ^3D_1 &= 11796.1, & ^3D_2 &= 12435.2, & ^3D_3 &= 14199.0, \\ ^1D_2 &= 17332.5, & ^3F'_2 &= 29406.7, & ^3F'_3 &= 30889.1, & ^3F'_4 &= 32503.7. \end{aligned}$$

A $^2S(s)$ term describes the normal state of Lu⁺⁺ atoms; a $^2D(d)$ term has levels at 6304.3 and 8648.1. There is no evidence that *f*-electrons play any part in the production of the spectra; it is concluded that the fourteen *f*-electrons in Lu form a closed shell of considerable stability.

19. The spark spectrum of cobalt (Co II). J. H. FINDLAY, *Princeton University*.—A further examination of the Co II spectrum, based on the previous work of Meggers (*Journ. Wash. Ac. Sci.* 18, No. 12, 1928), has been made. A magnetic analysis shows that Meggers' classification of the terms $d^7p^5F^0$, $^5D^0$ should be interchanged, except for the term $^5F_5^0$. Since Meggers' results were obtained from intensity rules, the author's $^5F^0F^0$ and $^5F^0D^0$ multiplets show irregular intensities. The strongest lines in these multiplets are, respectively, 5F_n $^5F_{n-1}$ and 5F_n $^5D_n^0$. The magnetic analysis also shows that Meggers' terms 3D should be d^7s^5P and that his $^3P^0$, $^3D^0$, and $^3F^0$ should be partly $d^7p^5P^0$ and $^5D^0$. In addition, the terms d^7s^3F , $d^7p^3D^0$, $^3F^0$, $^3G^0$, $^5S^0$, and the lowest terms d^8 3F have been found. The location of the second member of the $d^7s^5F^0F$ series gives an I. P. of 16.9 volts from d^7s to d^7 and 17.3 volts from d^8 to d^7 , in practically exact agreement with the predictions of Dr. H. N. Russell.

20. A surplus level in the arc spectrum of palladium. A. G. SHENSTONE, *Princeton University*.—The spectrum Pd I has been so thoroughly analyzed that the positions of all the structures to be expected are known. One even level, k_1 of Bechert and Catalan, is apparently not explainable in terms of the Hund theory unless it is a hyperfine structure component of $d^45d^3P_1$. That explanation is extremely improbable since (1) it makes the hyperfine structure greater than the fine structure and (2) no other levels are known to have structure. The lines due to k_1 are peculiar in being the only diffuse lines in Meggers' list which extends from $\lambda 4500$ to $\lambda 9200$.

21. Spectra of gases lighted with strong discharges. E. O. HULBURT, *Naval Research Laboratory*.—Spectra of condensed discharges through hydrogen at pressures up to several cms of mercury showed, as usual, the Balmer lines merging into the continuous spectrum. With increasing strength of the discharge the Balmer lines widened, the higher members of the series disappeared and the continuous spectrum became more intense, until with 1 microfarad at 15 kilovolts (the method of J. A. Anderson, *Astrophys. J.* 51, 37 (1920)) there were no Balmer lines left at all, only the continuous spectrum and some absorption lines due to aluminum from the electrodes, etc. Helium, oxygen and nitrogen exhibited similar changes, i.e., with increasing intensity of discharge in helium the lines gave way to a continuous spectrum, and in oxygen and nitrogen the molecular bands gave way to spark lines and these in turn to a continuous spectrum. The continuous spectra from all the gases were alike. The intensity

distribution across the continuous spectrum was rather even and hardly that of a black body. In the strong discharges the external characteristics of the atoms were pretty well effaced and the conditions approached those in the interior of a star.

22. Excitation processes in the hollow cathode discharge. R. A. SAWYER, *University of Michigan*.—The negative glow inside a hollow cathode in a rare gas discharge has often been used to excite metallic spark spectra. The excitation is largely due to collisions of the second kind between gas and metal atoms and ions. The exact processes may be inferred from the observed highest term excited and from maxima or abnormal intensities in the metallic spectrum. The available data have been examined. In general only those processes occur in which the metal can be excited to some term in the spark spectrum with gain or loss of only a small amount of kinetic energy to balance the reaction equation. If the metal has a low vapor pressure or sputters poorly cathodically the metal atoms in the normal state or a low metastable state if any will be excited by collisions with gas ions and metastable atoms. If the metal has a high vapor pressure metal ions will enter the reactions. In intermediate cases metal ions may or may not enter depending on conditions. The limit of excitation is fixed by the possible reaction yielding the greatest energy; the other possible reactions may produce maxima in the spectra.

23. Collisions of the second kind and their effect on the field in the positive column of a glow discharge in mixtures of the rare gases and mercury vapor. O. S. DUFFENDACK AND L. B. HEADRICK, *University of Michigan*.—Measurements were made of the electric field in the positive column in mixtures of helium-neon, helium-argon, neon-argon, in all proportions and mixtures of each of these gases with mercury vapor. Spectrograms were taken of the radiation from the positive column for each of these mixtures. The electrical and spectral characteristics of the positive column in mixtures of monatomic gases can be explained in terms of collisions of the second kind between the metastable atoms or the ions of one gas and the neutral or the metastable atoms of the other. The necessary condition for a large effect to be produced by a small amount of one gas added to another is that there exists a close resonance between the metastable states of the main gas and the ionized or excited states of the added gas. The introduction of only 0.15% argon into neon produced a marked increase in the electric field and the spectrum emitted changed completely from neon I to argon I, while the addition of 10% neon to argon had practically no effect.

24. Secondary emission from nickel in a neon discharge. W. UYTERHOEVEN AND M. C. HARRINGTON, *Princeton University*.—Continuing experiments on the secondary emission from a negatively charged metal collector placed in a neon discharge (Science 70, 586, 1929) we obtained additional evidence of a secondary electron current amounting to about 40% of the total current. With the experimental arrangement described before, a perforated collector with a Faraday box behind it, (Phys. Rev. 35, 438, 1930) an estimate can be made of the electron emission due to metastable atoms. This is found to be much more important than the part due to ion impact, namely about 30 to 35% of the total current. When this is deducted from the total secondary emission, values for the number of electrons liberated per incoming positive ion can be estimated. This comes out of the same order of magnitude (10%) as the values determined directly by Penning (Physica 8, 13, 1928).

25. The effect of intense electric fields on the photoelectric behavior of thin potassium films. ERNEST O. LAWRENCE AND LEON B. LINFORD, *University of California*.—Photoelectric thresholds of thin films of potassium on tungsten were observed at 5620Å with fields drawing the electrons from the surface of 260 volts/cm. Increasing the applied fields shifted thresholds towards the red, for example, to 5880Å by a field of 26,000 volts/cm. It is calculated from the data that at distances between $7(10^{-7})$ cm and $12(10^{-7})$ cm of such surfaces the field is entirely the Schottky image field while at greater distances the field exceeds the image field, indicating patched surfaces. Films of potassium on thick layers of oxygen on tungsten show no dependence on fields, indicating either that ion layers exist more than 300 atom diameters from the metal surface which produce fields greater than the Schottky field or that such surfaces are rough. Poor current saturation indicates the latter as more probable. Potassium on a thin oxide layer

has a threshold farthest to the red and exhibits dependence on applied fields assignable to image forces alone. Wentzel's wave mechanics theory of the photoelectric effect is verified in the respects that the whole photoelectric sensitivity curve shifts with the threshold and that the maximum sensitivity occurs at a frequency $3/2$ the threshold frequency.

26. A representation of the dynamic properties of molecules by mechanical models. C. F. KETTERING, L. W. SHUTTS AND D. H. ANDREWS, *General Motors Corporation*.—Mechanical models have been constructed to represent the dynamical systems found in the molecule. Assuming that the intramolecular forces lie along lines associated with the chemical bonds and that for small vibrations they obey Hook's law and have the mechanical character of spiral springs, it is possible to get a picture of the forces and masses which can be represented on a large scale by steel balls and spiral springs. Models have been constructed for some of the simpler nonpolar molecules. They are found to have characteristic frequencies which correspond very closely to the frequencies observed in the Raman spectra and it is possible by this means to identify the Raman lines with definite types of motion of particular atoms in the molecule. This substantiates the view that Raman lines correspond very closely to characteristic fundamental molecular frequencies.

27. The fluorescence spectrum of benzene. F. ALMASY, *University of Zurich*, AND C. V. SHAPIRO, *Cornell University*. (Introduced by R. C. Gibbs).—Using an improved technique, the fluorescence spectrum of benzene, excited by the radiation from a quartz Hg arc, has been photographed with a Hilger E_1 spectrograph, whose dispersion in the region under investigation is 3Å per mm. Wave-length measurements were made from an Fe spark comparison spectrum. The data so obtained are in excellent accord with those for the absorption spectrum in the range over which the two overlap. An energy level diagram is proposed which accounts for the majority of the bands on the assumption that the electronic origin of the system lies at 37489 cm^{-1} (see following abstract). The vibrational frequencies are 923 cm^{-1} for the excited state and 998 and 160 cm^{-1} for the normal state.

28. Electronic transitions in the spectra of benzene. C. V. SHAPIRO, R. C. GIBBS AND J. R. JOHNSON, *Cornell University*.—A review of the available data on the absorption and emission spectra of benzene, together with new data on the absorption of the vapor at higher concentrations, leads to the definite conclusion that only two electronic transitions need be assumed in setting up an adequate energy level scheme, as opposed to the recent suggestions of 5 and 3 respectively, by Austin and Black, (*Phys. Rev.* 35, 457 (1930)) and by Black, (*Nature*, 125, 274 (1930)). These two values are 37489 and 38612 cm^{-1} and are identical with those previously assigned by Henri, *Structure des Molecules*, Paris, (1925), pp. 109, 110. The observed fluorescence spectrum is confined solely to the first of these two systems, while the absorption spectrum is distributed between the two, though showing a much greater intensity in the second. The Tesla luminescence spectrum is very similar to the fluorescence spectrum, except that a few bands corresponding to the most intense of the absorption bands of the second system, do appear.

29. Polarization of sensitized fluorescence. ALLAN C. G. MITCHELL, *Bartol Research Foundation*.—The question of whether or not angular momentum of optical electrons is conserved on a collision of the second kind between an excited mercury atom and a cadmium atom has been investigated. It is well known that under certain conditions mercury resonance radiation is almost completely polarized. It is also known that an excited mercury atom can give its energy to a cadmium atom causing this atom to emit its resonance line $\lambda\ 3261$. In this experiment a mixture of Hg and Cd vapors was radiated by light from a quartz-mercury arc (giving the unreversed 2537Å Hg line). The electric vectors of the exciting light were in the X - Z plane. The Hg-Cd mixture was in a magnetic field (300 gauss) directed in the y direction. The fluorescence from the mixture was observed through a Savart Plate and Nicols prism in the X direction. Under the conditions of the experiment (low pressures of Cd and Hg vapors) the fluorescent light consisted of the 2537Å line of Hg and the 3261Å line of Cd. The Cd line was unpolarized whereas the Hg line was polarized. Had the polarization been carried over on collision one would have expected the Cd line to be polarized in the same direction as the Hg line.

30. The chemiluminescence of metallic sodium. JAY W. WOODROW AND R. M. BOWIE, *Iowa State College*.—It has been known for a long time that metallic sodium and potassium will give off a faint bluish glow when a fresh surface is exposed to the air. This has been attributed to direct oxidation upon contact with the oxygen in the air. A careful check of this effect, however, has shown that it is mostly, if not entirely, due to the water-vapor present. A special apparatus was constructed by means of which it was possible to feed into a gas chamber a fine thread of metallic sodium which always had a fresh surface. When carbon-dioxide or oxygen which had been bubbled through water was passed into this chamber, the sodium thread glowed quite brightly. The effect appeared to be as prominent for the moist carbon-dioxide as for the moist oxygen. On the other hand neither dry oxygen nor dry carbon-dioxide gave an effect which could be detected by the eye even after a half hour in absolute darkness, while at the same time a freshly cut surface of sodium, used as a check, was clearly visible in open air.

31. An electrical method of determining the gelation temperature of starch. E. C. McCracken, *Iowa State College*.—During an investigation of the electrical properties of the potato, it was observed that there was a discontinuity in the resistance-temperature curve. As the potato was heated by an electric current passing directly through it, a sudden decrease in the resistance took place at a temperature between 87° and 88°C. This effect was undoubtedly due to a disruption of the starch grains. Chapman and others have concluded from measurements with the viscometer that this phenomenon takes place at a temperature near 90°C. The electrical resistance method has been found to be quicker, simpler and more accurate for determining this gelation temperature than that in which the viscometer is used.

32. Absorption of ultraviolet light by lacquer films. W. P. DAVEY AND D. C. DUNCAN, *The Pennsylvania State College and Hercules Powder Co.*—Absorption tests on a series of nitro-cotton films, film solutions and their various individual ingredients yielded the following results: None of the films showed selective absorption. They were completely opaque to radiation of wave-length less than about 3300Å. Absorption decreased markedly with increasing wave-length, becoming inappreciable for wave-lengths greater than 4000Å. The absorption was found to be quite independent of viscosity, nitrogen content and such plasticizers as were used. The limitation of transmission to wave-lengths greater than 3300Å was found to be due to ester gum, a constituent common to all of the films. The nitrocotton constituent was quite transparent to wave-lengths greater than 3000Å. Similarly, tests on a series of cellulose acetate films, film solutions and their various individual ingredients yielded no evidence of selective absorption. In this series there was no close correlation between the absorption characteristics of the dried films and the solutions from which the films were made. This was found to be due to the fact that the absorption of the solvents present masked that of the other ingredients. Absorption of solvent-free cellulose acetate films for wave-lengths greater than 2900Å was found to be due to the particular plasticizer used.

33. Transmission of ultraviolet radiation by lake water. CHARLES D. HODGMAN, *Case School of Applied Science*.—Pure water, relatively transparent to the ultraviolet, is rendered less so by the presence of small quantities of dissolved salts and organic materials such as occur in natural river and lake waters. The extent to which ultraviolet radiation, either from the sun or from artificial sources, penetrates such media is of interest for many reasons. A series of measures of the transmission of unfiltered water from Lake Erie, made by the sector photometer and quartz spectrograph for a thickness of 2 cm shows a relatively low transmission ranging from about 74 percent at 0.40 μ to 12 percent at 0.22 μ . Determinations are in progress for water from the same source after filtration and as taken from the city water supply as well as from other sources.

34. Measurement of intensity of helium lines with voltage using a photoelectric device. JOSEPH RAZEK AND PETER J. MULDER, *University of Pennsylvania*.—The variation of intensity with exciting voltage for the lines 6678, 5876, 5016, 4713, 4471, of the helium arc spectrum has been measured using the automatic photoelectric spectrophotometer described by Mulder and Razek before the Ithaca Meeting of the Optical Society of America in Oct. 1929. It was found

the results on $6678(1^1P-2^1D)$, $5878(1^1P-2^3D)$, $5016(1^1S-2^1P)$, $4471(1^1P-3^3D)$ were generally smooth curves, differing somewhat from the results of Hughes and Lowe, (Proc. Royal Soc. A104, 1923 Pg. 480) whereas $4713(1^1P-3^3S)$ shows undoubted maxima near the critical exciting potentials consistent with the results reported by Cornog, (Phys. Rev. 32, 746-752 (1928)). The radiation was developed in a spherical equipotential space 20 cm in diameter, formed of a hollow copper ball. The equipotential cathode and grid from a commercial power tube formed the internal structure, the sphere itself being the anode. The filament, grid and outer sphere were connected to the positive of a battery, with the cathode as the only part inside the sphere at a lower potential. This resulted in a very uniform potential inside the sphere. Direct light from the cathode was cut out by means of a diaphragm on the window in the sphere through which the light was examined. Arc currents as high as 300 milliamperes were obtained with 50 volts across the tube.

35. Further experiments with an automatic photoelectric spectrophotometer. PETER J. MULDER AND JOSEPH RAZEK, *University of Pennsylvania*.—The automatic photoelectric spectrophotometer described by Razek and Mulder before the Optical Society of America, October 1929, has been satisfactorily applied to a series of problems, some of which are detailed. Certain changes in the instrument made possible operation at about ten times the former sensitivity when desired. In this way differences in very dark samples, having an intrinsic brightness of only a few percent, can be readily shown. By a series of tests on biological pigments, the instrument was shown to be admirably suited for testing any solutions that change color rapidly. Three records were taken on an acid hematin solution in six minutes, showing three different stages in its light transmitting property. Records have also been obtained on a 1% solution of oxyhemoglobin in water, both when fresh and when reduced. One record was obtained showing the oxyhemoglobin in the act of reduction. The effect of surface gloss of the sample was tested and found to be negligibly small. All records mentioned, and various other interesting color analyses will be shown.

36. Pictures in relief made with a large diameter lens. HERBERT E. IVES, *New York City*.—Pictures showing relief through a large range of angles and distances of observation (parallax panoramagrams) have heretofore been made by the use of a moving lens, and an opaque line grating slightly separated from the sensitive plate, both plate and grating also being moved in some schemes. All moving parts may be eliminated if a single stationary large diameter lens is substituted for the small moving lens, and provided (a) the transparency positive is placed in front of the grating instead of behind it, (b) the image is given a single inversion, as by a mirror, (c) a grating is used for viewing which has a slightly greater line spacing than the taking grating. The resulting relief pictures are visible through the angle subtended by the lens from the object. The method has the advantages of simplicity of apparatus and manipulation, and of greatly shortened exposure time.

37. Alloys for vacuum-tight glass-metal joints. BY D. E. OLSHEVSKY, *Yale University*.—Joints between materials possessing different physical properties constitute an essential feature of much apparatus involving high vacuum. A glass-metal solder joint occupies—as far as assembling and disassembling is concerned—a position intermediate between direct metal-glass seal and the classical ground joint. In an attempt to find suitable solders ternary alloys of Pb, Sn and Bi were investigated first and characteristic breakages occurring some time after solidification were found to be due to little hard crystals growing out of the interface and pressing against the surface of glass. Several alloys laying on straight lines $E-Pb$, $E-Sn$ and $E-Bi$ as well as in the $E-e_1$, $E-e_2$, and $E-e_3$ valleys (Int. Crit. Tables, v. II, p. 418) were investigated by pouring into Pyrex tubing moulds. An alloy lying on the $E-Pb$ straight line (Pb 50, Bi 37.5, Sn 12.5) was found to possess small glass cracking tendency. This is attributed to separation of soft Pb crystals on cooling. In agreement with the above, alloys obtained by shifting from the eutectic of Pb-Bi-Sn-Cd on a straight line toward the Pb corner (as Pb 31.1, Sn 12.5, Bi 47, Cd 9.4) were also found to have no tendency to burst glass, even in thin layers between glass and metal. The vacuum-tightness of the alloys is still unsatisfactory and joints must be backed by cement for high vacuum work. The joints proved in actual service to be mechanically strong, rigid, vacuum tight and replaceable. Further study is in progress.

38. Studies in contact rectification, II. The cupric sulfide-magnesium junction. MILTON BERGSTEIN, J. F. RINKE, AND C. M. GUTHEIL, *Research Laboratory, P. R. Mallory & Co., Inc.*—The commercial cupric sulfide-magnesium rectifier junction consists of a disk of heat-treated, compressed, cupric sulfide powder contacted with the suitably oxidized face of a magnesium disk. The efficiency of the rectifier unit increases with operating temperature within usual working limits. The phenomenon of "reverse rectification" (i.e. rectification in the direction opposed to normal) is related to the a.c. voltage across the junction. Oscillograms show that there is formation of a film which possesses resistive properties in one direction, that the film may be partially destroyed by continued passage of current in the conductive direction, that application of sufficient voltage in the resistive direction causes re-formation of the film in less than 0.004 sec., that there is no battery effect or thermoelectric effect sufficient to account for rectifying properties, and that formation of the film is probably electrothermic rather than electrolytic in origin.

39. The effect of cyclones and anticyclones upon the intensity of radio signals. R. C. COLWELL, *West Va. University*.—Observations made up by the signal variation of station KDKA at Pittsburgh have shown that the signal intensity increases after nightfall provided there is a low pressure area between Pittsburgh and Morgantown. Hence an increasing intensity after nightfall is an indication of cloudy or stormy weather the next day. An area of high pressure between Pittsburgh and Morgantown will cause the night signal to decrease, so that this type of signal curve indicates fair weather. If the low pressure area passes south of Morgantown, it does not effect the signal. Such a low pressure brings rain with an east wind changing to north and a storm of this kind is unpredictable by observations upon a station to the north of the observer. As with the barometer, the readings indicate weather conditions twenty-four hours in advance.

40. Reflection of radio waves from the surface of the earth. LAL C. VERMAN, *Cornell University*. (*Introduced by E. Merritt.*)—The reflection of an elliptically polarized electromagnetic wave from partially conducting and perfectly conducting surfaces is studied in detail. It is shown that in either case the interference of incident and reflected waves gives rise to a pseudo-stationary wave field above the surface of the reflector. This field is bodily propagated along the horizontal projection of the direction of the incoming wave with a velocity greater than that of light, i.e. $c/\sin \alpha$, where α is the angle of incidence. The resultant electric and magnetic vectors at any given point above the reflector describe two field ellipses lying in two different planes, whose orientation vary with height. This fact is made the bases of experimental measurements.

It is found that the 43 meter wave from WIZ, located in New Brunswick, N. J., holds its polarization and angle of incidence constant during morning hours at Ithaca, N. Y. The rapid fading that accompanies the signal is to be attributed to amplitude fluctuations. Observations on this station are analyzed on the basis of the above theory to obtain the angle of incidence and the polarization of the incoming wave. Polarization is found to be generally elliptical.

41. The x-ray fiber structure of alloys containing precipitated crystals. CHARLES S. BARRETT, *Naval Research Laboratory, Washington, D. C.*—Dahl, Holm, and Masing (*Wiss. Veröffentlich. Siemens-Konzern* 8, 154–185, 1929) prepared cold drawn wires of Be in solid solution in Cu which showed [111] and [100] directions along the wire axis. Annealing these at 350° precipitated a compound of CsCl structure with both [110] and [100] directions in the axis of the wire, the first of which is "a typical crystal position for (fibred) body-centered lattices." Their comparison to ordinary body-centered fibering is without significance because the precipitate was absent when the wire was drawn. The preferred orientation of the precipitate is not due to processes of slip in the precipitate itself, but is due to the precipitate forming with definite orientation on certain planes of the solid solution. Young (*Proc. Roy. Soc. A* 112, 630, 1926) observed such a relation of orientation in meteorites. Similarly, a solid solution of Ag in Al (21.3% Ag) precipitates on (111) planes, with (00.1) hexagonal close-packed precipitate planes parallel to (111) solid solution planes and with [11.0] and [110] directions in these planes parallel, as determined by an analysis of x-ray diffraction from wires.

42. An x-ray determination of crystal orientation in silver sheet, produced by cold rolling. CLEVELAND B. HOLLABAUGH, *The Pennsylvania State College*. (Introduced by Wheeler P. Davey.)—Sheet silver, 99.9%, free from preferred orientation was rolled in 2 1/4 inch rolls and the orientations determined after each pass using the method of Davey, Nitchie and Fuller. (Mines and Met. Tech. Pub. 243, E, 88.) Two symmetrical orientations were found which were independent of the technique of rolling. To picture the resulting preferred orientation, visualize a face-centered cube, with the cube face parallel to the surface of the sheet and with the face diagonal in the direction of rolling. Using the other face diagonal as an axis, rotate the cube until this diagonal makes an angle of not less than 10° , nor more than 42° with the surface. Allow this cube to be rotated at random about the rolling direction as an axis. Any point in this random rotation is within the preferred ranges, provided the face diagonal is in its range of positions. In one of the preferred orientations the direction of rotation is such as to raise that end of the face diagonal which points to the end of the foil entering the rolls first. The other orientation lowers this end of the face diagonal.

43. Radial-asterism in multi-crystalline materials. C. NUSBAUM, *Case School of Applied Science*.—The phenomenon of radial asterism as seen in a Laue photograph of a distorted single crystal is generally attributed to internal strain, whether the strain is produced by a uniform bending moment, compression or tension. It is thus a suitable means for the detection of the presence of internal strains in multi-crystalline materials. A study has been made of radial asterism in such iron samples when subjected to a variable but uniform bending moment. The results are qualitative in nature but are related to the magnitude of the distortion.

44. An x-ray study of very pure iron. O. L. ROBERTS. *The Pennsylvania State College*.—Iron, from chemically pure ferric nitrate, (Baker's Analyzed), was precipitated as the hydroxide and reduced to the metallic state by oxygen-free, dry hydrogen. The metallic powder was pressed into wire form, sintered and swaged. This should give a strictly carbon-free iron. Spectroscopic tests show that the iron is especially free from these impurities. Diffraction patterns were obtained at various temperatures close to the recalcence temperature so as to find the lowest temperature which would cause the change from the body centered to face centered cubic structure. The whole apparatus, including photographic film, was inclosed in an atmosphere of hydrogen. Grain growth was found to take place to a large extent. Face centered cubic structure exists at 921°C .

45. The effect of an electric field on the x-ray diffraction pattern of a liquid. RONALD L. MCFARLAN, *University of Chicago*.—An investigation is made of the effect produced on the x-ray liquid diffraction pattern by an electric field so designed as to give the Kerr effect for the liquid under examination. The liquid diffraction pattern is obtained by replacing the crystal of a Bragg spectrometer with a cell containing the liquid. The electric field is applied approximately normal to the x-ray beam. Under a potential gradient of 9 kv per cm nitrobenzene shows a 2.3 percent increase in the intensity of the diffraction peak, while for a gradient of 5 kv per cm it shows an 0.8 percent increase. Benzene, which shows no Kerr effect for the type of field used, gives a 0.3 percent decrease in peak intensity, the potential gradient being 9 kv per cm. The probable error in all these cases is 0.3 percent. There is thus indicated a small but detectable tendency of the nitrobenzene molecules toward a definite orientation with respect to the electric field.

46. X-ray diffraction in water 2° to 98°C : The nature of molecular association. G. W. STEWART, *State University of Iowa*.—X-ray diffraction ionization curves of water show (1) the presence of two definite peaks corresponding to the separation of diffraction planes of 3.27A and 2.11A; (2) the practically constant diffraction intensity of one peak over the temperature range, 2° to 98°C as compared with the gradual disappearance of the second peak with increasing temperature; (3) correspondence in angle of diffraction between these peaks and the chief diffraction intensities with ice crystals; and (4) the increase of peak width with increasing temperature with a movement indicating less distance of planes. It is difficult to reconcile these results with what was formerly regarded as the alteration, in complexity of

the water molecule. The simplest explanation emphasized by all the experiments in x-ray diffraction in liquids, is that the so-called molecular complexity is the arrangement of molecules in more or less orderly groups with intermolecular forces of distinct magnitude. With temperature increase the nature of the group changes, one set of planes becoming more poorly defined because of more slippage and less orderly arrangement. The alteration in grouping is also shown by the decrease in distance between planes. The group arrangement (cybotactic condition) describes the nature of what has formerly been termed "association" and what is now regarded by Longinescu as "molar concentration."

47. **Electron distribution in the chlorine ion.** G. G. HARVEY AND G. E. M. JAUNCEY, *Washington University, St. Louis*.—Jauncey and Claus (Phys. Rev. 31, 717 and 32, 12 (1928)) have obtained theoretical F values for the chlorine ion in rocksalt from the assumption of a Bohr model in which the Compton effect has been taken into account according to the method of Jauncey (Phys. Rev. 29, 757 (1927)). These theoretical values were in fair agreement with the experimental values. It occurred to the writers to subject both the Jauncey and Claus theoretical F curve and the experimental F curve for chlorine to a Fourier analysis, thus obtaining a U curve. The U curves for different values of D , the grating space, calculated from the experimental F values are independent of the value of D used, being practically superposable. Such is decidedly not the case with the theoretical curves, the general shape changing as well as the peaks shifting. This seems to show that the Compton effect cannot be taken account of in the way proposed by Jauncey and supports the theoretical finding of Waller (Phil. Mag. 4, 1228) and Wentzel (Zeits. f. Physik 43, 1 and 779) that a Schrodinger charge density may be assumed for the atom and the Compton effect disregarded in calculating F values.

48. **Temperature effect in diffuse scattering of x-rays from rocksalt.** W. D. CLAUS, *Washington University, St. Louis*. (Introduced by G. E. M. Jauncey.)—According to Debye (Ann. d. Physik 43, 49 (1914)), the intensity of x-rays diffusely scattered in a direction ϕ from a crystal should be equal to that scattered from an amorphous substance, multiplied by the temperature factor $(1 - e^{-M})$. Experiments by Jauncey (Phys. Rev. 20, 421 (1922)) show that the intensity scattered is proportional to $\sin(\phi - \theta) / \{\sin(\phi - \theta) + \sin \theta\}$ as predicted, where θ is the crystal angle. Experiments are at present being conducted to test the temperature effect. In the temperature range 295° to 135°K, a decrease of approximately 50 percent in intensity is to be expected (depending on slightly different assumptions used in calculation) for $\phi = 30^\circ$ and 60° . Results to date indicate a decrease of not more than 5 percent, in no wise comparable to the expected effect.

49. **Spectroscopic analysis of scattered x-rays.** J. A. BEARDEN, *Johns Hopkins University*.—Davis and his collaborators using a double crystal spectrometer have found a fine structure in the spectra of scattered x-rays. Several investigators using a single crystal method have failed to find any fine structure. The present experiment is a repetition of Davis' experiment using a double crystal spectrometer on the unmodified line. Greater scattered x-ray intensity has been obtained by using a line focus tube and placing the scattering blocks of aluminum and graphite about 5 mm from the focal spot. Two wave-lengths were used, the $K_{\alpha_1}K_{\alpha_2}$ line of silver and the $K_{\alpha_1}K_{\alpha_2}$ line of copper. The capacity of the electrometer system was about 12 cm and the sensitivity of the electrometer 20,000 scale dimension per volt. No fine structure lines of one tenth the intensity of the K_{α_2} line have been observed. Chemical analysis of the scattering blocks showed no trace of copper or silver as an impurity. Measurements have also been made on the Compton shift which agree very closely with the equation $\delta\lambda = (h/mc)(1 - \cos \theta)$.

50. **Scattering of x-rays and the distribution of electrons in helium.** ARTHUR H. COMPTON, *University of Chicago*.—An analysis of the theory of scattering of x-rays by monatomic gases makes it possible to express the probable distribution of the electrons in the atom as a Fourier integral. To evaluate this integral it is necessary to know the intensity of scattering of x-rays of known wave-length at different angles. With data recently obtained by C. S. Barrett the distribution of electrons in atoms of helium gas is thus determined. This distribution agrees

satisfactorily with that calculated by Pauling from wave-mechanics but differs by more than the experimental error from that predicted from Bohr's theory.

51. A direct-reading two-crystal spectrometer for x-rays. F. K. RICHTMYER, S. W. BARNES AND E. RAMBERG. *Cornell University*.—The two-crystal spectrometer developed by Bergen Davis and others provides a means of obtaining monochromatic x-rays of high intensity. Such a spectrometer, reading wave-lengths directly in angstroms, has been constructed, using the principle described by Nicholas (*J.O.S.A. & R.S.I.* **14**, 61, Jan. 1927) for the single crystal instrument. Details of construction and adjustment are described; and sources of error are discussed. The instrument is capable of absolute measurement of wave-lengths, with very high precision.

52. A vacuum spectrograph for the precision measurement of x-rays of long wave-length. CARL E. HOWE, *Oberlin College*.—The spectrograph has four unique features which make it fitted for precision measurements. (1) A slit system, consisting of five slits each one thousandth of an inch wide, excludes optical light and gives excellent collimation of the x-rays. (2) An x-ray tube with interchangeable targets, mounted on a micrometer slide enables the focal spot to be readily lined up with the fixed slit system. (3) A universal grating support permits the plane grating to be set at any desired angle and to be removed in vacuo from the path of the x-rays without disturbing any adjustments. (4) A set of two parallel plate holders at a fixed and known distance apart, placed at right angles to the slit system, permits accurate measurements of angles from the lines recorded on the two plates at different distances from the grating. The slit system and grating support are mounted as one unit which may be completely removed from the rest of the spectrograph for the purpose of making adjustments.

53. An instrument for high-voltage x-ray spectrography and radiography. FREDERICK SILLERS, JR., *Follansbee Bros. Co.* (*Introduced by Wheeler P. Davey*).—The increasing application of the x-ray diffraction method of crystal analysis to the study of materials of construction has led to the desire, in certain fields, for a more rapid method of obtaining results. Such a method may involve the adoption of higher voltages than are now in general use for this type of work. An instrument suitable for use with these higher voltages (in the neighborhood of 200 kv) will be described. The instrument consists essentially of a lead-lined drum equipped with four pin-hole or slit diffractometers, as well as an opening for radiographic exposures. It is adapted to a standard 200 kv installation employing a Coolidge tube. The instrument is so designed that comparable intensities of x-rays at all four diffractometers are available, rendering practicable the comparison of different patterns. Through the use of the present instrument x-ray spectrograms, by direct transmission, of coarse-grained polycrystalline material; e.g., high-silicon sheet steel about 0.02 in. thick for electrical uses, may be obtained in less than an hour. If radiographs are desired during the course of any study, they may be obtained by rotating the tube 90° on its axis.

Points to be discussed deal with strained materials, intensifying screens, optimum voltage, intensity variations, and radiography of fine effects.

54. The dielectric constants of aqueous KCl solutions. ALLEN ASTIN, *National Research Fellow, The Johns Hopkins University*.—Probable causes of the many discrepancies in existing data on the dielectric constants of aqueous electrolyte solutions have been determined and methods of either eliminating them or correcting for them worked out. It is shown that by use of a voltage resonance method, (Jezewski, *Zeits. f. Physik* **48**, 123 (1928)); (Kneikamp, *Zeits. f. Physik* **51**, 95 (1928)); (Lattey and Gatty, *Phil. Mag.* **7**, 985 (1929)) and (Astin, *Phys. Rev.* **34**, 300 (1929)), the necessary corrections are considerably simplified. The voltage resonance curve is also shown to be symmetrical, regardless of the amount of damping. The corrected results show that the dielectric constants of aqueous KCl solutions from concentrations of 0.00025N to 0.01N are no different from that of water, at least within the limit of error of the measurements. The probable error of the corrected results is 2 parts in 1000 at 0.001N. and 6 parts in 100 at 0.01N. The uncorrected results show an apparent decrease of the dielectric constant similar to that reported by most other observers. The magnitude of this apparent

decrease may be varied by changing either the frequency, the size of the test condenser or the dimensions of the leads. The lowering of the dielectric constant in solutions which was predicted by Hückel (Phys. Zeits. 26, 93 (1925)) is much smaller than any reported experimentally and is too small to be detected with the limit of error reported here. Frequency employed is 1.8×10^6 .

55. Time lag in changes of electrical properties of rubber with temperature and pressure. ARNOLD H. SCOTT, *Bureau of Standards*.—When the temperature of rubber is suddenly (within five minutes) changed from one value to another, the electrical properties do not at once assume their final values. Two hours or more may be required for the dielectric constant, power factor, and resistivity to become constant. Part of the data for one specimen are given in the following table:

Time after specimen reaches 150°C (125° Change) Minutes	Dielectric Constant	Power Factor Percent	Equilibrium Temp. corre- sponding to dielectric constant and power factor
3	3.07	2.96	107°C
15	3.52	7.83	120
25	3.83	8.87	128
63	4.32	6.22	144
155*	4.39	4.42	150

* (Equilibrium)

This time lag was studied with specimens of several compositions from soft to hard rubber following temperature changes varying in amount from 75 to 125°C. Data on the time lag with pressure were obtained on only one specimen using pressures between 1 and 700 atmospheres. Twenty-four hours were required for the electrical properties to become constant.

56. Changes in the specific resistance of aluminum. G. E. DAVIS AND GILBERT GREENWOOD, *University of Rochester*.—Measurements on aluminum wires confirm previous investigations concerning the increase of specific resistance with cold-working. Tammann attempted to explain this increase by assuming particle orientation. Such orientation has since been found in the fibrous texture of drawn wires. This explanation, however, requires anisotropic electrical properties of the metallic crystals. Such anisotropy is most unlikely in cubically crystallized aluminum. Furthermore aluminum wires, annealed until the increase in specific resistance is lost, show distinctly fibrous texture. The increase in specific resistance has sometimes been ascribed to lattice distortions caused by the stresses of cold working. v. Arkel investigated such distortions by the effects produced in Debye-Scherrer photographs. The α -lines in such photographs are actually doublets ($K\alpha_1$ and $K\alpha_2$), the sharpness of resolution of which decreases with increasing lattice distortion. Aluminum, completely annealed or cold-worked to different degrees, always shows a sharp resolution of these doublets. Distortions of the v. Arkel type cannot, therefore, be responsible for the increased resistance. Dehlinger discussed distortions extending throughout very minute regions of the lattice—possibly only along the surfaces of the particles. Such distortions would not cause a decrease in the sharpness of the doublets, and might be responsible for the increased specific resistance.

57. Contact resistance and microphonic action. F. S. GOUCHER, *Bell Telephone Laboratories*.—An experimental study of single contacts between granules of microphone carbon, the contact forces being of the order of 1 dyne. For established contacts Ohm's Law is obeyed up to 0.1 volt. The resistance decreases with increase of temperature, the temperature coefficient of resistance being of the same order of magnitude as that of solid carbon wires produced by a heat treatment which is similar to that used in the preparation of the microphone carbon.

Above 0.1 volt (up to 1.0 volt) there are departures from Ohm's Law which can be accounted for by the theory of contact temperature as a function of voltage when a reasonable value of the Wiedemann Franz ratio for carbon is assumed. The conclusion is that the conducting portions of such contacts are carbon to carbon. The temperature coefficient of resistance of a contact varies in a reproducible, but non-systematic manner as the resistance is changed in a reversible resistance force cycle. This shows that new surfaces having coefficients different from the average value are inserted into or removed from the circuit during the cycle.

58. **A theory of the resistance of alloys.** L. W. NORDHEIM, *University of Goettingen* (Introduced by *Alpheus W. Smith.*)—According to the new (Sommerfeld-Houston-Block) theory of metallic conductivity any resistance in a conductor is due to an imperfection of the crystal lattice. Thus the ordinary resistance is due to the heat motion of the atomic ions, and, therefore, is essentially dependent on the temperature, and vanishes at the absolute zero point. In alloys an additional disturbance is introduced because of the irregular distribution of the constituents. This disturbance can be calculated and gives the additional resistance, which is independent of temperature. Most facts about the resistance of alloys are easily explained by this picture. Formulae are given for the simplest cases, which are in good agreement with experiment.

59. **Shot effect of the emission from oxide cathodes.** H. N. KOZANOWSKI (Introduced by *N. H. Williams, University of Michigan.*)—Fluctuations in the electron space current from barium-strontium oxide cathodes at low accelerating potentials are many times as large as those observed in the case of currents from metallic emitters. When space charge is obliterated by the use of high accelerating potentials, the true value of the electronic charge, as predicted by Schottky, is obtained. The results indicate that at low accelerating potentials, positive ions leave the emitter, and travel into the space charge region under the action of the reverse space charge field. Due to the low mobility of the positive ion, large groups of electrons are affected by each positive ion, thus causing large, sudden variations in the space charge. A tube containing a tungsten filament and a Kunsmann emitter surrounded by a cylindrical collector gives the normal shot effect when only the tungsten is heated. The same abnormally high values observed with the barium-strontium emitter are obtained with this tube with a low accelerating potential when positive ions emitted from the Kunsmann emitter interact with the electron space charge around the tungsten filament. Even in this case, the true value of the electronic charge is obtained when the space current is temperature limited.

60. **Effect of positive ion shot effect on space charge limited electron currents.** LLOYD P. SMITH, *Cornell University.*—A transcendental equation has been derived which relates the electron current between two parallel plane electrodes (one of which is a hot cathode emitting positive ions as well as electrons, and the other is a collecting electrode at a potential positive with respect to the cathode) to the total positive ion emission as well as the difference of potential between the electrodes, their distance apart, etc. Curves have been plotted which give the electron current to the collecting electrode as a function of the total positive ion current at various collector voltages. From such relations, the variation in the electron current produced by statistical variations in the positive ion emission can be obtained. Such variations are large compared to the ordinary shot effect. This is to be expected since a positive ion moves relatively slowly through the space charge region liberating a group of electrons during one transit. From the curves it is possible to obtain the difference of potential between the electrodes, at which the fluctuations of the positive ion current produce the greatest variation in the electron current.

61. **Studies of abnormal shot effect in gaseous discharges.** JOHN S. DONAL, JR., *University of Michigan.* (Introduced by *N. H. Williams.*)—Space charge limited electron currents from hot filaments have been found to exhibit extremely abnormal fluctuations when the tube contained argon gas. The abnormality is due to the release of groups of electrons from the space charge region by the positive argon ions. A detailed study has been made of the variation of the abnormal fluctuations with the field, filament temperature and gas pressure, the results

have obvious application to the elimination of extraneous noises in vacuum tubes. Positive ion currents of the order of one microampere have been obtained from tungsten filaments undergoing attack by oxygen. These ions, when trapped in the minimum of potential surrounding a hot cathode, produce very abnormal fluctuations in space charge limited electron currents. An expression for the resulting shot voltage has been developed, which permits the calculation of the average anode current increase due to each positive ion, and the average time of life of the ions in the space charge region. When the positive ions are accelerated to a cold cathode, an abnormal shot voltage is obtained which is unusual in being independent of the positive ion current.

62. Effect of adsorbed thorium on the thermionic emission from tungsten. WALTER H. BRATTAIN, *Bell Telephone Laboratories*.—The thermionic emission from a tungsten ribbon filament on which thorium was deposited, has been investigated. The thorium was derived from a thorium filament placed parallel to one face of the tungsten ribbon. For each successive equal amount of thorium deposited, the corresponding increase in the logarithm of the emission, for a given temperature of the tungsten ribbon, was smaller and smaller until the emission reached a maximum. Continued deposition of thorium caused the emission to decrease and finally approach a stationary value. Further investigation indicated that migration of the thorium to the back side of the tungsten ribbon took place at an appreciable rate at 1500°K. At approximately 1800°K. there was definite evidence of diffusion of thorium into the tungsten ribbon. At higher temperatures, the thorium evaporated from the tungsten surface.

63. The ion-grid theory of the decrease in work function for composite surfaces. J. A. BECKER, *Bell Telephone Laboratories*.—When electropositive atoms are adsorbed on electro-negative surfaces, some of the atoms are ionized. These adsorbed ions act like a positively charged grid very close to the cathode. For a large plane surface, this ionic grid produces strong fields close to the surface but only small fields at larger distances. As a result, the work function is reduced by $4\pi\sigma l$ and the emission current saturates as well as it does for clean surfaces. σ = charge per cm^2 ; l = distance of ions above surface. In most experiments, however, the surface consists of irregularly oriented facets or else the ions form clusters due to the presence of electronegative gases. In these cases the distribution of the fields is greatly dependent upon the size of the facets or clusters. Computation shows that for small applied fields, the work function is decreased by a fraction of $4\pi\sigma l$. As the applied field increases, this fraction increases and the emission current increases much more rapidly than for clean surfaces. For large fields, the current saturates as well as or even better than for clean surfaces. Numerous experimental observations are accounted for by the finite extent of the ion-grid.

64. Grid glow tube relays. D. D. KNOWLES AND S. P. SASHOFF, *Westinghouse Elec. & Mfg. Co., East Pittsburgh*.—The name Grid Glow Tubes applies to a line of gaseous discharge glow and arc tubes, the breakdown of which is controlled by means of a grid. They are, then, essentially relays having a discontinuous grid-voltage plate-current characteristic. These tubes are made in two general types: tubes with a cold cathode and tubes in which the negative electrode is a hot filament—the characteristics of both types being similar. Grid Glow Tubes have been made in sizes ranging from a few milliamperes of plate current up to several hundred amperes. They can be filled with one of the inert gases neon, argon, or helium or with mercury vapor. A study of the behavior of these devices must necessarily include that of the type of circuit in which they are to be used. A series of curves plotted for both a.c. and d.c. voltages on the plate, a.c. and d.c. grid bias and various self biasing schemes are given. The effect of phase shift between the grid and plate voltages when alternating current is used is also illustrated.

65. The radioactivity of Stone Mountain. JAMES A. HOOTMAN AND W. S. NELMS, *Emory University*.—The radioactive content of the waters which issue from the base of the unique geological formation known as Stone Mountain (Georgia) was determined. Tests were made of a number of large springs well distributed around the base of the mountain, and of other shallower sources above and below the 1000 foot level. The method employed was the Schmidt

Shaking Method, in which a known volume of water is thoroughly shaken with a known volume of air in a closed container. The resulting mixture of air and radium emanation is then pumped into an electroscope, and the rate of fall of the leaf is a measure of the radioactivity of the water. The electroscopes were calibrated by means of the Duane and Laborde formula, and corrections were made for temperature and pressure. This method has been shown by Ramsey to have an accuracy of about 3%. A majority of the springs tested were highly radioactive, the value for the highest being $15,980 \times 10^{-12}$ Curies per litre. This value is nearly twice the maximum reported by Boltwood for forty-four radioactive springs, and more than half as large as the maximum reported by Lester for one-hundred-seventy-eight mineral waters of Colorado.

66. The measurement of the intensity of gamma rays of radium in *r*-units. OTTO GLASSER AND V. B. SEITZ, *Cleveland Clinic Foundation*.—Determinations of the intensity distribution of gamma-rays were made under various experimental conditions with a condenser intensitometer previously described. By using small ionization chambers and a system unaffected by penetrating radiations the difficulties usually encountered in such measurements were greatly reduced. The intensities obtained are given in *r*-units.

67. Disintegration constant of actino-uranium and ratio of actinium to uranium. ALOIS F. KOVARIK, *Yale University*.—With data of Fenner-Piggot and of Aston for broggerite, Karlhus, Norway, and also Aston's 206, 207, 208 line intensities in common lead mass spectrum in conjunction with my age formula (Phys. Soc., April 1929) amounts of common lead and AcD are calculated. AcD, uranium, and actinium: uranium ratio (3%) lead to $\lambda = 2.5 \times 10^{-9} \text{ yr}^{-1}$ or $T = 2.7 \times 10^8 \text{ yr}$. Boltwood's 8% (N. Car. uraninite), Hahn-Meitner's 3% (pitchblende) and others, including recent work of Wildish, indicate a variation of the ratio with age of mineral. Considering actino-uranium an isotope of uranium initially in correct proportion to UI, the ratio should vary and 400 million years difference in the age of the minerals will bring Boltwood's and Hahn-Meitner's values into agreement. Furthermore, calculation of this ratio for the age of Keystone, S. D., uraninite (1462 million years) gives 0.6% and for Sinyaya Pala, Carelia, uraninite (1852 million years) gives 0.25%. The latter values receive a check if AcD is practically the only lead isotope left after subtracting RaG and ThD from the total. Broggerites and cleveites do not give such a check because considerable amount of common lead is present.

68. An attempt to detect deBroglie waves of hydrogen atoms. THOMAS H. JOHNSON, *Bartol Research Foundation*.—Earlier work on the reflection of atomic hydrogen from NaCl failed to reveal deBroglie wave diffraction patterns. This was not unexpected because of the low intensity of the specular reflection and the great intensity of the diffuse background, arising principally from the reemission of adsorbed atoms. Lithium fluoride presents a much more favorable opportunity for detecting the wave character of atomic hydrogen. The specular beam is very intense and there is no reemission of monatomic hydrogen. The MoO_3 detecting plate therefore records only elastically reflected atoms. First order surface-grating bands from the LiF lattice were expected with abrupt maxima separated from the specular beam by 20° to 30° . These bands were found, showing that the total number of atoms going into any one is certainly less than 5% of the number in the specular beam. If the crystal was heated to 600° C a diffuse band appeared extending asymmetrically to about 20° on either side of the specular beam. With the crystal at room temperature this largely disappeared.

69. Satellites of electron diffraction beams. H. E. FARNSWORTH, *Brown University*.—While investigating electron diffraction by a copper crystal, for normal incidence on a (100) face, certain beams have been found which require a refractive index of unity. A search for other weak beams of this nature reveals a whole set of such beams which accompany the intense diffraction beams. In many cases these satellites are so close to the regular beams that they are not completely resolved, and hence are not observed by the usual method of measurement. In the (100) azimuth the satellites which accompany the 4 first-order beams below 325 volts all occur within 2 volts of the theoretical values for unit refractive index;

that of one second-order beam occurs within 11.9 volt; that of the other second-order beam is missing. In the (111) azimuth, the satellites of 3 first-order beams are within 2.7 volts of theoretical values; that of the other first-order beam below 325 volts is within 7.3 volts; those of 2 second-order beams are within 5 volts; that of the other second-order beam is within 19.5 volts; that of 1 third-order beam is within 5 volts. These satellites are as sharp in voltage and colatitude angle as the main diffraction beams, and are not confined to large colatitude angles. Hence they are not due to a two-dimensional surface grating. The significance of these diffraction beams is discussed.

70. The capture of electrons by alpha-particles. A. H. BARNES, BERGEN DAVIS AND H. L. HULL, *Columbia University*.—Abstract of this paper is withheld for revision by the authors.

71. Absorption of sodium vapor in the extreme ultraviolet. S. A. KORFF AND J. L. NICKERSON, *Princeton University*.—Employing a vacuum spectrograph, sodium vapor was examined for absorption in the region from 1300 to 300 Angstrom units, against a background of many lines. Vapor pressures used ranged up to 1 mm of Hg. No broad absorption peaks were observed in this region. Extremely narrow peaks would not be distinguishable, however, by this test. This region includes the point at twice the series limit, or 1205.9 Angstrom units. In general, sodium vapor was found to be almost perfectly transparent to radiation in the observed range.

72. Most probable 1930 value of the electron and related constants. R. A. MILLIKAN, *California Institute of Technology*.—This paper discusses, in the light of Zwicky's results on the block structure of crystals, the reliability of old and new measurements on the relations of e and h , and by combining experimental and theoretical considerations assigns most probable 1930 values to these constants.

73. The nature of cosmic radiation. L. F. CURTISS, *Washington, D. C.*.—Two Geiger-Müller tube counters placed vertically above each other show, in addition to accidentals, coincidences which have been ascribed to cosmic rays. Absorption experiments by Bothe and Kohlhörster indicate that these rays are corpuscular. The author has made observations with the poles of a large electromagnet between two counters, recording the number of coincidences with and without the magnetic field. With the field used of 7000 gauss over an area 24 cm in diameter, a parallel beam of 10^9 volt electrons which passes through the upper counter would be deflected sufficiently just to miss the lower counter in spite of the fact that the $H\rho$ for such electrons is approximately 3×10^6 . Since the radiation is actually diffuse with a maximum in the vertical direction, using two counters one can expect only a slight decrease in the coincidences if they are caused by high-speed electrons. However, if they are due to ultra γ -rays, no such effect should be observable. Making the theoretical allowance for accidentals, a decrease of the order of 25% has been observed in the coincidences which may be attributed to cosmic radiation. This confirms the existence of a corpuscular radiation of very high energy.

74. The absorption of acetylene and ethylene in the near infrared. RICHARD M. BADGER, *California Institute of Technology*. (Introduced by Richard C. Tolman).—The absorption spectra of gaseous acetylene and ethylene have been investigated photographically in the region 6800A–9200A. In the case of acetylene a band with very sharp lines, and showing marked intensity alternation was found, with center at about 7886A. It resembles a band found by Levin and Meyer at 3.0μ , of which it is probably a harmonic, but shows strong convergence on the short wave length side indicating a considerable increase in the average moment of inertia due to oscillation. In the case of ethylene a band was found with center at about 8706A which apparently also shows convergence, but which has a rather complex structure. An investigation of the structure of these bands is in progress.

75. The effect of high pressure on the near infra-red absorption spectra of certain liquids. J. R. COLLINS, *Cornell University*.—The state of polymerization of liquids composed of polar molecules is supposed to depend on the temperature, pressure, etc. The near infra-red absorption

bands of these substances, which are due to molecular vibrations, should be affected by changes in the state of polymerization, and hence also by changes in the temperature, etc. Experiments have shown that changes in the temperature changed the spectral position and intensity of absorption bands of water and certain alcohols, while the bands of benzene, a nonpolar substance, were unaffected by changes of temperature. The present experiments are measurements of the absorption of water, methyl alcohol, and iso amyl alcohol as examples of polar substances, and of toluene as a nonpolar substance, when these substances were subjected to pressures up to 5000 atmospheres. The pressure chamber was designed by P. W. Bridgeman and the measurements were made in the Jefferson Laboratory at Harvard University. No change was found in the position of any of the absorption bands studied. The conclusion is made that, in this pressure range, the state of polymerization does not depend on the pressure.

76. Bismuth-black and its applications. A. H. PFUND, *Johns Hopkins University*.—If a bit of bismuth be evaporated from a spiral of incandescent tungsten wire in a space evacuated to a pressure of about 0.25 mm of mercury, the bismuth is deposited as an intensely black film. For visible light, the diffuse reflectivity of "bismuth-black" is but one sixth that of camphor black. Tests have shown that bismuth-black films which are opaque to visible light, transmit and reflect at normal incidence, less than 1% of infra-red radiation out as far as 13μ . It was decided to use this new material on the receiving areas of delicate thermopiles, radiometer vanes, etc. Quite apart from the blackness and small heat capacity of bismuth-black, a further advantage is gained because of the circumstance that the most delicate surfaces may be blackened without the least danger of harming them. Because of the fineness of the particles, films of bismuth-black on plate glass reflect specularly at grazing incidence. Films which are rough at all angles of incidence may be produced by depositing, first, an extremely thin (grayish) film of soot from burning camphor upon which the bismuth-black is subsequently thrown down. It appears that the soot particles act as centers of condensation and, as a result, the bismuth-black is built up in the form of minute pyramids. Delicate surface bolometer's were made by forming a layer of nitrocellulose so thin as to show first-order Newton's colors. Upon this film was deposited a highly reflecting film of bismuth. The best attainable vacuum—less than 10^{-4} mm Hg—was required. This film was an excellent conductor for electricity. Air was then admitted so as to raise the pressure to 0.25 mm and the absorbing film of bismuth-black was thrown down. This general mode of procedure is being applied to the construction of thermopiles.

77. The effect of aberrations in limiting the resolving power of infra-red spectrometers. R. BOWLING BARNES AND A. H. PFUND, *Johns Hopkins University*.—Because of the increasing demand for high dispersion infra-red measurements, it seems timely to call attention to some of the difficulties which arise when very small "slit-widths" are used, and to a method of overcoming them. In the usual spectrometer, concave mirrors must be used off the optic axis, and unless these are parabolized along the proper axes, noticeable aberrations are present. Due to astigmatism and coma the slit image is broad and accompanied by a diffuse wing. If the eye is placed behind S_2 , and the grating viewed in monochromatic light only a small portion of it will be illuminated, the jaws of the narrow slit having blocked out the light from some parts. One then, never gets the advantage of the full aperture, and the spectrum used is very impure. By a method somewhat similar to that described by Pfund (*J.O.S.A.*, April 1927), spherical mirrors of aperture $f \cdot 4$ can be used along the optic axis, and to full advantage. The radiation, after falling upon each of the spherical mirrors, M_1 and M_3 , is reflected along the axis to the plane mirrors, M_2 and M_4 respectively. These mirrors, containing oversized slits at their centers, are placed just in front of the slits S_1 and S_2 , and are inclined to the optic axes at the desired angles. With this arrangement the eye looking through S_2 , sees the entire grating filled with light no matter how narrow the slits are made. This is a necessary result if one wishes to work with very small "slit-widths".

78. On the theory of the Brownian motion. L. S. ORNSTEIN, *University of Utrecht, Holland* AND G. E. UHLENBECK, *University of Michigan*.—Using a method first indicated by Ornstein (*Proc. Acad. Amst.* 21, 96, 1917) the mean values of all the powers of the velocity

u and the displacement s of a free particle in Brownian motion are calculated. It is shown that $u = u_0 \exp(-\beta t)$ and $s = u_0/\beta [1 - \exp(-\beta t)]$ where u_0 is the initial velocity and β the friction coefficient divided by the mass of the particle, follow the normal Gaussian distribution law. For s this gives the exact frequency distribution corresponding to the exact formula for S^2 of Ornstein and Fürth. Discussion is given of the connection with the Fokker-Planck partial differential equation. By the method exact expressions are obtained for the square of the deviation of a harmonically bound particle in Brownian motion as a function of the time and the initial deviation. Here the periodic, aperiodic and overdamped cases have to be treated separately. In the last case, when β is much larger than the frequency and for values of $t > \beta^{-1}$, the formula takes the form of that previously given by Smoluchowski.

79. A test of the Dalton-Gibbs law of partial pressures. LOUIS J. GILLESPIE. *Massachusetts Institute of Technology (Introduced by F. G. Keyes).*—According to Gibbs' formulation the pressure of a gaseous mixture equals the sum of the partial pressures, $P = \sum_i p_i$, when p_i is conceived as the pressure of pure gas 1 that would just prevent the gas 1 in the mixture from escaping through a membrane permeable to it alone. This can be shown equivalent to the statement: The "density" (or concentration) of a gas is the same at equilibrium on either side of a membrane permeable to it alone. Examination of the data of Larson and Black and of Lurie and Gillespie shows the following: (1) The mole fraction of ammonia mixed with 3:1 hydrogen-nitrogen mixture at temperatures from -20 to $+20^\circ$ C, and of ammonia mixed with nitrogen at 45° , is greater than that calculated from the Gibbs formulation, by an amount that increases with the pressure at low pressures (50 atm. plus). (2) In the case of the hydrogen-nitrogen mixtures the difference appears to pass through a maximum at 100-300 atmospheres. (3) The difference may reach 25% of the observed mole fraction. (4) Considered as a possible basis for the thermodynamic treatment of gaseous equilibrium the Gibbs formulation must be regarded as approximate, like its analog, the fugacity rule of Lewis and Randall.

80. A rational basis for the thermodynamic treatment of mixtures of real gases. JAMES A. BEATTIE, *Massachusetts Institute of Technology.*—In the treatment of the thermodynamic properties of gas mixtures several assumptions are necessary. It is now found that two assumptions suffice: One relates to the isothermal variation of the energy of pure gases and the other to the isothermal variation of the ratio of the equilibrium pressure of a gas in a mixture to the total pressure multiplied by the mole fraction of the gas. From these two assumptions it can be shown that at infinitely low pressures the following relations hold for all real gases: (1) The laws of Boyle and Avogadro, (2) the energy, entropy, heat content and thermodynamic potentials of a mixture of gases are equal to the sums of the corresponding quantities for the component gases existing each by itself with the same value of its volume, temperature and chemical potential as in the gas mixture; (3) the energies and heat capacities of gases and gas mixtures are functions only of the temperature; (4) $p_v = nRT$ for pure gases and $p_v = \sum_i (n_i)RT$ for gas mixtures where T is thermodynamic temperature.

81. A thermodynamic theory of excitation of nerves. N. RASHEVSKY, *Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.*—In their ionic theory of nervous excitation, W. Nernst (Pflügers Archiv, 122, 275, 1908) and A. V. Hill (Journal of Physiology, 40, 190, 1910) considered the motion of ions near a membrane, correspondingly between two membranes. Though the last case, worked out mathematically by Hill, accounts for the general features of the experimental excitation time curve, it does not account, without additional hypothesis, for the fundamental fact that the rate of increase of the exciting current is of prime importance. In the present paper, it is first pointed out that the boundary conditions, used in the mathematical treatment of Hill, cannot correspond to physically real cases, and a modified treatment is considered. Furthermore, it is shown that not only the general shape of the excitation time curve, but also the dependence on the rate of change of the exciting current, can be accounted for by purely thermodynamical considerations, which do not involve any special hypothesis about the ionic mechanism of excitation, and are based on considerations of systems with several equilibria.

82. The energy of dissociation of normal Cd_2 . J. G. WINANS AND R. ROLLEFSON, *University of Wisconsin*.—Kapusinski and Jablonski (Zeits. f. Physik 57, 692, 1929) give an interpretation of the Cd absorption flutings between $\lambda 2825$ and 2590 which yields 1.0 volts for the dissociation energy of normal Cd_2 . From an interpretation of the Cd absorption band at $\lambda 2212$ Winans (Phil. Mag. 7, 555, 1929) obtained 0.20 volts for this dissociation energy. Walter and Barrett found that cadmium vapor from which electronegative elements had been excluded failed to show the $\lambda 2825$ – 2590 flutings but still gave the 2212 band in absorption. They attributed the flutings to impurities in the cadmium and the 2212 band to cadmium molecules. The value of the dissociation energy obtained from the flutings is therefore doubtful. Also one should not expect an energy of dissociation as high as one volt for molecules like Cd_2 . Since cadmium is a closed shell atom, a molecule formed by the union of two unexcited Cd atoms must be held together by polarization forces only. That such forces are too small to account for a large energy of dissociation of Cd_2 is made very plausible by consideration of the fact that the alkaline earths and helium which have a similar electronic configuration show no molecular absorption. The work of Koernicke on Hg_2 indicates that the energy of dissociation of such molecules is of the order of 0.1 volts.

83. The composition of the interior of the earth. A. A. BLESS, *University of Florida*.—The high density of the whole earth as compared with the density of the crust is usually accounted for by the hypothesis that the core of the earth is composed of iron. This hypothesis is inadequate for a number of reasons, the chief of which is that it gives an iron content for the earth much too high compared with the abundance of this element in the sun or in other stellar bodies. Without introducing such a radical hypothesis the high density of the interior of the earth may be explained as being due to the ionization of the materials composing the core, the ionization being produced by the collision of atoms moving with the high velocity of thermal agitation. A temperature sufficient to cause ionization by collision would be reached at a depth of 2000 miles if the temperature gradient observed near the surface remains constant for this distance. At a comparatively short distance from the surface the high temperature would cause decomposition of molecules. The permanent gases so liberated would form an envelope around elements which are solid at ordinary temperatures, these elements forming the core. The ionization of the material of the core by decreasing the size of the atom, would increase the density sufficiently to account for the observed mass of the earth. The suggested distribution of the material gives the proper value for the moment of inertia of the earth, and is also in qualitative agreement with data concerning the propagation of seismic waves.

84. Striations and magnetic effect in electrodeless discharges. J. TYKOCINSKI-TYKOCINER AND JACOB KUNZ, *University of Illinois*.—Electrodeless tubes filled with H_2 (0.01 mm Hg) were placed in the field of a coil with high frequency currents (3000–12000 kc.) of constant amplitude. Striations appearing in pairs were observed. Their number decreases with current density. Moving a tube away from a flat spiral coil is equivalent to decreasing the density of the discharge current, consequently the number of striations increases. At a certain critical distance the striations pass through a transitory stage of irregular movements to and fro and disappear then altogether giving place to a uniform glow. Striations were also obtained with the axis of the tube directed perpendicularly to the axis of the exciting coil, showing that the striations are not necessarily connected with ring discharges. A magnetic field applied perpendicularly to the axis of the tube produces a rotational deflection of each striation clockwise and perpendicular to the direction of the magnetic field. This deflection may be interpreted by the Biot-Savart action of the magnetic field on the radial component of currents formed by carriers moving spirally with increasing radii around the axis of the tube and directed outward. A similar interpretation is applicable to striations produced by high frequency discharges in tubes supplied with inner or outer electrodes.

85. High frequency electrodeless discharge characteristics. OTTO STUHLMAN, JR., M. D. WHITAKER, M. L. BRAUN, *University of North Carolina*.—These discharges are classed as primarily due to electrostatic and to electromagnetic fields. Excitation by damped and by un-

damped frequencies are considered. The investigation involved the production of a glow discharge in mercury vapor as a function of frequency, pressure, current, and visual intensity. With a predominant electrostatic excitation and damped frequencies no simple relation was found to exist between visual intensity of the discharge and pressure, current, or frequency. However, consistent irregularities, characteristic of the gas and the mode of excitation, were obtained. With continuous wave and predominant electromagnetic excitation the minimum currents necessary to initiate, and necessary to sustain, the glow discharge were investigated at pressure ranging from 0.1 to 2.0 mm. For each frequency there exists a critical pressure at which the current through the coil required to initiate the glow discharge, and the current required to sustain it, are at minimum values. The ratio of these two currents is not constant for all pressures, but generally increases with increase in pressure. A characteristic arc transition from spark discharge at high pressure to arc discharge at lower pressures, occurred near 0.025 mm.

86. Relative intensities of arc and spark lines of the electrodeless discharge in mercury vapor. O. P. HART AND O. STUHLMAN, JR., *University of North Carolina*.—Excitation of discharge took place in a 12.5 cm spherical bulb placed inside a helical coil 14.5×44 cm when the latter was supplied with damped high frequency current. Three sets of spectrograms were taken—(A) Radiation intensity as a function of pressure with frequency and potential constant. (B) Intensity as a function of frequency with potential and pressure constant. (C) Intensity as a function of potential with frequency and pressure constant. Spectrogram series (A) showed that as the pressure was decreased (0.026 to 0.0005 mm) the intensity of the arc lines increased, whereas the intensity of the spark lines decreased. Series (B) showed that as the frequency of the excitation current was increased the intensity of the arc lines increased. No spark lines were observed at low pressures (0.0002 mm). Series (C) showed that as the potential between the terminals of the coil was increased the intensity of the arc lines increased. No spark lines appeared at this pressure (0.0002 mm). At low pressure and with increasing potential the triplet 4358, 5460, 4047 first appeared followed by the singlets 5790, 4347, 3906 in order of decreasing intensities.

87. Time lags in spark discharges at high overvoltages. J. C. STREET, *University, Va.*—Further studies of the long time lags in dry filtered gases at high overvoltage, first reported by Beams and Street (Phys. Rev. 35, 658 A), have been made. Surge potentials were applied and the time lags were measured by a comparison method. Several enclosed gaps were constructed and tested, care being taken to remove the residual ions. In each case for air, nitrogen or hydrogen at atmospheric pressure the lags remained longer than 10^{-6} sec. until fields of about 3×10^5 volts per cm were reached. With an increase to 3.3×10^5 volts per cm the lags became less than 5×10^{-8} sec. The magnitude of the field, at which the transition from long to short lags begins, is little affected by increase in pressure, amounting only to about 3.4×10^5 volts per cm at three atmospheres. On the other hand it is remarkably increased by a previous treatment consisting of discharges between the electrodes at reduced pressures in hydrogen. After this procedure, fields of 6×10^5 and 5×10^5 volts per cm for spherical electrodes of brass and steel respectively were required to produce lags shorter than 10^{-6} sec. Fields of the same order of magnitude as those just mentioned were required to produce a spark under the same circuital conditions in high vacuum between the same electrodes.

88. A direct measurement of the velocity of cathode rays. CHARLOTTE T. PERRY AND E. L. CHAFFEE.—The method used in this experiment makes no assumptions as to the law of deflection of moving electrons in magnetic and electric fields but measures the time of flight of the electrons directly in their passage over a distance of about 75 cm. Electrons are projected through a long tube by a potential E . In their journey they pass through two very localized alternating electric fields. These deflecting fields are produced by a very high frequency oscillator connected so that the fields are 180° out of phase. Only those electrons which pass when the fields are zero reach the end of the tube. The time required to travel the distance between fields is an even multiple of the half period of oscillation of the fields. The accuracy of determination of velocity is better than 0.1% and results are given for various driving voltages E .

89. The ionization of helium and neon by electron impact. PHILIP T. SMITH AND JOHN T. TATE, *University of Minnesota*.—The total positive ion current per electron per centimeter path has been measured as a function of the energy of the impacting electrons up to 3000 volts in neon and up to 4500 volts in helium, using a modified Jones type of apparatus (T. J. Jones, *Phys. Rev.* **29**, 822 (1927)). Both helium and neon exhibit well-defined maxima which occur at 110 and 170 volts respectively. The ratio of the positive ion current to the electron current per centimeter path reduced to 1 mm pressure and 0°C at the maxima was 1.256 for helium and 3.056 for neon. At 3000 volts the ratio was 0.172 for helium and 0.605 for neon. It was found that for energies from about 500 volts to 3000 volts the efficiency of ionization of neon is a linear function of V^{-1} , where V is the energy of the impacting electrons in volts. In helium the efficiency is a linear function of $V^{-1/2}$ from about 500 to 2000 volts. Beyond 2000 volts the efficiency approaches a linear function of V^{-1} . The empirical formula

$$3.383 (V_0/V)^{1/2} \left[1 - \exp \left(-\frac{54V_0}{V} \right) \right]^{1/2} \left[1 - \exp \left(-\frac{V - V_0}{2.28V_0} \right) \right]$$

expresses the efficiency of ionization of helium, within the experimental error, from the ionization potential V_0 to 4500 volts. The above results were free from any effects due to secondary electrons, and were independent of the pressure, electron current, and the magnetic field.

90. The absorption coefficient for slow electrons in gases. C. E. NORMAND AND R. B. BRODE, *University of California*.—The absorption coefficients or the effective collision cross sections have been measured in H_2 , He, Ne, A, N_2 and CO for velocities of the electrons from 0.5 to 400 volts. With a higher resolution of velocity a fine structure in the absorption coefficient curves has been found for all of these gases. At the lowest velocities, about 0.5 volts, all of the curves are rising with decreasing velocity. The minimums in the absorption coefficients occur between 0.5 and 1.2 volts for these gases. Ramsauer and Kolloth (*Ann. d. Physik* **4**, 91 (1930)) have reported minimums for He and A and none for the other gases. Their scale of velocity is, however, in disagreement with the velocities measured here, being 0.5 volts lower. When adjusted for this difference the data are in agreement.

91. Heating of a cathode by positive gas ions, and their "accommodation coefficient." C. C. VAN VOORHIS AND K. T. COMPTON, *Princeton University*.—Positive ions of helium, neon or argon were produced by a low voltage arc at low pressure and were made to bombard a spherical molybdenum collector with regulated velocities up to 140 volts. The resulting heating of the collector was measured by a thermal junction and found to be *considerably less* than the product of current by bombarding voltage. The problem was to account for the undetected remainder of the energy. Both calculations and experimental tests showed that this cannot possibly be explained as the result of part of the apparent ion current actually consisting of secondary electron emission or of ions losing energy at collisions with molecules. After making all such corrections, we are still forced to conclude that a fraction of the kinetic energy of the incident ions is carried away by ions (atoms) after neutralization. The fractions of their energies delivered to the cathode by the ions are the following "accommodation coefficients": He 0.4 to 0.5, Ne 0.7, A 0.8, which are strikingly similar to the gas kinetic values. There are a number of interesting applications of this discovery.

92. Angle and energy distribution of electrons rebounding from gaseous molecules. A. L. HUGHES AND J. H. McMILLEN, *Washington University, St. Louis*.—The distribution of electrons rebounding at definite angles from gaseous molecules was investigated. An electrostatic re-focusing arrangement was used to analyse the energies of the electrons. In helium, it was possible to identify the following energy losses at several angles, 21.12, 22.97, and 23.62 volts for a primary electron beam of 100 volts, but not the 19.77 and 20.55 volt losses. The number of electrons, rebounding without loss of energy, was measured for different angles of rebound (7° to 80°) from argon, helium, and molecular hydrogen molecules, and for various energies (50 to 15) volts. In almost all cases, the number decreased rapidly as the angle in-

creased. The higher the energy of the electrons, the more rapidly did the number fall off with increasing angle. The steepness of the curves increases as we go from argon to helium to hydrogen for the slower electrons. For the faster electrons their curves are practically superposable.

93. An attempt to detect collisions between photons. G. E. M. JAUNCEY AND A. L. HUGHES, *Washington University, St. Louis*.—It has been shown that if two photons, of identical frequency, moving along paths making an angle of 120° with each other, collide, and produce one photon travelling forward along the line bisecting the 120° angle, and another photon traveling in the opposite direction, the frequency of the photon traveling forward must be 1.707 of the frequency of the original photons (Hughes and Jauncey, *Phys. Rev.* **33**, 290 (1929)). This suggested the following experiment. Two beams of sunlight (one suitably deflected by a mirror), filtered through red glass, were passed through lenses 10 inches in diameter, so that the beams, whose axes made an angle of 120° with each other, intersected at a common focus. As the diameter of the beams at the focus amounted to only 4 mm, great concentration of light was obtained. The point of intersection of the beams was examined through a green filter with the eye which had been rested in total darkness for periods up to an hour. No light was detected. It was estimated that if the photon has a cross section, effective for the type of collision here contemplated, it must be less than 10^{-11} cm.

94. On the principle of Huyghens. G. E. UHLENBECK, *University of Michigan*.—Attention is called to the general formula:

$$\int_0^\infty d\nu \int_{-\infty}^{+\infty} f(\xi) \sin \nu(x - \xi) d\xi = P \int_{-\infty}^{+\infty} \frac{f(\xi)}{x - \xi} d\xi$$

where P denotes Cauchy's principal value. An exact (not published) proof of this has been given by Droste, when $f(\xi)$ fulfills the Dirichlet conditions. One has to compare this with the Fourier's integral theorem:

$$\int_0^\infty d\nu \int_{-\infty}^{+\infty} f(\xi) \cos \nu(x - \xi) d\xi = \pi f(x).$$

By integrating the wave equation in n dimensions $(\partial^2/\partial t^2 - \Delta_n)\psi = 0$ with given initial values for ψ and $\partial\psi/\partial t$ according to the method of Fourier-Cauchy, one can show that the curious difference between the formula's (1) and (2) reflects the well-known fact that the principle of Huyghens is not valid in spaces with n even number of dimensions and valid in spaces with an odd number.

95. The Stark effect near the series limit. JANE DEWEY, *University of Rochester*.—The number and position of the lines appearing near the limit in a hydrogen-like spectrum have been investigated on the Bohr theory, extending the work of Robertson and the writer (*Phys. Rev.* **31**, 973 (1928)). From a study of the limiting cases, for which the complete equation can be handled more easily than in the general case, it appears that only orbits with principal quantum number less than a given number (approximately $43/F^{1/4}$) are periodic in the presence of a field. The region in which both lines and continuous spectrum appear is due to the large displacement of the lines. The outer components of the last group of lines appearing in a field of 1 e.s.u. per centimeter are displaced 50 cm^{-1} . For small fields the position of all the lines is given correctly by the perturbation theory if the second order terms are taken into account, as lines for which the series would not converge do not appear. The large displacements and large number of lines which appear near the series limit in a field make it probable that the lines observed in discharges in this region are the central components of the group of lines having the same principal quantum numbers and that the other components are spread over the background by the stray fields necessarily present. The apparent sharpness of the lines is thus not a criterion for no spreading out of the lines and an experimental investigation of the effect would be very difficult as it would probably not be possible to maintain a field sufficiently constant to observe the higher series members distinct from one another.

96. Zeeman effect in the calcium hydride band spectra. WILLIAM W. WATSON AND WILLIAM BENDER, *Yale University*.—The Zeeman effect in the red CaH bands has been investigated at several field strengths to 30,000 gauss, with a dispersion of 2.1 Å per mm. For $K < 7$ in the $^2\Sigma \rightarrow ^2\Sigma$ system, the P_1 and R_1 lines (parallel S) are unaffected at all fields, while the P_2 and R_2 lines (anti-parallel S) mostly become diffuse doublets shading away from the no-field position. All P_1 and R_1 lines of higher K value have at low fields only a strong, broad component shifted to the red with the extreme edge at about $\Delta\nu_{\text{norm}}$, the breadth decreasing as K increases. At 30,000 gauss a broad weak violet component appears. The P_2 and R_2 lines with $K > 8$ are merely broadened to the violet, the overall width being approximately $\Delta\nu_{\text{norm}}$. The lines of low K values in the $^2\Pi \rightarrow ^2\Sigma$ band give field patterns as expected from Hill's theory. For $K > 22$, the lines involving F_1 states rapidly broaden out, and for highest K values are of negligible intensity. The lines arising from F_2 levels, remain sharp and strong for all high rotational states, but shifted to the violet by about $1/2(\Delta\nu_{\text{norm}})$. These effects can be explained by a consideration of the "rho-type" doubling involved.

97. Electro-optical modifications of light waves. L. H. STAUFFER, *University of California* (Introduced by Ernest O. Lawrence).—Broadening of the satellites of the Hg green line $\lambda 5461$ was observed when the light passed between the plates of a Kerr cell on which was impressed a varying E.M.F. having a frequency of $2 \times 10^7 \text{ sec}^{-1}$. The E.M.F. was obtained by superposing the output of a vacuum tube oscillator upon a steady potential of about 7000 volts. The maximum oscillator voltage was about 5000 volts. With this voltage the fine structure of the Hg green line became so diffuse that two satellites having a separation of 0.045 Å were scarcely resolved by the Lummer-plate. The broadening was observed to increase rapidly with the oscillator voltage. The observed effect is predicted by the classical electromagnetic theory and constitutes a proof of the generalized Doppler principle. The high frequency voltage effects a rapid variation of the refractive index of the nitrobenzene in the Kerr cell which in turn produces a corresponding variation in optical path, giving the source a virtual velocity. The observed broadening is in agreement with the predictions of classical theory.

98. The electric double refraction in gases. J. W. BEAMS AND E. C. STEVENSON, *University of Virginia*.—A method for the study of the electric double refraction or Kerr effect in gases as a function of pressure has been devised. Light of known frequency was passed through a Nicol prism, between two parallel metal plates, through a second Nicol prism and into a photoelectric cell. The two Nicols and the metallic plates across which the electric potential was applied were inclosed in a heavy steel tube with glass ends. As a result, the Kerr effect in the gas could be studied at a few hundred atmospheres pressure without introducing errors due to strains in the windows. Intense electric fields could also be employed because of the large value of the dielectric strength of the gas at high pressures. The precision of the method was limited only by the precision with which the potential across the plates could be measured. The results indicate that in the case of CO_2 the Kerr constant per molecule does not change by as much as 2 percent between 15 and 45 atmospheres pressure at 21°C . An easily measurable Kerr effect was observed in O_2 and N_2 at 100 atmospheres pressure.

99. Spontaneous temperature changes accompanying magnetization in steel. W. B. ELLWOOD, *Columbia University*.—The purpose of this experiment is to determine the dissipation of energy accompanying magnetization in iron by observing the change in temperature of a test specimen produced by a change in the magnetizing force at consecutive intervals in a single cycle of magnetization. The test specimen is in the form of an ellipsoid consisting of 104 bars of #57 drill rod alternate with 104 similar copper rods arranged in coaxial concentric cylinders. One hundred and two thermocouples in series are constructed by connecting adjacent copper and steel bars with 3 mm lengths of constantan and copper wire. Adequate thermal insulation isolates the specimen from the magnetizing solenoid in which it is placed. A temperature change of 3×10^{-6} degrees Centigrade can be detected. The specimen is put in a cyclic magnetic state and allowed to come to thermal equilibrium. On traversing the hysteresis loop from $+290$ to $+20$ gauss, heat is evolved by the iron and is measured as an increase in temperature.

On further demagnetization from +20 to -6 gauss the iron cools suddenly. From -6 to -90 gauss, the iron heats most rapidly. Increase of the field to -290 gauss is accompanied by cooling of the iron. Temperature-magnetization curves for various other magnetic paths are described.

100. The propagation of large Barkhausen discontinuities along wires. K. J. SIXTUS AND L. TONKS, *General Electric Co.*—Preisach has shown that by applying increasing tension or torsion to a wire of nickel iron alloy, the Barkhausen discontinuities in magnetization become larger and larger. Finally, at a tension near to the elastic limit, a rectangular hysteresis loop is produced whose discontinuous change in magnetization includes 97 percent of the whole difference between positive and negative saturation. Langmuir suggested that this sudden change in magnetization starts at a nucleus from which it propagates along the wire. Investigation based on this view shows that the nucleus forms in a uniform field at a somewhat variable critical field strength, and at different points along the wire, depending apparently on uncontrolled factors. The nucleus can be made to form at a definite point, however, by applying locally a small additive field, and the discontinuity will then propagate into the uniform portion of the field, the strength of which can be smaller than the critical field strength. The velocity of propagation increases for a given sample with increasing field strength and tension. A 10% Ni-90% Fe wire of 0.038 cm diameter showed velocities up to 14000 cm sec⁻¹

101. The mobilities of ions in moist and dry air. JOHN ZELENY, *Yale University*.—Using the method recently described (Phys. Rev. 34, 310, 1929) the distribution of mobilities of aged ions in *dry air* has been determined and the values for moist air remeasured because of a neglected correction. The dissymmetry in the distribution of mobilities around the most numerous kind noted in the previous paper for *negative ions* in moist air, was found more pronounced in air dried by calcium chloride. In air dried further by passage through coils and filters immersed in liquid air a second distinct group of negative ions constituting about 35 percent of the total number and having a peak mobility of about 1.45 cm/sec was partially resolved. Under the last conditions the positive ion distribution curve also shows some dissymmetry indicating a possible group with a peak mobility of about 1.5 cm/sec. The mobility of the ions at the main peak of the distribution curve *decreased* for *positive ions* from 1.36 cm/sec for air with a water content of about 2 mg/liter to 1.05 cm/sec for the driest air used. Under similar circumstances the mobility of the *negative ions increased* from 2.08 cm/sec to 2.45 cm/sec. The existence of the two groups of negative ions is ascribed to a difference in size of the ion clusters arising from a difference in constitution at or near their centers.

102. Restriking of short a.c. arcs. F. C. TODD AND T. E. BROWNE, JR., *Westinghouse Elec. and Mfg. Co., East Pittsburgh*.—The restriking after zero current of short a.c. arcs with melting electrodes and of rapidly moving arcs with cold electrodes was investigated with a cathode ray tube of the Braun type. Long exposure photographs and observations of the volt-ampere traces on the fluorescent screen show the effect of the electrode vapor on the magnitude and variation of the restriking voltage. Brass, copper, iron, tungsten, and carbon were used as hot electrodes. The restriking characteristics of rapidly moving cold electrode arcs are influenced by the condition of the electrodes, magnitude of the driving magnetic field, and rate of rise of the voltage after current zero.

103. Extinction of short a.c. arcs between brass electrodes. T. E. BROWNE, JR. AND F. C. TODD, *Westinghouse Elec. and Mfg. Co., East Pittsburgh*.—Results are given which show that the dielectric recovery after current zero of short, stationary, a.c. arcs between brass electrodes is similar to that of cold-electrode arcs previously investigated and described. These results also show that the rate of recovery of dielectric strength of hot-electrode arcs after a current zero *may be greatly increased* by reducing, within limits, the electrode separation. An explanation is suggested on the basis of ionic diffusion to the electrode surfaces and the deionizing action of blasts of metal vapor from the boiling electrodes.

104. Problems suggested by an uncertainty principle in acoustics. G. W. STEWART, *State University of Iowa*.—At the suggestion of Professor A. Landé the principle adopted is

$\Delta\nu \cdot \Delta t \sim 1$, where ν is the intrinsic frequency of an acoustic signal and Δt is its time duration. Applying this principle one finds that it is consistent with experiments on the change in ν in the vibrato and the failure to detect it by ear, with recorded tests on minimum perceptible differences in frequency, and with the minimal time for tone perception. The problems suggested by the principle are: (1) variations in Δt and $\Delta\nu$ by an artificial vibrato with aural observations of detectable $\Delta\nu$, (2) redetermination of minimum perceptible differences in frequency as dependent upon Δt and (3) an examination of Δt required for tone perception with varied values of $\Delta\nu$ required for so-called tone perception.

105. The dispersion formula and Raman effect for the symmetrical top. MORRIS MUSKAT, *Gulf Research Laboratory Pittsburgh*.—Schroedinger's theory of dispersion is applied to the symmetrical top. The dipole of the top is assumed to lie along the axis of symmetry, and the wavelength of the incident light to be large as compared with the dimensions of the top. An explicit expression is derived for the index of refraction of a gas composed of symmetrical tops, as a function of the frequency of the incident light. As the perturbed eigenfunction is a linear function of only three unperturbed eigenfunctions, the dispersion formula, for a given state, consists of only two terms. The moments for the Raman effect transitions for the symmetrical top are also computed. Simple closed expressions are obtained, again because of the simplicity of the perturbed eigenfunctions. The polarization of the Raman radiations is computed with the result that the unshifted lines are unpolarized, whereas for the shifted lines, $|m_z|^2/|m_x|^2 = 4/3$.

106. The measurement of the variation in intensity of the helium lines with voltage by means of selected filters and a photoelectric cell. PETER J. MULDER AND JOSEPH RAZEK, *University of Pennsylvania*.—A method has been developed by which the variations in the intensity of individual spectrum lines can be measured without resolution through a spectroscope, making use of a photoelectric cell and the recording amplifier described by Razek and Mulder as part of their automatic spectrophotometer (other paper, this meeting). This method has its application in the spectrophotometry of weak sources. We have used the method to study the variation of intensity of helium arc lines with voltage. The deflection of the amplifier galvanometer with various filters of known transmission coefficients for the lines to be measured interposed successively in the beam is noted. Assuming that all the energy recorded is limited to n lines, and that n filters are used, n equations soluble for ϕ_a of the form $L_a = a_1\phi_1 + a_2\phi_2 + \dots + a_n\phi_n$ can be written, where L_a is the total light intensity as recorded with filter a interposed, $a_1 \dots a_n$ are the appropriate filter transmission coefficients, and $\phi_1 \dots \phi_n$ are the intensities of the lines multiplied by a factor depending on the wave-length sensitivity of the cell. To increase accuracy, more filters may be used and a reduction made to n normal equations by Gauss' method. In our work the helium lines were treated in four groups to reduce computation. The results generally checked with those obtained independently by a direct method.

107. The polarization and the electric moment of tung oil. A. A. BLESS, *University of Florida*.—The dielectric constant of a solution of tung oil in benzene of different concentrations was measured for three frequencies 10^6 , 4×10^6 , 10^8 , using an electrical resonance method. The molar polarization of the solutions was calculated by the aid of the Clausius-Mosotti relation. The molar polarization proved to be a linear function of the mole fraction of tung oil, showing that the interaction of the polar molecules is in this case negligible. The polarization of the pure oil was found to be -364 cc, giving an electric moment of 2.195 e.s. units. The values found are substantially the same for each of the three frequencies for which the electric constant was measured.

108. Methods of acoustic interferometry for the measurement of velocity and absorption of sound in gases. J. C. HUBBARD, *Johns Hopkins University*.—In the well known acoustic interferometer of Pierce (Proc. Am. Acad. 60, 271, 1925) the piezoelectric plate serves at the same time as generator of electric and acoustic oscillations. In order to eliminate the crystal as an essential part of the power circuit and use it only as a source of sound waves, thus to secure greater adaptability to the study of sound velocity and absorption over a range of temperatures and pressures, the writer has applied the method of forced piezoelectric vibrations used in the

sonic interferometer for liquids developed in collaboration with Mr. A. L. Loomis (Phil. Mag. June, 1928; J.O.S.A., Oct. 1928). The audible beat note of two Hartley circuits is adjusted in unison with a tuning fork, one of the circuits being provided with a secondary coil connected to the electrodes of the piezoelectric plate of the interferometer system. Cyclic variation of beat note as the gas column is lengthened is compensated by a vernier condenser in the exciting circuit, from the readings of which the velocity and attenuation of the sound in the gas are deduced. Acknowledgment is made to the Rumford Fund of the American Academy of Arts and Sciences, and to Mr. A. L. Loomis for the use of quartz plates.

109. Independence of x-ray absorption on temperature. J. A. BEARDEN, *Johns Hopkins University*.—Measurements have been reported (Read, Phys. Rev. **27**, 373 and Phys. Rev. **28**, 898) which indicated a change in the absorption coefficient of x-rays with change in temperature of the absorbing screen. Due to the theoretical importance of this effect the measurements have been repeated with much higher precision than was obtained in the previous work. The present method consists in comparing the intensity transmitted by two screens, first with both screens at the same temperature (about 24°C) and then with one screen raised to a higher temperature while the other was retained at 24°C. It can be shown that the percent change due to the expansion of the hot screen should be equal to $2\alpha T\mu\chi$ where α is the linear expansion of the metal, μ the linear absorption coefficient of the transmitted beam, and χ the thickness of the screen. By making χ and μ large the expected change due to expansion in the present experiments was equal to 10 to 18 percent at 600°C. Measurements with wave-lengths from 0.4Å to 1.5Å showed no change from the expected change due to expansion.

110. On the heat of formation of molecular oxygen. L. C. COPELAND (*National Research Fellow in Chemistry*) (Introduced by E. C. Kemble, *Harvard University*).—Molecular oxygen at pressures of 0.1 mm to 0.4 mm has been dissociated by the electrodeless discharge. The percent dissociation in the flowing gas was determined from pressure measurements on the high pressure side of a set of small orifices, using Knudsen's formula. Palladium black freshly deposited on a platinum surface has been shown to cause total recombination. A calorimeter consisting of such a surface fastened to a Beckmann thermometer and calibrating resistance coil with Woods metal was used to measure the energy of recombination. It has also been shown that the palladium black surface, poisoned with mercury vapor, or a shiny platinum surface do not cause total recombination. Several preliminary experiments have been made with about twenty-five percent dissociation at a rate of flow of 0.75 cc per minute.

111. On the mechanism of very absorbable radiation emitted by compressed crystalline substances under high potentials. ISAY A. BALINKIN, *University of Cincinnati* (Introduced by S. J. M. Allen).—Following the work of Reboul, the emission from specially designed "radiating cells" was studied photographically. Powdered alum with the average size of the grains 0.0032 in. was subjected to a pressure of 300 kg/cm² in an atmosphere of 55% relative humidity. Under a potential difference of 5000 volts the emission from the cell was completely absorbed by celluloid, $t=0.13$ mm, and only partially absorbed by cellophane, $t=0.02$ mm. This corresponds to a range between very soft x-rays and short ultraviolet. A similar effect on the photographic film can be obtained by passing a spark discharge in an electrostatic field of about 1000 volts per centimeter in which the negative and positive ions are separated and then drawn into a recombination chamber. A Bunsen flame as an ionizing agent under the same circumstances, produces the same effect. The mechanism of the radiation emitted by the "radiating cell" under high potentials is explained by the external recombination of the ions which were produced in the interstices of the compressed crystalline substance. The wave-length of the emitted radiation corresponds to the ionization potentials of oxygen and nitrogen as given by the relation, $h\nu = Ve$. For a value of 14 volts, $\lambda=900\text{Å}$ which agrees with the results given by the experiment.

112. A 21 ft. vacuum spectrograph for intensity measurements in the Schumann region. GEORGE R. HARRISON, *Stanford University*.—A 21 ft. concave grating ruled by Wood with 15,000 lines per inch and having a very bright first order has been mounted in vacuum for use in the Schumann region. The case consists of a 20 ft. vanadium steel tube of 16 inch internal

diameter, closed with tinned bronze castings. Three oil pumps exhaust this volume of 863 liters to 0.01 mm pressure in two hours; four large steel condensation pumps using n-dibutyl phthalate trapped with CO_2 lower the pressure to less than 10^{-4} mm in three more hours after 50 hours of outgassing with the pumps off. The camera box holds 4 x 16 inch plates or films, recording at one setting a range of 900A with a dispersion of 2.7A per mm. Thirty exposures to different sources can be made without destroying the vacuum. The instrument, designed particularly for making intensity measurements on multiplets of multiply ionized atoms using the photometric methods developed by Leighton and the author for the Schumann region, has only been used to photograph the region 2200-1300A thus far; the strength of the spectrum indicates that 1000A should be reached without difficulty

113. Photographic record of the first order diffraction of hydrogen atoms by a lithium fluoride crystal. THOMAS H. JOHNSON, *Bartol Research Foundation*—A beam of hydrogen atoms was reflected from a cleaved surface of a crystal of lithium fluoride at an angle of incidence of 30° . The plane of incidence made an angle of 45° with the cleavage edges of the crystal. In addition to the specularly reflected beam, first order beams appeared on the MoO_3 detecting plates having the positions calculated from the wave-length $\lambda = h/mv$ and from the grating spacing of the rows of similar ions.

114. Double crystal spectra of scattered x-rays. NEWELL S. GINGRICH, *University of Chicago*.—To get high scattered intensity, two molybdenum metal x-ray tubes of small diameter were used with a graphite scattering block between them. A total current of 95 m.a. at 50 k.v. was used. The effective scattering angle was about 109 degrees. Successive spectra taken in the neighborhood of the $K\alpha$ lines are not identical, since the experimental error is relatively large when measuring weak ionization currents. Nevertheless it can be said from the spectra obtained that the intensity of any fine structure line in the unmodified spectrum is probably not greater than 10 or 15 percent that of the $K\alpha$ line. The spectrum of the modified $K\alpha$ lines is observed at the position calculated from the equation $\delta\lambda = 0.0243 (1 - \cos \phi) \lambda$. No evidence is found of fine structure lines in the modified spectrum as reported by Davis and Purks.

THE PHYSICAL REVIEW

POSSIBLE EFFECTS OF NUCLEAR SPIN ON X-RAY TERMS

BY G. BREIT

DEPARTMENT OF PHYSICS, NEW YORK UNIVERSITY

(Received May 5, 1930)

ABSTRACT

It is shown that magnetic moments of nuclei are likely to cause small but presumably measurable separations of x-ray terms. A nucleus having a spin of $9/2$ (in units of $\hbar/2\pi$) and a magnetic moment $9/2$ in protonic units should cause the K terms of the heaviest elements to split into two components separated by about 22 volts. Such separations require for their detection a resolving power of 4200. For lighter elements the effect is relatively smaller. The same nuclear spin and magnetic moment would cause a separation of only 0.9 volts in Mo which would require for its detection a resolving power of 1.9×10^4 .

The calculations are made using Dirac's equation for a single electron without approximations. The effect of electrons in another shell, however, is neglected. It is estimated to be very small for a single K electron. If the observation of hyperfine structures in the K series of the heavier elements proves feasible, it should offer a simple means of determining magnetic moments of nuclei having a known spin.

THE hyperfine structure of spectral lines is at present attributed to the nuclear spin. The quantitative theory of the effect has been worked out by Hargreaves, Fermi, Goudsmit and Bacher and by Casimir.¹ A quantitative application of the theory is simple in a few cases such as e.g. the Li^+ hyperfine structure. For most spectra it is necessary to use approximate solutions for the electronic eigenfunctions which are at present usually carried out by the Hartree method. Quantitative determinations of the nuclear magnetic moment become, therefore, difficult. An examination of Fermi's result shows however that the order of magnitude of the effect can be expected to be much larger for the spectral terms in the x-ray region than for visible spectra. The absolute value of the splitting of an s term due to a single electron is according to Fermi

$$(F) \quad (8\pi/3)[(2k+1)/k]\mu\mu_0\psi^2(0)$$

where k is the angular momentum of the nucleus, μ its magnetic moment, μ_0 the Bohr Magneton, and $\psi(0)$ is the value of the Schroedinger function

¹ J. Hargreaves, Proc. Roy. Soc. A124, 568 (1929). E. Fermi, Zeits. f. Physik 60, 320 (1930). S. Goudsmit and R. F. Bacher, Phys. Rev. 34, 1501, (1929). S. Goudsmit and L. A. Young, Nature, March 22, (1930).

at $r=0$. For large atomic numbers the value of $\psi(0)$ for a $(1s)K$ electron is large. In fact it is seen that $\psi^2(0)$ must increase as the cube of the reciprocal of the radius of the K orbit i.e., as Z^3 where Z is the atomic number. The energy of the K level increases only as Z^2 so that the splitting $\Delta\nu$ increases more rapidly than the term value ν . The values of the magnetic moments of the nuclei are not known at present and so it is necessary to be content with approximate estimates using the known orders of magnitude derived from hyperfine structure observations in the visible region. Making such estimates it is found that for heavy elements the separation $\Delta\nu$ may be expected to be of the order of $1/5000$ of the frequency of the K line. The double crystal spectrometer developed by Bergen Davis appears to offer at least a possibility of observing such separations. The main purpose of this note is to call attention to the possibility of determining the magnetic moments of the nuclei by means of observations of the hyperfine structure of the lines in the K series. Corresponding effects in the L and M series are estimated to be smaller, though not necessarily beyond the range of experimental accuracy.

In order to form proper estimates for the case of x-rays it is necessary to perform somewhat more precise calculations than those of Fermi. The inaccuracy of his method lies in the fact that $E + (Ze^2/r) + mc^2$ is replaced by $2mc^2$. This is a good approximation as long as the region of large values of Ze^2/r is relatively small and as long as $E \sim mc^2$. Both of these conditions are satisfied for the lighter elements. The approximate dimensions of the regions in which the eigenfunction is appreciable are then of the order of 10^{-8} cm while $e^2/r > mc^2$ only if $r < 2.5 \times 10^{-13}$ cm. For the heavier elements this is not so because the charge density is more concentrated and Ze^2/r is greater for the same r . It thus becomes necessary to use exact solutions of Dirac's equation as a starting point in the calculation of the perturbation due to the magnetic moment of the nucleus.

Using Gordon's form of the solution of the Dirac equation for a Coulomb field of force² it is seen that for s terms of a single electron any set of four ψ_i 's can be expressed as a linear combination of the following two sets

$$(I) \quad \begin{aligned} \Psi_1 &= ((i/r) \cos \theta \phi_1, (i/r) \sin \theta e^{i\phi} \phi_1, \phi_2/r, 0) \\ \Psi_2 &= ((i/r) \sin \theta e^{-i\phi} \phi_1, -(i/r) \cos \theta \phi_1, 0, \phi_2/r) \end{aligned}$$

where ϕ_1, ϕ_2 are two functions (denoted by Gordon as ψ_1, ψ_2) given by

$$(G) \quad \phi_1 = (1 - E/mc^2)^{1/2} (\sigma_1 - \sigma_2); \quad \phi_2 = (1 + E/mc^2)^{1/2} (\sigma_1 + \sigma_2)$$

where $\sigma_1 = c_0^{(1)} e^{-k_0 r} r^\rho F(-n' + 1, 2\rho + 1; 2k_0 r); \quad \rho = (1 - \alpha^2)^{1/2}$

$$\sigma_2 = c_0^{(2)} e^{-k_0 r} r^\rho F(-n', 2\rho + 1; 2k_0 r); \quad \alpha = 2\pi Ze^2/\hbar c$$

$$F(\alpha, \beta; x) = 1 + \frac{\alpha x}{1\beta} + \frac{\alpha(\alpha+1)x^2}{2\beta(\beta+1)} + \dots; \quad k_0 = (2\pi mc/\hbar) [1 - (E/mc^2)^2]^{1/2}$$

$$c_0^{(1)}/c_0^{(2)} = -n'/[1 + \alpha(1 - (E/mc^2)^2)^{-1/2}]; \quad E/mc^2 = [1 + \alpha^2/(n' + \rho)^2]^{-1/2}$$

Here $n' = 0, 1, 2, \dots$ for $(1s), (2s), \dots$ terms.

² W. Gordon, Zeits. f. Physik **48**, 22 (1928).

In particular for (1s) terms $c_0^{(1)}/c_0^{(2)}=0$ and σ_2 contains only one term.

The perturbation function due to the magnetic moment of the nucleus we take to be the same as Fermi's

$$w = (e/r^3) \vec{a} [\vec{y} \times \vec{r}].$$

The unperturbed orthogonal Eigenfunctions can be taken to be

$$\begin{aligned} &u_k^{(1)}, u_{k-1}, \dots, u_{-k}^{(1)} \\ &u_k^{(2)}, \dots, u_{-k+1}^{(2)}, u_{-k}^{(2)} \end{aligned} \quad (1)$$

corresponding to angular momenta

$$(k + \frac{1}{2}, k - \frac{1}{2}, \dots, -k - \frac{1}{2})(h/2\pi)$$

To every angular momentum in the direction of the Z axis there correspond in general two unperturbed functions. Each of these is a rectangular matrix. The superscripts (1), (2) indicate whether Ψ_1 or Ψ_2 of I are used. Thus the function $u_{k-l}^{(1)}$ has for elements zeros in the first l rows; Ψ_1 stands with its four elements in the l th row, and the remaining elements are zero. This is exactly as in Fermi's article. We remark that in the secular determinant we can have matrix elements only between such functions which are in the same vertical column of (1).

There are two multiple roots of the secular determinant one of which occurs $2k+2$ and the other $2k$ times. The functions at the extreme right and left correspond to the first of these two roots. This can be calculated first and the remaining root can be ascertained by obtaining the diagonal elements of the subdeterminant formed by the combinations of any other vertical pair in (1). The first root is therefore $\int u_k^{*(1)} w u_k^{(1)} d\tau$. This integral sign is of course understood to include in it a summation over the indices of the matrix eigenfunctions. The operations μ are on the columns and the operations α are on the rows. We are therefore only interested in that part of $w u_k^{(1)}$ which on performing the operations μ involves the index k . This part is due to μ_z and is $(e\mu/r^3) (x\alpha_y - y\alpha_x) u_k^{(1)}$. The remaining operation is entirely on Ψ_1 . Performing it and substituting in the integral it is found that

$$w_1 = \int u_k^{(1)*} w u_k^{(1)} d\tau = (16\pi/3) e\mu \int_0^\infty (\phi_1 \phi_2 / r^2) dr \quad (2)$$

This is therefore one of the roots. The sum of the two roots is $\int [u_{k-1}^{(1)*} w u_{k-1}^{(1)} + u_k^{(2)*} w u_k^{(2)}] d\tau$, with the same understanding about the integral as before. The calculation of the first term in brackets is the same as before with the difference that a factor $(k-1)/k$ is introduced. In the second term the result (2) is obviously obtained but with opposite sign due to the occurrence of Ψ_2 instead of Ψ_1 . The sum of the two roots is therefore

$$w_1 + w_2 = -w_1/k. \quad (3)$$

Hence

$$\Delta\nu = w_1 - w_2 = ((2k+1)/k) w_1. \quad (4)$$

The difference between this result and Fermi's can be expressed by saying that Fermi's

$$\psi^2(0) \rightarrow (2e/\mu_0) \int_0^\infty (\phi_1 \phi_2 / r^2) dr = - (8\pi mc/h) \int_0^\infty (\phi_1 \phi_2 / r^2) dr.$$

Equation (4) is practically exact for any s term; in a Coulomb field the only approximation made being that of supposing the effect of the nuclear magnetic moment to be small.

In applying (4) it must be remembered that ϕ_1, ϕ_2 are supposed to be normalized in such a way that

$$4\pi \int (\phi_1^2 + \phi_2^2) dr = 1 \quad (5)$$

as is obvious from (I). For (1s) terms

$$\phi_1 = -C[1 - (E/mc^2)]^{1/2} e^{-k_0 r}; \phi_2 = C[1 + (E/mc^2)]^{1/2} e^{-k_0 r}. \quad (6)$$

These expressions are substituted into (4), the normalization constant C being determined by (5). The integrals are expressible by means of the Γ function. Using $\Gamma(x+1) = x\Gamma(x)$ and the relations G it is found that the exact quantity which replaces Fermi's $\psi^2(0)$ is (see (4'))

$$(4\pi mc/h)^3 (\alpha^3/8\pi) [2\rho^2 - \rho]^{-1}. \quad (7)$$

Here the first two factors are Fermi's $\psi^2(0)$, and the factor in brackets is a correction due to relativity effects brought in by this calculation.* Substituting (7) into (F)

$$\begin{aligned} \Delta\nu &= 0.0169Z^3(k + \frac{1}{2})(1840\mu/2k\mu_0)[2\rho^2 - \rho]^{-1} \text{ cm}^{-1} \\ &= 2.08(Z/100)^3(k + \frac{1}{2})(1840\mu/2k\mu_0)[2\rho^2 - \rho]^{-1} \text{ volts.} \end{aligned} \quad (8)$$

In order to estimate the order of magnitude of the effect we suppose that $k=9/2$ and that $1840\mu=2k\mu_0$. We find for

	U	Bi	W	Mo
$Z =$	92	83	74	42
$\Delta\nu =$	22.5	12.6	7.31	0.896 volts
$\nu_{K\alpha} =$	(9.395	7.436	5.912	$1.734) \times 10^4$ volts
$\nu_{K\alpha}/\Delta\nu =$	4175	5911	8092	19361

Of these elements Bi is known³ to have a nuclear spin 9/2. It is clear from the above table that for the heavier elements the separation is sufficiently large not to be confused with chemical effects and that the resolving power tabulated in the last row is sufficiently small to make the possibility of experimental detection of $\Delta\nu$ at least hopeful.

In a similar way the separation of 2s terms has been worked out. In this case the correction factor to Fermi's formula is

$$[2/(1 + \rho)]^{3/2} [1 + (2\rho + 2)^{1/2}] \cdot [\rho(4\rho^2 - 1)]^{-1}.$$

* In fact it is readily found that $\psi^2(0) = 1/\pi a_0^3 n^3$ where $a_0 = \hbar^2/(4\pi^2 m Z e^2)$ and n is the total quantum number.

³ E. Back and S. Goudsmit, *Zeits. f. Physik* **43**, 321 (1927); **47**, 174 (1928).

This correction factor is even larger than that derived for 1s electrons. For U it is 3.94. Neglecting screening the splitting of the L_{11} level of U can be expected to be $3.94/2.78 \times (1/8) = 1/5.64$ of the K level splitting. For the lighter elements this fraction approaches $1/8$. It is presumably much less accurate however to apply the present method of calculation to the L electrons because screening effects must be more important here. Their importance may be expected to be least for the heaviest elements. The order of magnitude of the splitting of the L_{11} level of U supposing its nucleus to have a spin $9/2$ and a magnetic moment $9/2$ proton units is 4.0 volts. The frequency of the $L_{11}-M_{21}$ line of the L series is 1221×13.55 volts. For the L series $\nu/\Delta\nu$ is therefore also of the order 4150. This estimate is, however, not as accurate as the one for the K series on account of the screening effects. It is mentioned here only because it is of interest to see that the same order of magnitude of the splitting can be expected for both series and because the L series is more accessible experimentally.⁴

The writer is very grateful to Dr. E. Wigner for an interesting discussion.

⁴ A single observation of the fine structure separation of the K levels gives only $(2k+1)\mu/k$. In order to obtain μ it will be necessary to determine k either by optical means (band spectra, hyperfine structure) or else by observing multiplicities of other X terms, or perhaps by intensity measurements of the hyperfine structure components in the K series.

ON THE REFLECTION OF THE $K\alpha$ LINE OF CARBON FROM A GLASS MIRROR

BY JEAN THIBAUD

LABORATOIRE DE PHYSIQUE DES RAYONS X, PARIS

(Received January 14, 1930)

ABSTRACT

The author recalls previous experiments which he tried in order to determine the limiting angle of total reflection from a glass grating, for a set of radiations between 20 and 65Å, making a slight correction to a recent work of E. Dershem on the reflection of the $K\alpha$ line of carbon. In the case of glass, with $\lambda=44.9\text{Å}$, if we take into account the discontinuities of absorption in the dispersive medium, the Kallman-Mark dispersion formula leads us to a result ($\delta=1-n=5.73\times 10^{-3}$) of the same order as the Drude-Lorentz simplified formula. The reflected intensity from the mirror is calculated from the angle of incidence, account being taken of the absorption. The result is then compared with the experimental curve given by Dershem for the $K\alpha$ line of carbon, and shows that it is possible to determine the critical angle of total reflection from glass ($\theta_m=6^\circ 12'$) and the refractive index ($\delta=1-n=5.84\times 10^{-3}$).

IN a previous work,¹ I have endeavored to determine the critical angle θ_m of total reflection for a beam of soft x-rays (wave-length between 20 and 65Å) by varying the glancing angle of incidence of the beam upon a glass grating and measuring the angles $\theta_{1/2}$ at which the intensity of each line of the spectrum had decreased to one-half value. The conclusions were then: *a.* The reflected intensity does not *suddenly* decrease for a certain angle θ_m : instead of this limit in total reflection, we find for the reflected intensity a somewhat *flattened* curve, the shape of which may be computed by using the Fresnel formulae and taking into account the intense absorption of soft x-rays in the medium.² *b.* An increase in the flattening of the reflection curve is observed, with increase of the wave-length (from $\lambda=45\text{Å}$ to $\lambda=65\text{Å}$). *c.* The $\theta_{1/2}$ angles of half-decreased intensities increase in proportion to the wave-length λ . They are equal to several degrees. $\delta=1-n$ (n =index of refraction) therefore varies as the square of λ .

The simplified form of the Drude-Lorentz dispersion formula seems to be verified:

$$\delta = \frac{e^2}{2\pi m} \frac{N}{c^2} \lambda^2, \quad (1)$$

if we add a numerical coefficient 0.5 in the calculation of $\theta_{1/2}$.

Recently E. Dershem³ has determined the curve connecting the reflected intensity with the glancing angle of incidence for the $K\alpha$ line of carbon and a glass mirror. He concludes that his measures do not confirm my previous

³ E. Dershem, Phys. Rev. 34, 1015 (1929).

results. A mistake has crept in Dershem's paper regarding his interpretation of my results. The θ_m angles in my numerical table are not connected with the complete disappearance of the reflected line (I have assumed for θ_m almost the same number as for the measured angle $\theta_{1/2}$). I insisted rather (see for instance reference 2) upon the gradual decrease of the intensity with increase of angle, and upon the great difficulty of locating with some definiteness the critical angle of total reflection.

The only difference between Dershem's results and mine is that the decrease as a function of the angle in the intensity diffracted by a grating seems more rapid than when determined from an ordinary glass mirror. Prins⁴ has made a remark on this subject. A grating seems thus less fit for an accurate determination of θ_m . At another place⁵ Dershem says that the shape of the curve makes it difficult to determine the limiting angle θ_m and that, on the other hand, it seems doubtful to him whether the index of refraction may be computed from the simplified Drude-Lorentz formula. I wish to discuss further these two points.

1. Kallman and Mark have changed, for the case of x-rays, the dispersion formula as quoted in Eq. (1) into another expression, which takes into account the presence of critical frequencies in the dispersive medium:

$$\delta = \frac{e^2}{2\pi m} \sum \frac{N_i}{\nu^2} = 1 + \frac{\nu_i^2}{\nu^2} n \left(1 - \frac{\nu^2}{\nu_i^2} \right) \quad (2)$$

and which seems to be correctly verified with ordinary x-rays.⁶

I have already pointed out⁷ that the results as computed from Eq. (2) in the case of about 50Å x-rays, the absorption discontinuities being taken into account, show but little difference from the numbers given by the simplified formula (1): the atomic "resonators" for the wave-length considered effect no important disturbance of index.

Let us consider with especial care the case of the reflection of the $K\alpha$ carbon line ($\lambda = 44.9\text{\AA}$) from an ordinary glass mirror.

If we take into account⁸ the K and L discontinuities of the different constituents of glass (Si, O, Na, Ca, etc.), we find by using formula (2):

$$\delta = 5.73 \times 10^{-3},$$

whereas formula (1) would give:

$$\delta = 7.08 \times 10^{-3}$$

which is quite of the same order.

The discrepancy between the results of the two formulae becomes appreciable only for wave-lengths very near (1 or 2Å) to an L , or especially an

⁸ The calculation will appear very soon in the *Journ. de Physique*.

M or N discontinuity of one of the constituent elements of the reflecting mirror. But for glass and ordinary metals, the latter case is reached only for radiations of more than 100Å.

2. Reflected intensities may be computed from angles, in the case of a medium strongly absorbing for the radiation, by using the Fresnel equations relative to the components of incident and reflected radiations, which are parallel to the mirror plane. In the case of a complex index⁹

$$n' = (1 - \delta) - i\kappa$$

(κ =extinction coefficient; $\kappa = \mu\lambda/4\pi$; μ =absorption coefficient for λ in the medium). We thus arrive at an expression of the ratio A of reflected and incident intensities as a function of the angle θ ,

$$A = \frac{(1+m)^2 + 2(m^2 + a^2)^{1/2} + 2(1+m)[2(m^2 + a^2)^{1/2}]^{1/2} + a^2 \cos \phi/2}{(1+m)^2 + 2(m^2 + a^2)^{1/2} - 2(1+m)[2(m^2 + a^2)^{1/2}]^{1/2} \cos \phi/2} \quad (3)$$

in which: $\theta = (1+m)\theta_m$; $a = \lambda/2\delta = \mu\lambda/4\pi\theta_m^2$; $\tan \phi = -a(1-\delta)/m$; $\pi < \phi < 2\pi$. The graphic representation of (3) is given on Fig. 1 for different values of the coefficient a between 0.01 and 1.

Fig. 1.

It is easy to see, with formula (3), that the reflecting power A_0 connected with the angle $\theta = \theta_m$, goes through a minimum ($A_0 = 0.17$) for $a = 0.5$. Thus, for wave-lengths much longer than 45Å and very strong absorptions μ , one would notice an *increase* in the reflected intensity for angles $\theta > \theta_m$.

The curves show that, in the neighborhood of $a = 0.5$, the reflecting power A_0 suffers only small variations, around 20 percent, and that for $\theta_{1/2} = 0.5\theta_m$, the reflected intensity is about one-half of incident intensity.

In the case of the reflection of the $K\alpha$ line of carbon, from a glass mirror, we have no accurate measurements of the absorption coefficient μ of glass.

⁹ See also: R. Forsler, *Helv. Phys. Acta* **1**, 18 (1927). and J. Prins, *Zeits. f. Physik* **47**, 479 (1928).

The most probable value, as concluded particularly from unpublished measurements of Holweck, is $\mu = 10^5$. If we adopt the above computed value $\delta = 5.73 \times 10^{-3}$, we find: $a = 0.31$.

One may notice a close similarity between the curve $a = 0.3$ (Fig. 1) as computed from (3), with the experimental curve of reflection given by Dershem. For $a = 0.3$ we find $A_0 = 0.19$. The angle θ for which the reflected intensity is reduced to 19 percent of initial intensity is equal, on Dershem's curve to $6^\circ 12'$. It is the critical angle θ_m of total reflection of the $K\alpha$ carbon line from glass. The corresponding value of the index is:

$$\delta = \frac{\theta_m^2}{2} = 5.84 \times 10^{-3}.$$

It is therefore possible to determine, from the experimental curves of reflection, the limiting angle and the refractive index $n = 1 - \delta$. The result is in good accord with the value as deduced from the Kallman and Mark formula (2) ($\delta = 5.73 \times 10^{-3}$). It follows moreover that the extinction coefficient, in the case of the $K\alpha$ line of carbon and glass, is approximately: $\kappa = \alpha \times 2\delta = 3.5 \times 10^{-3}$.

Lastly the curves show that the desired limiting angle θ_m is almost double the angle $\theta_{1/2}$, and thus we find the reason a 0.5 coefficient was to be introduced in my previous researches when θ_m was (arbitrarily) taken equal to $\theta_{1/2}$.

MOLYBDENUM *L*-SERIES WAVE-LENGTHS
BY RULED GRATINGS

By J. M. CORK

DEPARTMENT OF PHYSICS, UNIVERSITY OF MICHIGAN

(Received May 12, 1930)

ABSTRACT

With plane ruled gratings having 30,000 lines per inch and 14,400 lines per inch and grating to photographic plate distances up to a meter in length in vacuo, about 160 plates were taken of the Mo *L*-series lines. The wave-lengths for $L\alpha_1$, and $L\beta_1$, as given by Siegbahn using a gypsum crystal are 5.3943Å and 5.1658Å. If a calcite crystal were employed and approximate correction made for refraction, wave-lengths 5.3960Å and 5.1674Å should be expected, whereas the average of the ruled grating measurements gave 5.4116Å and 5.1832Å. A comparison of the two values leads to an apparent value of the electronic charge 4.8162×10^{-10} e.s.u., being slightly higher than Bearden's value using Cu *K* lines. The possibility of the variation being due to anomalous variation in the refractive index of the crystal is discussed.

THE possibility of the absolute determination of x-ray wave-lengths by means of ruled diffraction gratings, has now been demonstrated.¹ The most precise results so far obtained² indicate that x-ray wave-lengths determined by the ruled grating method are somewhat longer than when determined by the crystal reflection method. Unfortunately, however, agreement regarding the magnitude of this discrepancy is still lacking. Since this wave-length difference may be given the interpretation that the Avogadro number, used in calculating the dimensions of the unit cell in the fundamental crystal lattice, was in error and hence also the value of the electronic charge, its importance is evident. In comparing wave-length values obtained by the two methods, the results from the crystal method should first be corrected for the index of refraction of the crystal. For long wave-lengths, that is, crystals of large lattice constant, this correction is appreciable and it may be further complicated at certain wave-lengths by anomalous effects.

It was the original intention in this investigation to report on the *L* series wave-lengths for the metallic elements from Mo 42 to Ba 56 and several plates were taken for each of these elements, but in view of the significance of the results it was considered more important at this time to carry out an exhaustive study with one of the elements. For various reasons molybdenum was chosen for the target material.

Granting a certain error in setting upon a spectral line in the measurement of the photographic plates, the overall accuracy is increased by having the final result depend upon large distances upon the photographic plate. For a

¹ Compton and Doan, Proc. Nat. Acad. Sci. 11, 598, 1925; Thibaud, Comptes rendus, 182, 55, (1926).

² Wadlund, Phys. Rev. 32, 841, (1928); Bäcklin, Dissertation, Upsala, 1928, Bearden, Proc. Nat. Acad. Sci. 15, 528, (1928).

given wave-length, two main factors contribute to the distance between lines on the photographic plate, namely, the grating constant (i.e. distance between adjacent ruled lines) and the distance between grating and photographic plate. For large displacements the grating constant should be small and the distance between grating and photographic plate large. The dispersion also depends to a slight extent upon the value of the incident grazing angle employed, being greatest when this angle is least. The use of inside spectral orders, that is, those lying between the regularly reflected beam and the diffracted beam parallel to the grating, has been proposed,³ since it leads to very large dispersion when the diffracted beam becomes parallel to the grating. Although this method is eminently satisfactory to show fine structure in this narrow region, its value in the absolute determination of wave-length must not be overestimated. The use of sufficiently large incident angles to give linear displacements on the plate comparable with those of high outside orders is prohibited due to the critical grazing angle for the grating material.

Fig. 1. Diagram of spectrometer and x-ray tube as viewed from above.

APPARATUS

For this wave-length region the complete spectrometer must be in a vacuum with no absorbing layer between the x-ray tube and diffraction chamber. Fig. 1 is a schematic drawing of spectrometer and x-ray tube as viewed from above. The x-ray tube was made of glass and provided with a water-cooled target. The cathode was an activated platinum spiral. Both cathode and anode were removable by ground glass joints. The tube as a whole was mounted on the end of the brass spectrometer tube by a ground glass to metal joint.

Radiation from the target was collimated by parallel slits so as to be incident upon the grating at grazing angles from ten to forty minutes of arc. The slits were approximately 0.05 mm in width and were adjustable in distance from 12 cm to 24 cm. In the adjustment of the grating, part of the collimated beam was allowed to miss the grating surface, giving a

³ Howe, Phys. Rev. 35, 717 (1929).

beam direct to the photographic plate one edge of which was sharply defined by the shadow of the grating edge.

The photographic plate is carried by a plate holder in such a position that the direct beam is incident upon it normally. The plate holder travels upon a heavy grooved track carefully adjusted for parallelism. Four definite positions for stopping are provided by allowing the carriage to make contact with stops, the distances between which were accurately measured upon the same comparator used for the photographic plates. Two positions would have sufficed to determine the distance between plate and grating by triangulation. The photographic plates were changed by removing a metal cap from the end of the spectrometer tube, fitted by ground metal joint.

The slit system, grating and plate holder bed were all a single rigidly connected unit which could be removed completely from the tube without disturbing the adjustment. The containing brass tube had a diameter of 21 cm and a length of 110 cm. The x-ray tube and spectrometer chamber were evacuated by separate mercury vapor pumps with liquid air traps, although gas could pass freely between them through the slit system. The spectrometer tube and the end brass castings were tinned inside and out by immersion for a short time in a bath of molten tin.

The mounting for the grating was provided with adjusting screws so that the grating could be tilted in any direction. In the present investigation four different glass gratings were employed. Three of these were nominally ruled 30,000 lines per inch by Professor R. W. Wood at Johns Hopkins University, while the fourth was a 14,400 line per inch grating ruled at this University by Professor E. F. Barker and Mr. Weyrich.

CALCULATION

The fundamental grating relationship for constructive interference is

$$n\lambda = \pm d[\cos \theta - \cos \phi]$$

where θ is the small grazing incident angle and ϕ is the angle between the diffracted beam and the grating surface. The distance in Angstroms between adjacent ruled lines on the grating is represented by d , and n represents the spectral order. For the regularly reflected beam θ and ϕ are equal, while for outside orders, ϕ exceeds θ and the plus sign is used, whereas for inside orders ϕ is less than θ and the sign is negative.

The dispersion for a given setting of θ then (for outside orders) becomes:

$$\frac{\partial \phi}{\partial \lambda} = \frac{n}{d \sin \phi}.$$

This is not independent of θ since for smaller values of θ the value of ϕ and hence $\sin \phi$ for any particular wave-length becomes smaller.

In the upper part of Fig. 1 is shown an enlarged sketch of the grating with the direct and reflected beam. It is evident that the ray m in the direct beam and the ray n in the reflected beam have a common origin in the edge of the

grating at 0. Thus by measuring on the photographic plate the distance between outside edges of direct and reflected lines and dividing by the distance between the grating edge and photographic plate the $\tan 2\theta$ and hence θ is at once determined.

The origin of the spectral lines is not the edge of the grating but an effective diffracting center which may be as much as a millimeter farther from the plate if a 2 mm width of the ruled surface is employed. To determine the distance between the photographic plate and the effective grating centre, the following procedure is carried out. With some particular x-ray source, spectrograms are obtained for the photographic plate in each of the four positions. By measuring the distance between any pair of these lines sufficiently far apart on any two of the plates and solving by similar triangles the origin or effective center may be located. While two positions would be sufficient, in most cases all four positions were used for confirmation of results. Such spectra for three positions for a molybdenum target are shown in Fig. 2.

Fig. 2.

Now to calculate wave-lengths, the distance between the outside edge of the direct beam and each spectral line is measured on the comparator. This distance in each case divided by the respective normal plate to grating distance gives $\tan (\theta + \phi)$ and hence the ϕ for any spectral line. Since θ is already calculated for all of the lines the approximate value of λ is at once determined. The term approximate is used, since the edge of a line may be somewhat altered in position by growth of blackening due to over exposure. This does not, however, lead to any error in the final result because the spectral line is observed in many orders, thus on the molybdenum plates shown in Fig. 2 seven orders are available for calculation. Now if the wave-lengths as calculated from the various orders show a systematic variation, the results may be made concordant by the addition or subtraction of a small amount from all observed distances of the spectral lines from the edge of the direct beam. Experience shows that errors in the value of θ by as much as $15''$ of arc,

would automatically be corrected by this same operation, leading always to the same final values of λ when agreement between the various orders is obtained. Thus a real error in the exact location of the edge of the direct beam or of the incident angle θ need, if not too large, produce no appreciable error in final results, if several orders of some spectral line are available on the plate. In making the wave-length calculations, particularly in obtaining the cosines of the small angles, the fifteen place 'Andoyer—Tables Trigonométriques' is invaluable.

RESULTS

The grating constant for the 30,000 line gratings was determined by an optical spectrometer using the strong lines in the mercury arc spectrum as known wave-lengths. The result of this experiment gave the number of lines per inch as 30,011 or d equal to 8,463.3 Angstrom units. This is somewhat at variance with the result obtained by Thibaud⁴ for gratings from the same source, namely 29,972 lines per inch or d equal to 8,477 Angstrom units. This latter value would lead to even longer wave-lengths than those recorded in this paper.

Since the ruling machine was available on which the 14,400 line grating was ruled, it became possible to determine the constant for this grating in another way. This machine employed a wheel having 720 teeth mounted on the head of a screw whose pitch was nominally 1/20 of an inch. If the pitch of the screw therefore were accurately determined this would give the width of 720 lines. A special steel bar was prepared and ruled with light lines, one for every ten revolutions of the screw. This scale was then calibrated in terms of the International meter. The result showed the pitch of the ruling machine screw in the part used to be very uniform and to be 0.050008 inch, such that there were 14,397.6 lines per inch or a value of d equal to 17,641.8 Angstrom units. In all, about 160 plates were taken on molybdenum using the different gratings with different adjustments on each, as well as various plate to grating distances. The average of all calculations are given in Column 1 in the following Table I in Angstrom units.

TABLE I.

⁵ Siegbahn and Hjalmar, Nature 115, 85, (1925).

$d_{\text{calcite}}/d_{\text{gypsum}}$ be obtained with different wave-lengths, a variation in this quantity from 0.39976 at 1A to 0.39959 at 5.5A is observed, with anomalous peaks at 3.06A and 5.01A corresponding to the *K* absorption edges of calcium and sulphur respectively. This relationship may then be employed to calculate what the wave-lengths of the Mo *L* lines would be if measured by a calcite crystal since for gypsum, $d=7.578\text{A}$, was used at all wave-lengths. Such results are given in column 3. These values may now be corrected for the deviation to the Bragg law due to ordinary refraction in the crystal, by the approximate formula, as follows:

$$\lambda = \lambda' \left[1 - 5.4 \frac{\rho d^2}{n^2} \cdot 10^{-6} \right]$$

where λ' denotes the apparent wave-length, n the spectral order, ρ and d the density and lattice constant of the crystal respectively. For calcite this gives a correction factor of 0.014 percent for the first order spectra. Such results are recorded in column 4, and are the values to be compared with those of column 1.

It should be noted that the ratio $d_{\text{calcite}}/d_{\text{gypsum}}$ changes by as much as one half of a tenth of a percent for wave-lengths from 1A to 5A. This variation is of the nature of a difference effect and it may well be possible that the variation in calcite alone may be much greater than this.

The dispersion formula showing the effect of wave-length change upon the index of refraction as developed from polarization theory is as follows:

$$\delta = \mu - 1 = \frac{e^2}{2\pi m} \sum \frac{N_e}{\nu_e^2 - \nu_x^2}$$

where μ represents the index of refraction, N the total number of mobile electrons per cm^3 , N_e the number of electrons per cm^3 having the natural frequency ν_e and ν_x represents the x-ray frequency. For x-rays in which ν_x is large compared with ν_e , the quantity δ is negative leading to a correction to the Bragg law as shown above, i.e. true wave-length less than apparent. Now as the x-ray wave-length increases or as the frequency decreases, the value of δ becomes more negative but upon passing through the *K* absorption limit of calcium the contribution of the calcium *K* electrons changes from negative to positive and at longer wave-lengths δ may actually become positive, in which case the true wave-length will be greater than the apparent.

If possibilities of error due to this variable refractive index be overlooked, the values of column 1 may be compared with column 4 to determine what would be implied regarding the value of the electronic charge. The value of the electronic charge as determined by the oil drop method as corrected by Birge⁶ for best values of the viscosity of air, velocity of light and transformation factors to change from International to absolute electrostatic units is $4.768 \pm 0.005 \times 10^{-10}$ abs. e.s.u. Tempering this value by the consideration of Wadlund's result from x-rays, the most probable value was

⁶ Birge, Phys. Rev. Sup. 1, 40, (1929).

given as $(4.770 \pm 0.008) \times 10^{-10}$ e.s.u. However, in the most accurate determination by calculation, of a fundamental crystal lattice, namely that of calcite by Compton, Beets and DeFoe,⁷ the Avogadro number was assumed to be $(6.0594) \times 10^{23}$ which combined with Birge's most probable value of the Faraday, $(2.89270 \pm 0.00021) \times 10^{14}$ e.s.u. means that e was assumed to be 4.7739×10^{-10} e.s.u. The calcite lattice constant as so computed agreed exactly with the value as used by Siegbahn in his wave-length determinations, namely 3.02904 Å at 18°C.

For the α_1 line the wave-length by ruled grating is 0.288 percent greater than the corrected crystal measurement, while for the β_1 line a difference of 0.304 percent is observed. The average of these values gives for the electronic charge the apparent value of 4.8162×10^{-10} e.s.u. and for the Avogadro number $(6.0062) \times 10^{23}$. This value of the electronic charge is thus even larger than Bearden's value of 4.804×10^{-10} e.s.u. obtained by CuK wave-lengths.

The explanation of this effect as due to a surface contraction as discussed by Zwicky⁸ is unlikely. Such contractions are supposed to be only a few atomic layers deep and certainly many hundred atomic planes must cooperate in the x-ray reflection even up to 5 Angstroms. Also there is good agreement between crystal measurements by the transmission and reflection methods. Furthermore, a surface contraction would have to be interpreted as increasing the discrepancy rather than decreasing it, since instead of multiplying the observed $\sin \theta$ by an average d one should use the smaller surface d .

Attempts to explain the effect by altering the general grating formula for the case of grazing incidence, narrow grating width and ruling defects seem to prove inadequate for differences as large as observed.

THE INDEPENDENCE OF X-RAY ABSORPTION
ON TEMPERATURE

BY J. A. BEARDEN

JOHNS HOPKINS UNIVERSITY, BALTIMORE

(Received May 12, 1930)

ABSTRACT

If the absorption coefficient of x-rays is dependent upon the temperature of the absorber it is pointed out that the effect can be made easily measurable by increasing the thickness of the absorber. Using this method in which the thickness was made very great, measurements have been made on Al, Cu, Fe, Ni, Ag, and Pb. Heterogeneous x-rays were used with voltages from 30 to 80 k.v., also the monochromatic x-ray lines $K\alpha_{1,2}$ of silver and copper were used. All measurements showed no effect of temperature on the absorption coefficients within the probable error involved in the thermal expansion coefficients.

It is also pointed out that the effect of temperature on the absorption of x-rays and γ -rays, as found by previous investigators, was probably due to an error in the determinations of the linear absorption coefficient. When their results are corrected, using the absorption coefficient of the beam transmitted by the absorber, the results are in agreement with the present experiments.

MEASUREMENTS have been reported^{1,2} which indicated a change in the atomic absorption coefficient of x-rays with a change in the temperature of the absorbing screen. In the first¹ series of these measurements using the direct x-rays from a Coolidge tungsten x-ray tube and absorbing screens of Al, Cu, Fe, Ni, Ag, and Pb an increase in the atomic absorption coefficient was observed as the temperature of the absorber was increased. The increase was about 0.2 percent per 100°C up to temperatures near the melting point of the absorber. The second² series of measurements were made using narrow bands of x-rays of various wave-lengths absorbed in Ag and Ni. For some wave-lengths the absorption was greater than the normal absorption and for others it was less. Similar observations³ have been made using γ rays and absorbers of Pb, Fe, Sn, and Al. In each case it was found that the absorption coefficient increased with an increase in the temperature of the absorber. For both γ -rays and x-rays, if the change in absorption is expressed as a linear function of the temperature as $\mu' = \mu(1 + \beta T)$ where μ' and μ are the linear absorption coefficients of the absorber when hot and cold respectively it is found that β is proportional to the thermal expansion coefficient of the absorber.

Existing theories of absorption of x-rays and γ -rays offer no explanation of such an effect. Thus the effect offers a critical experimental check on the theoretical correctness of absorption theories. The present experiments were

² Read, Phys. Rev. 28, 898 (1926).

³ Bastings, Nature CXIX, 51 (1927), Phil. Mag. 7, 337 (1929).

undertaken with the purpose of making more accurate observations of the change in absorption of x-rays with various wave-lengths and absorbing screens.

METHOD

The expected change in the intensity transmitted by the absorber when cold and hot due to the thermal expansion of the absorber may be calculated as follows:

Let I_0 , I_c and I_h be the intensities of the direct x-ray beam, the beam transmitted by the absorber when cold, and when hot respectively.

Then $I_c/I_0 = e^{-\mu_c x}$

and

$$\frac{I_h}{I_0} = e^{-\mu_h x / (1 + \alpha T)^2} \quad (1)$$

where μ_c and μ_h are the linear absorption coefficients of the absorber when cold and hot respectively, x the thickness, and αT the linear expansion of the absorber. The ratio of intensity transmitted by the absorber when cold and hot is then

$$\frac{I_h}{I_c} = e^{(\mu_c - \mu_h)x + 2\mu_h \alpha T x} \quad (2)$$

For a heterogeneous beam μ_c and μ_h refer to the effective linear absorption coefficient of the beam transmitted by the absorber when cold and hot respectively. This of course would have to be measured by using absorbers of the same material and extrapolating to a thickness equal to the thickness x of the absorber used in Eq. (2). The percentage change in transmitted x-ray intensity is

$$\frac{I_h - I_c}{I_c} = (\mu_c - \mu_h)x + 2\mu_h \alpha T x \quad (3)$$

in this equation μ is really μ_h but since μ and μ_h cannot differ by more than 0.1 percent, the use of the normal absorption coefficient introduces practically no error in the value of $(I_h - I_c)/I_c$.

From Eq. (3) it will be seen that the greatest change in x-ray intensity will be for an absorber of maximum thickness x . Experimentally one must make x such that I_c and I_h are easily measured. For direct radiation from an x-ray tube the area of the collimating slits can be made very great and correspondingly x made larger. In the case of x-rays reflected from a crystal the area is very limited but with water cooled x-ray tubes where the x-ray intensity is very great x can still be made large. It will be noticed in Eq. 3 that a measurement of the intensity I_0 which may be 1000 times I_c or I_h is not needed. In the present experiments I_c and I_h were measured using two exactly similar pieces of metal for the absorbing screen so placed on an eccentric that either could be inserted in the path of the x-ray beam. One piece was placed in a furnace and the other kept at room temperature. After a series of measurements of I_c and I_h had been made the two absorbers

were interchanged and a new set of readings taken. This procedure was adopted to make it possible to obtain I_c and I_h without a time lag and without a change in temperature of slits, sensitivity of electrometer, etc. Previous experiments^{1,2,3} have indicated that

$$(\mu_c - \mu_h)x = \mu_h \alpha T$$

so if one makes x large enough to make $(I_h - I_c)/I_c = 0.1$ or larger the effect of such a change in absorption would change the x-ray intensity by 5 percent or more. Such a change in intensity can be easily measured.

APPARATUS

The high voltage outfit consisted of a regular high voltage transformer (165 k.v. 500 m.a.) connected to a four kenetron full wave rectifier. The kenetrons and all filament transformers were immersed in oil in order to reduce the corona discharge. The source of a.c. was a motor generator set (15 k.w.) with the field of the generator connected to a large capacity storage battery. With this arrangement it was possible to hold the primary a.c. constant to 0.2 percent over a long period of time. Two x-ray tubes were used, one was a water-cooled copper target Coolidge tube, the other a water-cooled silver target Coolidge tube. A thin window (0.01 mm al.) was provided

Fig. 1. Diagram of apparatus as used with heterogeneous x-rays. For the $K\alpha_{1,2}$ lines of Ag and Cu a calcite crystal was inserted between S_3 and the ionization chamber.

for the copper target tube to reduce the absorption of the characteristic copper x-rays. The x-ray tubes were operated at 20 to 40 m.a. and 25 to 80 k.v.

The ionization chamber was 7.5 cm in diameter and 30 cm long filled with argon. The electrometer (Compton type) was mounted directly above the chamber in order to reduce the electrical capacity. The sensitivity of the electrometer was about 10,000 division per volt.

The furnace was made up from a heavy wall copper tube 7 cm long with copper top and bottom (Fig. 1). The tube was insulated with asbestos on the top and sides and was heated with a gas flame from the bottom. The openings for the x-rays to pass through were made by inserting brass tubes into the side of the furnace and covering the ends of the tubes with aluminum (0.01 mm thick). The furnace was filled with hydrogen to prevent oxidation of the absorbing screens. The temperature was measured with a 600°C mercury in glass thermometer, placed so the bulb of the thermometer was very near the absorbing screen. The absorbing screen was mounted on a rod (Fig. 1) so it could be placed in or out of the path of the x-rays by rotating the supporting rod from outside the furnace. A long arm was attached to the supporting rod outside the furnace and a stop arranged so the absorber could be rotated

back into exactly the same position for each measurement. A similar method was used for moving the cold absorber in and out of the x-ray beam. In the case of the thin foils it was found necessary to use a frame (made of the same material as the absorber) to hold the absorbers so they would not bend or warp when heated. This was accomplished by making two frames and placing the foil between the frames and then fastening the frames to the rotating support.

METHODS OF MAKING MEASUREMENTS

Three types of radiation were used. First, the copper $K\alpha_{1,2}$ line and the silver $K\alpha_{1,2}$ line reflected from calcite; secondly, the direct rays from the copper and silver targets operated at voltages from 20 to 80 k.v. and third, the direct ray from these tubes filtered through copper and aluminum. The disposition of the apparatus is shown in Fig. 1. The slits were made of lead in the usual manner and were protected by sheets of asbestos from the heat given off by the furnace so that no appreciable expansion took place. When the heterogeneous rays from the tube were used, the slits were 4 mm wide and 2 cm high. In the case of the x-rays reflected from calcite the slits were 1 mm wide and 2 cm high. It will also be noticed that an expansion or shift of slits cannot effect the results taken by this method of comparison. The cold absorber A was placed perpendicular to the x-ray beam. With the furnace cold the angular position of the absorber B in the furnace was adjusted until it absorbed the same amount (to within 1 percent) of x-rays as the absorber A outside the furnace. The furnace was then heated to 600°C and allowed to cool to room temperature again. A series of measurements (usually 10) were then made, alternately placing the absorber A and B in the path of the rays. The furnace was then raised to a temperature 90 to 100°C above room temperature. A series of measurements similar to those made above were then made. This process was repeated advancing the temperature in steps of 90 to 100°C for each series until a temperature of 600°C (except in the case of Pb) had been reached. The process was then reversed and the temperature lowered in similar steps and similar measurements taken until the furnace was brought back to its original temperature (room temperature).

The intensity transmitted by each absorber was never exactly the same so a small correction factor (less than 1 percent) had to be applied in order to obtain the true values of I_c and I_h . The absorption coefficient μ in Eq. (3) was measured by placing A or B in the path of the x-ray beam and then adding thin layers of the same material in the path of the x-ray beam and measuring μ for each layer. By extrapolation the value of μ was obtained for 0 thickness of added absorbers which was the value used in Eq. (3).

The values for the thermal expansion coefficients used were taken from the tables of Landolt and Börnstein, 5th edition.

RESULTS

The results for the heterogeneous x-rays are plotted in the graphs of Fig. 2, in which the values of $I_h - I_c/I_c$ are plotted against the temperature of the

absorber. The solid line is calculated from Eq. (3) in which the term $(\mu_c - \mu_h)x$ has been neglected. The dotted line was calculated assuming that

$$(\mu_c - \mu_h)x = \mu\alpha T$$

which seemed to fit with the experimental measurements of previous experiments.^{1,2,3} The circle represents the experimental values obtained in the

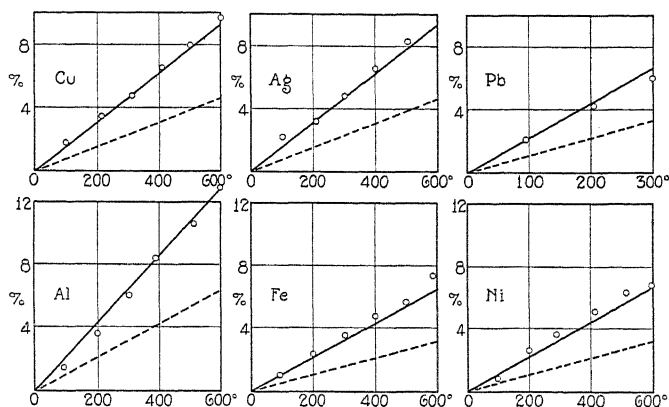

Fig. 2. The experimental points (small circles) were determined with heterogeneous x-rays from a Cu target operated at 50 kv. The solid line is drawn assuming no temperature effect on absorption of x-rays.

present work. It will be seen that the experimental points lie on the solid line within the error of the measurements and the error which must be present in

Fig. 3. Same as Fig. 2 except the monochromatic $K\alpha_{1,2}$ lines of Ag and Cu were used.

the thermal expansion coefficients. In the case of aluminum and copper the experimental points seem to be a little higher than the solid line but there

are differences in the thermal expansion coefficients given by various experimenters which would account for the difference observed here. The results using the monochromatic wave-length $K\alpha_{1,2}$ of copper and silver absorbed in silver, aluminum and copper are shown in Fig. 3. In each case the experimental points, as above, agree with the theoretical curve within the error of the measurements and the error involved in the thermal expansion coefficient.

Similar results were obtained using x-rays filtered through copper and aluminum. The x-ray measurements are believed to be more accurate than the thermal expansion coefficients are known. Thus the method may be conveniently used to measure the change in the thermal expansion coefficients with change in temperatures.

DISCUSSION AND CONCLUSION

The change in absorption found by Read in his first experiments¹ using a heterogeneous x-ray beam is undoubtedly due to the use of the wrong absorption coefficient μ in Eq. (3). He measured μ by removing the absorber and measuring I_0 of the direct beam. This gives a value of μ which is entirely too high. It is clear from the way in which Eq. (3) is derived that the correct μ is the μ of the transmitted beam and not that obtained by using the I_0 of Eq. (1). If this were not the case, the change in absorption with temperature would be a function of the thickness of the absorbing screen which obviously cannot be true.

The error in the second series of measurements² is not so apparent. In these measurements, narrow bands of wave-lengths were used so the above effect would be greatly reduced. These measurements seemed to be somewhat erratic and some undetected experimental error must have been present. Precision absorption measurements are extremely difficult to make so that an error of a fraction of 1 percent is easily made. In the measurements of Bastings³ on the temperature coefficient of γ -ray absorption he derives an equation

$$\beta = \frac{n'\mu'd'(1 + 2\alpha T) - n\mu d}{n\mu d T} \quad (4)$$

in which n is the number of atoms per cc, μ is the linear absorption coefficient, d the thickness of the absorber, α the thermal expansion coefficient, T the temperature of the absorber, and the prime letters refer to the absorber when hot. This equation also neglects the change in effective wave-length of the heterogeneous γ -rays in passing through an absorber. Even though there were no change in absorption with temperature it can be shown that Eq. (4) would give $\beta \propto \alpha$ which is what Bastings observes. Substituting the results of Bastings in Eq. (3) using an estimated value of μ from other sources gives no temperature effect within the error of the calculation.

Thus one is lead to the conclusion that there is no effect of temperature on the absorption of x-rays or γ -rays within the error of the present determinations of the thermal expansion coefficient.

THE EFFECT OF AN ELECTRIC FIELD ON THE X-RAY DIFFRACTION PATTERN OF A LIQUID

BY RONALD L. MCFARLAN

RYERSON PHYSICAL LABORATORY, UNIVERSITY OF CHICAGO

(Received April 28, 1930)

ABSTRACT

An investigation is made of the effect produced on the x-ray liquid diffraction pattern by an electric field so designed as to give the Kerr effect for the liquid under examination. The liquid diffraction pattern is obtained by replacing the crystal of a Bragg spectrometer with a cell containing the liquid. The electric field is approximately normal to the x-ray beam. Nitrobenzene is found to show an increase in peak intensity, on applying the field, ranging from four to seven times the probable error of observation, while benzene shows no observable effect. For the type of field used nitrobenzene shows a large Kerr effect, while benzene shows only a slight effect. Theoretical considerations indicate that this effect cannot be due to molecular orientation alone, but that an increase in the regularity of the spatial distribution of molecular scattering centers must occur.

INTRODUCTION

THE form of the x-ray liquid diffraction pattern is usually interpreted as being primarily due to the arrangement of the molecules in the liquid, the arrangement of the atoms in the molecule and the electrons in the atom producing secondary effects. To the space array of molecules producing this pattern one worker has given the name cybotaxis.¹ In attempting to derive a theoretical expression for the observed distribution of intensity in the liquid diffraction pattern Prins² assumes that;

1. The electricity (average electron density) is distributed continuously in each molecule.
2. This electricity vibrates in the plane of incidence of the x-ray wave.
3. The phases of the emitted partial waves from all the elementary volumes must be added in order to calculate the intensity of the diffracted ray for any particular angle of diffraction.

Starting with these assumptions Prins arrives at the following formula for the intensity of the scattered rays as a function of the angle of diffraction.

$$I(s) = N\bar{A}^2 + N\bar{A}^2 \int_0^\infty dr 4\pi r^2 g(r) \frac{\sin sr}{sr} \quad (1)$$

where $s = 4\pi/\lambda \sin \phi/2$, ϕ is the angle of diffraction, r represents the distance from a fixed but arbitrary center, and N is the number of molecules which scatter the x-rays. The scattering power A of a rigid molecule is thought of as localized at this center. The average of the scattering power over all possible

¹ Stewart and Morrow, Phys. Rev. 30, 232 (1927).

² J. A. Prins, Zeits. f. Physik 56, 617 (1929).

orientations of the molecule is indicated by the horizontal line above A . The function $g(r)$, first introduced by Zernicke and Prins,³ describes the distribution of molecular scattering centers throughout the liquid, and is defined in such a way as to make $4\pi r^2 dr g(r)$ represent the probability that a molecular center will lie between a distance r and $r+dr$ from a fixed but arbitrary center. The first term on the right-hand side of Eq. (1) gives the intensity due to N molecules scattering independently. The second term takes account of the interference between the rays scattered by the different molecules, and may have a negative sign.

It is a well-known phenomenon of optics that if certain liquids are placed in a strong electric field they become slightly double-refracting, behaving somewhat like a uniaxial crystal. This experiment was originally performed by J. Kerr,⁴ and is known as the Kerr effect. It has, perhaps, been most successfully explained by the orientation hypothesis as developed, by Langevin Born, and others.⁵ According to this hypothesis when an electric field is applied across a liquid an asymmetry is produced in it as a result of a tendency of the molecules to orient themselves in a definite direction with respect to the field because of the electric moment associated with each molecule. Two factors may contribute to the presence of this moment. In the first place the molecule may not be equally polarizable in all directions, and consequently will endeavor to set itself so that its axis of maximum polarizability is turned parallel to the field. Secondly, there may be a permanent moment associated with the molecule. Both factors are usually present.

Now, if an electric field applied across a liquid produces in the molecules a tendency to orient themselves in a particular direction with respect to the field, and consequently produces an asymmetry in the liquid it might be expected that the angular distribution of the intensity of the scattered x-rays would be altered. Since the liquid diffraction pattern is primarily molecular in origin there are two possibilities to be considered. The first is the effect which the electric field would have on the scattering of the molecules considered separately, while the second is the effect on the distribution of molecular scattering centers throughout the liquid.

CALCULATION OF THE ANTICIPATED EFFECT

The effect of the field on the molecules scattering separately can be considered in the following manner. Assume that the molecules are diatomic, that they have a permanent moment m , and that the scattering power of each atom is located at its center. Then, referring to Fig. 1, the scattered intensity due to the electric vector of the incident beam which is parallel to the plane XOP will be⁶

$$I_{11} = 4\beta A_\phi^2 \cos^2 \left(\frac{4\pi a}{\lambda} \sin \frac{\phi}{2} \cos \alpha \right) = 4\beta A_\phi^2 \cos^2 (x \sin \alpha)$$

³ Zernicke and Prins, *Zeits. f. Physik* **41**, 184 (1927).

⁴ J. Kerr, *Phil. Mag.* **50**, 337 (1875).

⁵ Cf. P. Debye, *Marx Handbuch der Radiologie*, Vol. VI, p. 754

⁶ A. H. Compton, *X-rays and Electrons*, Appendix IV, p. 384.

where $2a$ represents the distance between the atomic centers, $A_\phi = zAe^2 \cos \phi / rmc^2$, z represents the number of scattering electrons in each atom, ϕ is the angle of diffraction, β is a constant defined by $I = \beta A^2$ and $x = 4\pi a / \lambda \sin \phi / 2$.

Fig. 1.

If an electric field of strength E is applied in the direction OQ the probability that the moment m will lie in a solid angle $d\Omega = \sin \alpha d\alpha d\psi$ is, according to the Boltzmann-Maxwell law

$$\frac{1}{4\pi} e^{mE \cos \alpha / kT} \sin \alpha d\alpha d\psi.$$

The average intensity of I_{11} that is scattered in the direction ϕ on applying the field E is then

$$\begin{aligned} I_{11} &= \frac{4\beta A_\phi^2}{4\pi} \int_{\psi=0}^{\psi=2\pi} \int_{\alpha=0}^{\alpha=\pi} \cos^2(x \cos \alpha) e^{mE \cos \alpha / kT} \sin \alpha d\alpha d\psi \\ &= 2\beta A_\phi^2 \left[P(x) + \frac{m^2 E^2}{2k^2 T^2} Q(x) \right] \end{aligned}$$

where

$$P(x) = 1 + \frac{\sin 2x}{2x}, \quad Q(x) = \frac{1}{6} + \frac{\sin 2x}{2x} \left[1 + \frac{1}{4x^2} \right] - \frac{\cos 2x}{2x^2},$$

and powers of mE/kT greater than the second are neglected. Following the usual method the total intensity of the scattering at an angle ϕ is found to be

$$I_\phi = 2ZI_e \left[P(x) + \frac{m^2 E^2}{2k^2 T^2} Q(k) \right] \quad (2)$$

where I_e is the scattering at an angle ϕ due to a single electron. It will be seen that the effect should be proportional to the square of the field applied. A similar calculation was carried out for a model of the nitrobenzene molecule in which five CH groups and one NO₂ group were evenly spaced on the circumference of a ring. It was assumed that these groups scattered as units, and that the ring possessed a permanent moment due to the asymmetry produced by the NO₂ group. An intensity formula analogous to Eq. (2) was obtained and as in Eq. (2) $P(x)$ and $Q(x)$ were found to be of approximately

the same order of magnitude. In order to estimate the relative importance of the additional term introduced because of the presence of the electric field let E be taken as 5 k.v. per cm, one of the values used in this experiment, let m be given the value 3.9×10^{-18} e.s.u. as determined by polarization measurements,⁷ let T be taken as 300°K , and k given its usual value 1.39×10^{-16} . The value of $m^2 E^2 / 2kT^2$ then becomes of the order of 10^{-6} . It would thus seem that the effect of the field on the scattering of the molecules considered independently would be very small, probably too small to be detected by the usual methods of measuring intensity.

On the other hand the optical effect of the electric field on the liquid is to make it act as if it were a uniaxial crystal. If the electric field tends to arrange the molecules into something approximating crystalline structure the second term on the right-hand side of Eq. (2) would be affected, in that the distribution function would correspond to an increased regularity in the spatial arrangement of the scattering centers. The effect on the diffraction pattern would be an increase in the intensity of the peak, and also a sharper peak. Thus in looking for an effect of the electric field on the liquid diffraction pattern it would appear best to investigate the peak intensity with and without the field. This has been done in the following experiment.

EXPERIMENTAL PROCEDURE

The cell in which the liquids were put for investigation is shown in Fig. 2. The window was made of cellophane 0.025 mm thick, on the inner side of

Fig. 2. Diagram of cell.

which aluminum leaf 0.00065 mm thick was fastened. The high potential was applied to the aluminum leaf by means of the electrode E , Fig. 3, and a strip of aluminum foil leading from the electrode to the inner side of the window. Separated from the window by a distance of 3.5 mm was a heavy aluminum foil disk which was grounded by means of the earthed brass back of the cell. The x-rays entering through the window were scattered by the liquid lying between the window and the aluminum foil disk. In this way the field was given the direction OQ of Fig. 1 with respect to the x-ray beam. Fig. 3 illustrates the arrangement of the apparatus used.

In order to apply the field as nearly at right angles to the x-ray beam as possible, since the Kerr effect is observed when the light beam is traveling

⁷ P. Debye, *Polar Molecules*, p. 54.

normal to the field, the ordinary Bragg crystal reflection method was used to obtain the x-ray diffraction pattern. The incident x-ray beam was collimated by a Soller slit set each slit of which was 9 cm long, 1.5 cm high, and 0.045 cm wide. Attached to the front of the ionization chamber and rotating with it was another slit set with slits 6 cm long, 1.5 cm high, and 0.022 cm wide. An adjustable slit, kept at a width of about one mm, was placed between the second slit set and the celluloid window of the ionization chamber. This slit system served to prevent the rays scattered either by the cellophane-aluminum window, or the aluminum disk at the back of the cell from entering the ionization chamber. The chamber was filled with methyl bromide at atmospheric pressure, and the ionization currents were measured by a Compton electrometer adjusted to a sensitivity of 10,000 mm divisions per volt at a scale distance of 3 meters. Unfiltered x-rays obtained from a molybdenum-target tube operated at 35 k.v. and 32 milliamperes were used. The current supplied to the x-ray tube was rectified by means of a full-wave balanced-circuit kenotron rectifier.

Fig. 3. Arrangement of apparatus.

Since the Kerr effect is most prominent when the electric field consists of a rapid succession of short, sharp peaks it was thought best to look for the effect with the same type of field. In order to synchronize the peaks of the applied field with the peaks of the voltage across the x-ray tube the same high voltage source was used for both. The voltage applied to the cell was stepped down by means of a water rheostat. The peaks of the electric impulses across the cell were sharpened by means of a spark gap, across which a jet of air was blown, inserted between the rheostat and the cell. This device permitted the use of higher fields, and also gave a field more nearly like that used in observing the Kerr effect for nitrobenzene.

With this arrangement the liquid diffraction curves shown in Fig. 4 and Fig. 5 were obtained. These curves do not differ appreciably from the diffraction curves obtained by other methods. They show the same approach toward zero scattering at small angles of diffraction, and the same principal maximum of intensity. The nitrobenzene curve appears to be somewhat broader than the benzene curve.

To observe the effect of the electric field on the diffraction pattern the cell and ionization chamber were set at angles corresponding to the diffraction

peak. The following procedure was observed in taking all readings. The field was applied across the cell, and 45 sec. later an observation of the intensity was made. The field was then removed, and 45 sec. were allowed to

Figs. 4 and 5. Diffraction curves.

elapse before the reading without the field was taken. Alternate readings, with and without the field, were taken in this way for nitrobenzene and benzene.

RESULTS

The results obtained are shown in Table I. The + sign is used to indicate an increase in peak intensity on applying the field, the - sign a de-

TABLE I.

Liquid	Field Applied	Intensity Change	Probable Error
Nitrobenzene	5 kv per cm	+0.8 percent	0.2 percent
Nitrobenzene	9 kv per cm	+2.3 percent	0.3 percent
Nitrobenzene	14 kv per cm	+2.0 percent	0.8 percent
Benzene	9 kv per cm	-0.3 percent	0.3 percent

crease. The probable error listed in each case is the probable error of the arithmetic mean as computed in the ordinary way from least squares theory. The values given for nitrobenzene under fields of 5 k.v. per cm and 9 k.v. per cm, and for benzene represent the average of 100 pairs of readings taken as described above. The change in intensity listed for nitrobenzene under a field of 14 k.v. per cm is the average of 37 pairs of readings, the breaking down of the cell preventing further observations at this voltage. With so strong a field it was difficult to obtain steady conditions, and the results are not as reliable as the others listed.

The same type of field was used for all observations. With this type of field benzene shows only a slight Kerr effect. As is seen the change in peak intensity for benzene is not significant, and is in the direction of lesser instead of greater intensity. This lack of any definite shift for benzene rules out the possibility that the effect observed for nitrobenzene might be due to mechanical causes such as the bending of the cellophane window as a result of electrostatic forces of attraction.

The increase in peak intensity for nitrobenzene appears to be a function of the potential drop across the cell. On the basis of the observations made for the two lower voltages it might appear as if the effect varied approximately as the square of the potential applied. Further experiment is necessary, however, to decide this point definitely. But it is reasonably certain that over a range of field strengths less than 9 k.v. per cm the effect increases with increasing field strength. The observations made at 14 k.v. per cm are not sufficiently accurate to permit any definite conclusions to be drawn from them.

CONCLUSIONS

Since the observed changes in intensity range from four to seven times the probable error, and as mechanical effects do not produce them it seems reasonably certain that the type of electric field described above produces an increase in the peak intensity of the nitrobenzene diffraction pattern. This change is a function of the strength of the field applied, and from the data now available appears to vary as the square of the field strength over a range of potential gradients less than 9 k.v. per cm.

The effect is far larger than would be expected from the orientation of the molecules considered as scattering separately. It would thus appear that molecular orientation alone is not capable of producing the observed change. If, however, the effect of the field is to bring about a more orderly arrangement of the molecular scattering centers with an increased regularity in the spatial distribution of these centers then such an effect as that observed might be expected. Such a tendency toward a crystalline arrangement was the explanation originally advanced by Kerr to account for the effect he observed.

It is possible that the effect just described is not associated with the Kerr effect, and that the correlation obtained for nitrobenzene and benzene is due to the large difference in their permanent moments. Liquids are known with permanent moments of the same order of magnitude as nitrobenzene but which do not show a Kerr effect of the same order of magnitude. Experiments with some of these liquids are desirable in order to gain further information regarding this point.

In conclusion the author wishes to express his appreciation to Professor A. H. Compton for his very helpful advice and his constant interest in the problem.

THE RESOLVING POWER OF CALCITE FOR X-RAYS AND THE NATURAL WIDTHS OF THE MOLYBDENUM $K\alpha$ DOUBLETBY SAMUEL K. ALLISON AND JOHN H. WILLIAMS
UNIVERSITY OF CALIFORNIA, BERKELEY

(Received May 14, 1930)

ABSTRACT

The half widths at half maximum of the rocking curves in parallel positions of the double x-ray spectrometer have been observed for the first five orders of reflection of $\text{MoK}\alpha_1$ from calcite. The calculated half widths for a single crystal have been compared with the theoretical results of Darwin and Ewald. The observed values are of the same order of magnitude as the theoretical, but slightly larger (1.4 times as large in the first order).

The rocking curve widths in 8 anti-parallel positions for $\text{MoK}\alpha_1$ at 50 k.v. have been observed. Geometric corrections arising from the vertical spread of the beam have been applied. The half width at half maximum of $\text{MoK}\alpha_1$ has been found to be 0.147 X.U. corresponding to an energy width of 3.6 volts. The variation of this width with voltage from 25 to 50 k.v. has been studied, and no significant variation found. The half width at half maximum of $\text{MoK}\alpha_2$ at 50 k.v. was observed in 2 positions and found to be 0.161 X.U., the corresponding energy width being 3.9 volts. The observed difference between α_1 and α_2 is close to the experimental error and may not be real. The observed values are 2.5 times as great as the width to be expected from a classical electronic oscillator damped by its electromagnetic radiation.

The computed life of the excited K state of molybdenum is 1.8×10^{-16} seconds. No evidence of fine structure of $\text{MoK}\alpha_1$ or α_2 was obtained.

THIS paper is a report of experiments performed with the double x-ray spectrometer recently constructed in this laboratory. Experiments analogous to those described here have been carried out by Davis and Stempel,¹ Wagner and Kuhlenkampff,² Ehrenberg and Mark,³ Ehrenberg and von Susich,⁴ Davis and Purks,⁵ and Allison.⁶ These experiments will be discussed later in connection with various topics in this report.

APPARATUS

The double spectrometer with which these results were obtained has been described elsewhere.⁷ Constants of the spectrometer, some of which were

⁷ Williams and Allison *J.O.S.A. and R.S.I.* **18**, 473 (1929). Opportunity is taken here to point out some errors in this paper. The equation on page 474 is only approximately true, the correct expression being Eq. (1) of the present paper. On page 475 the tube holding the slits is stated to be 35 cm long whereas it actually is 30 cm. It is also stated that "the horizontal width of the slits can be adjusted to give the maximum resolving power" whereas the resolving power of the double spectrometer is independent of the slits mentioned.

not previously given, are as follows: distance from the focal spot of the x-ray tube to the first crystal (crystal *A*), 53 cm; distance between the axes of crystals *A* and *B*, 19 cm; distance from the axis of crystal *B* to the ionization chamber window, 4.5 cm; length of the ionization chamber, 40 cm; diameter of the chamber, 4.3 cm. The ionization chamber was filled with a mixture of ethyl bromide and argon at partial pressures of 17 cm and 59 cm respectively. The slit for admitting x-rays into the ionization chamber was 3 mm wide.

Two slit systems were used simultaneously which will be referred to as the horizontal and vertical slits respectively. The vertical slits limited the spread of the beam in a horizontal plane (more generally, a plane perpendicular to the axes of rotation of crystals *A* and *B*). The horizontal slits limited the spread of the beam in a vertical plane (one including the axes of rotation). The vertical slits were 30 cm apart and each 1.5 mm in width. The horizontal slits were 30.95 cm apart. The widths used for them will be given later.

Molybdenum target tubes supplied by the General Electric Company for crystal analysis work were used. In these tubes the face of the target is normal to the impinging electron beam which lies in the long axis of the tube. The radiation used in the spectrometer was taken at a glancing angle of 8° from the target face. It will be shown later that this is not the most desirable arrangement for the double spectrometer. The tubes were cooled by pumping kerosene through the targets.

The high potential for operating the tubes was supplied by a 550 cycle transformer-kenotron-capacity set in which the calculated voltage fluctuations at 50 k.v. and 20 milliamperes tube current were 1.8 percent. The voltages were read on a high voltage electrostatic voltmeter which had been calibrated by measuring the short wave-length limit of the continuous spectrum.

The electrometer has been described in a previous paper.⁷

The calcite crystals used were freshly cleaved from an optically clear parallelepiped whose surfaces were cleavage planes, by placing a razor blade as accurately as possible parallel to the cleavage direction and tapping it sharply with a light hammer. The faces from which the x-rays were reflected were the fresh faces from a single fracture and were rhombs whose sides were 1.9 cm long. These faces were not by any means optically flat. Close inspection showed that the fracture had not been all in one plane but that there were very thin "steps" on the crystal face. The holders for the crystals could be slipped out of the dove-tailed guides⁸ and replaced in them without changing the orientation of the crystals more than about 10 seconds of arc about a vertical axis. The crystals were removed in this manner after each set of readings and placed in a dessicator over dehydrated calcium chloride and a few sticks of sodium hydroxide. This was done to safeguard the fresh surfaces from attack by acid fumes which might be in the

⁸ See reference 7, Fig. 2 p. 476. The springs *K* were unhooked, and *E* and its superstructure slid out of *F*.

air. There was no evidence of deterioration of the surfaces during the period of observation.

A thermometer which could be read to a few hundredths of a degree centigrade was placed over the spectrometer and read at frequent intervals while working in anti-parallel positions.

ADJUSTMENTS

It is convenient to speak of a "central ray" which may be defined as a ray passing through the geometric centers of the slit apertures. The adjustment of the instrument must insure the following conditions.

- (1) The central ray must pass through the center of the focal spot of the x-ray tube.
- (2) The central ray must intersect the reflecting surface of crystal *A* near its geometric center.
- (3) The axis of rotation of crystal *A* must intersect the central ray at the point where the ray intersects *A*'s surface.
- (4) The axis of rotation of crystal *A* must lie in its reflecting surface.
- (5) The central ray, after reflection from crystal *A*, must intersect the reflecting face of crystal *B* near its geometric center.
- (6) The axis of rotation of crystal *B* must intersect the central ray at the point where the ray intersects *B*'s surface.
- (7) The axis of rotation of crystal *B* must be parallel to that of *A*.
- (8) The axis of rotation of crystal *B* must lie in its reflecting surface.
- (9) The central ray after reflection from crystal *B*, must enter the ionization chamber through the center of its slit and pass down the long axis of the chamber.

A necessary condition for the fulfillment of these requirements is that the central ray, the focal spot of the tube, the geometrical centers of the reflecting faces of the crystals and the axis of the ionization chamber lie in the same (horizontal) plane. This is accomplished partly in the original construction of the instrument and partly in the judicious placing of the crystals on their holders.

The spectrometer was levelled by means of levelling screws. The reflecting face of *A* was made vertical as follows. A cathetometer carrying a horizontal slit system was set up about 150 cm from the axis of *A*. The cathetometer was used merely as a rigid support for the slit system. The horizontal slit system of the cathetometer could be rotated about a horizontal axis until its central ray was horizontal to within 30 seconds of arc. This was accomplished by means of a sensitive spirit level. A parallel beam of light from an arc-lens combination was sent through the slits carried by the cathetometer and reflected from crystal *A*. The cathetometer was set in such a position that the reflected beam from the surface of *A* almost coincided with the incident beam. By means of a set screw in the crystal holder,⁹ *A* was tilted about a horizontal axis until the beam reflected from it was in the same horizontal plane as the

⁹ See reference 7, Fig. 2 476. *R* is the set screw referred to here.

incident beam. Due partially to the step-like structure of the cleavage surfaces previously mentioned, the reflected beam was not perfectly defined and this allowed an error of perhaps 2 minutes of arc to remain in the verticality of *A*.

The vertical slit system of the spectrometer was then made vertical by a plumb line or by setting an accurate right angle on the upper flat surface of the spectrometer and sighting past its vertical arm through the slits. The mechanism for closing the jaws of the vertical slits was such that they necessarily opened symmetrically about the central ray. The slits were then made about 0.05 cm wide and a beam of light from an arc sent into the spectrometer. This beam was observed on a ground glass or other translucent material after it had passed the axis of crystal *A*. Crystal *A* was then translated horizontally and rotated about its vertical axis until the ground glass showed that its face, when parallel to the light beam, extended just halfway into it. The crystal was then rotated through 180°. In this new position it did not, in general, again bisect the beam. Half of the adjustment necessary was taken up by rotation of the slit system about a vertical axis and half by translation of *A* horizontally and rotation about its vertical axis. *A* was then rotated through 180° again and the process repeated. By this method requirements (2), (3), and (4) of the preceding list could be satisfied.

In the adjustment of crystal *B* it was assumed that in the construction of the instrument requirement (7) has been met. It will be seen that this uncertainty may be a cause of error in the curves obtained in parallel positions. Crystal *A* was removed from the spectrometer. Crystal *B* was made vertical by the cathetometer method, and the arm carrying *B*'s axis of rotation (this arm revolved about the axis of *A*) was set so that the beam of light from the spectrometer slits passed approximately over *B*'s axis. The accurate adjustment was made similarly to that of *A* by repeated rotations of *B* through 180°. In this case the arm carrying the axis of *B* and the horizontal translation of *B* were adjusted until the surface of *B* was half-way across the beam at positions 180° apart. In this way requirements (5), (6), (7), and (8) were satisfied. In subsequent settings of the instrument the arm carrying the axis of *B* was rotated through twice the angle that the crystal *A* was turned around its axis.

The ionization chamber was set by noting where the beam of light entered its window. Later the position corresponding to requirement (9) was more accurately found by moving the ionization chamber across the reflected beam of x-rays from crystal *B* and setting it at the center of the angular range through which radiation entered its window.

When the adjustments of crystals *A* and *B* and the preliminary adjustment of the ionization chamber had been made the x-ray tube and horizontal slits were put in place. By means of a fluorescence screen it was ascertained that the x-ray beam (which in the actual experiments had a rectangular cross section about 0.15×0.1 cm at crystal *A*) was horizontal. The vertical slits were then further narrowed and the instrument used as a single crystal spectrometer with only crystal *A* in use. An emission line of the target was

found and the x-ray tube shifted horizontally until the maximum intensity was obtained. This made certain that the central ray passed through the most intense part of the focal spot of the tube.

PURPOSE OF THE EXPERIMENTS

The purpose of the experiments can best be understood by a brief outline of the theory of the instrument. A notation for the double spectrometer has been suggested by the authors in a previous paper.¹⁰ This notation has been of the greatest service in guiding the course of the experiments and will be retained. A fundamental expression for the instrument is that the dispersion D may be written as follows:

$$D \equiv \frac{d\theta_B}{d\lambda} = \frac{n_A}{2d \cos \theta_A} + \frac{n_B}{2d \cos \theta_B} \quad (1)$$

in which the meaning of the symbols and the convention as to sign of n_B have been previously given.¹⁰ n_A is to be considered always positive. n_B is negative when the first incident and last reflected rays are on opposite sides of the first reflected ray,¹¹ otherwise it is also positive. A setting of the instrument is described by giving the values of n_A and n_B in the form (n_A, n_B) and of the wave-length reflected. Eq. (1) is derived by differentiation of the Bragg law and addition of the dispersions of the crystals.

The second equation for the double spectrometer that we shall consider here gives the observed width of the rocking curve for any line in the spectrum at any setting of the instrument. We will temporarily assume that geometric widths due to slit heights and deviations of the crystals from verticality have been made negligibly small. We then have¹²

$$W = (W_A^2 + W_B^2 + D^2 W_\lambda^2)^{1/2}. \quad (2)$$

In this equation, W represents the half width at half maximum in angular measure of the observed rocking curve, W_A the half width at half maximum in angular measure of the curve (assumed Gaussian error curve) representing the intensity of reflection from crystal A as a function of the deviations from the Bragg angle, W_B is the analogous quantity for crystal B , D is defined in (1) and W_λ is the half width at half maximum of the line in question in linear measure. In the derivation of (2) it is assumed that the line has a Gaussian error curve distribution of intensity.

From Eqs. (1) and (2) it is seen that the positions of the double spectrometer naturally fall into two classes, so-called parallel and anti-parallel positions. Parallel positions are distinguished by having $D=0$, or $n_B = -n_A$. If $D=0$ in Eq. (2) we see that the observed width is due to the angular range through which a crystal may be turned and reflect a single wave-length, in

¹⁰ Allison and Williams, *Phys. Rev.* **35**, 149 (1930). The interpretation of negative values of D from Eq. (1) is also found here.

¹¹ Schwarzschild, *Phys. Rev.* **32**, 162 (1928).

¹² Schwarzschild, reference 11. This equation may be obtained by combining Eqs. (43) and (45) of his paper. Important special cases of this equation had been previously developed by Ehrenberg and Mark, reference 3.

other words, the widths in such positions are closely related to the limit of resolution of the instrument. Anti-parallel positions have $D \neq 0$ and are all positions for which $n_A \neq -n_B$. From Eq. (2) it is seen that the rocking curves in such positions include, in addition to the factors giving the widths in parallel positions, contributions from the widths of the spectrum lines themselves.

RESULTS IN PARALLEL POSITIONS

If $D = 0$ in Eq. (2), it becomes

$$W = (W_A^2 + W_B^2)^{1/2}. \quad (3)$$

If we now assume that $W_A = W_B = W_c$ we may write this

$$W = 2^{1/2} W_c \quad (4)$$

where W is the observed width and W_c the interference pattern width from a single crystal.

We have investigated the values of W for the reflection of $\text{MoK}\alpha_1$ in the first five orders from the cleavage face of calcite. If the adjustments previously described were not perfect, there would be an appreciable width to the rocking curve in these positions due to geometric causes, that is, there would be a width even if the width of the interference pattern of the crystals were zero. It has been shown by Schwarzschild¹³ that this width would be

$$\delta\theta'_B = \frac{2\phi(\delta_A + \delta_B)}{\cos \theta} \quad (5)$$

where $\delta\theta'_B$ is the angular range in parallel positions through which crystal B may be turned and yet reflect some of the radiation sent to it by A . δ_A and δ_B are the angular deviations of the reflecting faces of crystals A and B from verticality, θ is the glancing angle, (the same for both crystals) and ϕ is one half of the maximum angle between any two rays in a plane parallel to the axes of rotation of the crystals. Eq. (5) is derived on the assumption that the axes of rotation of crystals A and B are parallel.

In our experiments it was found that the widths of the rocking curves in parallel positions were very sensitive to deviations from verticality of the crystals. The method of setting for verticality previously described was not sufficiently accurate in general to produce the narrowest curves. The following procedure was adopted. The face of crystal A was set vertical within the limits of accuracy of the cathetometer method. (The reflected light beam was somewhat sharper from A than from B). Crystal B was then set vertical within the limits of error and a rocking curve taken. B was then rotated in small steps¹⁴ around a horizontal axis (a minute of arc at a time) and rocking curves taken for each position until a minimum width was found. If at this position δ_A and δ_B are zero, then from Eq. (4) the width observed should be

¹³ Schwarzschild, reference 11. see Eq. (24) of his paper in which $R = 2(\delta_\alpha + \delta_\beta)/\cos \theta$ and $\phi = s/L$

¹⁴ See the figure mentioned in reference 9. The screw R is used.

independent of ϕ . Several experiments were made to test this by changing the value of ϕ after the position of minimum width had been found. ϕ was varied by varying the width of the horizontal slits. The maximum value of ϕ was limited by the height of crystal *B* and was about 0.015.

TABLE I. Minimum half width at half maximum in parallel positions as a function of ϕ . $\text{MoK}\alpha_1$.

Position	ϕ	Observed <i>W</i> seconds
(1, -1)	.015	3.0
(1, -1)	.012	3.0
(2, -2)	.015	1.0
(2, -2)	.0072	1.1
(2, -2)	.0054	.90

Table I shows that from a value of ϕ of 0.0054 to a value of 0.015 the changes in the width of the rocking curve observed were within the limit of error to which a given experiment could be duplicated. The low intensity of reflections such as (4, -4) and (5, -5) made the use of the larger value of ϕ very desirable and Table I seems to justify this procedure.

Fig. 1. Observed rocking curves in parallel positions. Ordinates are proportional to ionization currents, abscissae to angular settings of crystal *B*. The vertical scale is not the same for all the curves.

Fig. 1 shows some of the rocking curves obtained, and in Table II the half widths at half maximum, together with the values of W_c calculated from Eq. (4) are listed.

TABLE II. Minimum half widths at half maximum in parallel positions. $\text{MoK}\alpha_1$

Position	<i>W</i> (seconds)	<i>W_c</i> (seconds)
(1, -1)	3.0	2.1
(2, -2)	.90	.64
(3, -3)	.95	.67
(4, -4)	1.1	.78
(5, -5)	1.2	.88

DISCUSSION OF RESULTS IN PARALLEL POSITIONS

Sources of error. Probably the most important source of error in the values of Table II arises from a possible lack of parallelism of the vertical axes around which *A* and *B* were rotated. Unfortunately the apparatus was designed in such a manner that these axes were rigid with respect to each other and no adjustment could be made. Other sources of error are (1) irregularities in the slow motion screw moving *B*; (2), temperature differences between crystals *A* and *B*. No evidence of irregular motion of *B* was obtained; rotation in regular steps of one-half second of arc seemed possible. Although variations in the temperature of the room of a few tenths of a degree centigrade sometimes occurred while a curve was being taken, the possibility of significant temperature difference between the two crystals (19 cm apart) seems excluded.

Fig. 2. A. Theoretical reflection curve from a perfect crystal for polarized x-rays (Eq. (6) and (7) and (8), or Eq. (9) and (7) and (8)). B. Theoretical reflection curve for unpolarized rays. The innermost curve represents the reflection of the component whose electric vector lies in the plane of incidence. The intermediate curve represents reflection of radiation polarized so that its electric vector lies perpendicular to the plane of incidence. The outermost curve is the sum of these components.

Comparison with theory of a perfect crystal. The reflection of plane waves from a so-called perfect or ideal crystal in which there is no warping or mosaic structure has been theoretically studied by Darwin¹⁵ and Ewald.¹⁶

Plane, monochromatic waves fall on an idealised crystal made up of electrons lying on planes separated by a constant distance. The radiation is polarized in such a plane that the electric vector lies perpendicular to the plane of incidence. Fig. 2a shows the intensity of reflection to be expected as a function of glancing angle. The curve is symmetrical about a glancing angle which may be obtained from that calculated by Bragg's law by correcting for the index of refraction. The extent of the region of 100 percent reflection is given by

$$\Delta\theta = 4\delta \operatorname{cosec} 2\theta \quad (6)$$

¹⁵ Darwin, Phil. Mag. 27, 325 and 675, (1914).

¹⁶ Ewald Phys. Zeits. 26, 29 (1925).

where $\Delta\theta$ is the range of glancing angle θ ; δ is the deviation of the index of refraction from unity. Outside the region of perfect reflection, the intensity falls off rapidly. The equation of the curve in these regions is given by

$$I_{\theta'-\theta} = I_0 \left(\frac{\Delta\theta}{2(\theta' - \theta) + (4(\theta' - \theta)^2 - \Delta\theta^2)^{1/2}} \right)^2, \quad \theta' - \theta > \frac{1}{2}\Delta\theta \quad (7)$$

$$I_{\theta'-\theta} = I_0 \left(\frac{\Delta\theta}{2(\theta' - \theta) - (4(\theta' - \theta)^2 - \Delta\theta^2)^{1/2}} \right)^2, \quad \theta' - \theta < -\frac{1}{2}\Delta\theta \quad (8)$$

where $I_{\theta'-\theta}$ is the intensity at a glancing angle θ' , I_0 is the incident intensity, and $\Delta\theta$ is defined by Eq. (6). If $I_{\theta'-\theta}/I_0$ is set equal to $\frac{1}{2}$ in Eq. (7), and the half width at half maximum calculated it is found to lie at a value of $\theta' - \theta$ equal to $1.06\Delta\theta/2$.

If the incident radiation is plane polarized in such a manner that the electric vector lies in the plane of incidence, the analogous equation to Eq. (6) is

$$\Delta\theta = 4\delta \cot 2\theta. \quad (9)$$

The radiation used in these experiments was a characteristic emission line of the target, known to be unpolarised. We may consider the unpolarised incident light resolved into two components, with electric vectors parallel and perpendicular to the plane of incidence. The intensity of each one of these components will be half the incident intensity. The reflection curve for unpolarised incident rays will then be the sum of two curves given by Eqs. (6) and (9) and the Eqs. (7) and (8) appropriate to each. Such a curve is shown in Fig. 2b.

The half width at half maximum for the unpolarised curve will be slightly greater than $2\delta \operatorname{cosec} 2\theta$ by a factor which approaches 1.06 as the glancing angle is decreased and falls off to unity at larger glancing angles. As will be seen later this correction is less than the uncertainty in the structure factors involved and will therefore be disregarded.

For a real crystal, the electrons are of course not situated on equidistant planes but are distributed throughout the structure. In this case the formula for the half width at half maximum for unpolarised radiation becomes

$$2F\delta \operatorname{cosec} 2\theta/Z \quad (10)$$

where

$$F = \sum_i F_i e^{2\pi ni(hx_i + ky_i + lz_i)}. \quad (11)$$

In the preceding equations, F is the structure factor, or equivalent reflecting power of the Z electrons in the unit cell of the crystal, F_i is the ionic structure factor, n is the order of reflection, h, k, l are the Miller indices of the plane, and x_i, y_i, z_i are the coordinates of the atom i in the unit cell.¹⁷ The unit cell of

¹⁷ Our thanks are due Professor Linus Pauling for his aid in calculating the structure factors given here.

calcite contains two molecules of CaCO_3 . Its sides are not parallel to those of a natural cleavage parallelepiped, so that the Miller indices of a plane in the true unit and the cleavage unit are not the same. The cleavage plane, which has indices (100) in the cleavage unit, has indices (211) in the true unit,¹⁸ and these are the values to use in Eq. (11) for hkl . The ionic structure factors for calcium and oxygen were taken from Bragg and West.¹⁹ The ionic structure factor for carbon was assumed to be one-fourth of that for oxygen. The calculation of the structure factors used is indicated in Table III.

TABLE III. Structure factors for (100) planes of calcite for $\text{MoK}\alpha_1$.

Order	$(\sin \theta)/\lambda$	F_{Ca}	F_{C}	F_{O}	F
1	0.165	15.1	1.8	6.6	$2(F_{\text{Ca}} + F_{\text{C}} + F_{\text{O}}) = 47.0$
2	.330	10.5	.9	3.3	$2(F_{\text{Ca}} + F_{\text{C}}) - 2F_{\text{O}} = 16.2$
3	.495	7.6	.4	1.7	$2(F_{\text{Ca}} + F_{\text{C}} + F_{\text{O}}) = 19.4$
4	.660	5.9	.2	.9	$2(F_{\text{Ca}} + F_{\text{C}}) + 6F_{\text{O}} = 17.6$
5	.825	4.5	.1	.5	$2(F_{\text{Ca}} + F_{\text{C}} + F_{\text{O}}) = 10.2$

The theoretical half widths at half maximum for the unpolarised $\text{MoK}\alpha_1$ radiation from calcite may now be found by inserting the values of F from Table III in Eq. (10), using $Z=100$. The value of δ taken from A. H. Compton²⁰ is 1.84×10^{-6} . In this way the theoretical values of Table IV were obtained, in which experimental values due to Davis and Purks²¹ are included.

TABLE IV. Comparison of theoretical and observed values of W_c (Eqs. (10) and (4)). $\text{MoK}\alpha_1$

Order	W_c Theory Eq. (10)	W_c Exp. Eq. (4)	W_c Davis and Purks

2	.28	.64	.45
3	.22	.67	
4	.16	.78	
5	.08	.88	

The values of Table IV are shown graphically in Fig. 3. It is seen that the crystal reported by Davis and Purks has very nearly the predicted half width for a perfect calcite crystal, while those used in this investigation were less perfect on this criterion. It is interesting to note that the theory gives results which agree well with experiment for the widths of the curves, although it is known that the intensity predictions are not verified.

¹⁸ Strukturbericht of the Zeits. für Krystallographie, pp. 292-295.

¹⁹ Bragg and West, Zeits. f. Krystallographie **69**, 118 (1928).

²⁰ A. H. Compton, X-rays and Electrons, p. 218 Table VII-2.

²¹ Davis and Purks Phys. Rev. **34**, 181 (1929). These investigators state that their observed widths are less than those predicted for a perfect crystal. They used a theoretical formula, however, in which an effective width had been calculated for the purpose of expressing the reflected energy as the product of the incident intensity by this effective region of 100% reflection.

RESULTS IN ANTI-PARALLEL POSITIONS

In the nomenclature which we have adopted for the instrument, D is finite in anti-parallel positions. The total geometrical width in anti-parallel positions is given by the formula

$$\delta\theta_B = \frac{1}{2}D\lambda\phi^2 \quad (12)$$

in which $\delta\theta_B$ is the *total* angular range through which crystal B can be turned while reflecting the wave-length λ .²² Since what we have measured is the half width at half maximum, the correction for geometric width should not be the entire amount of Eq. (12). The purely geometric rocking curve corresponding to Eq. (12) is not symmetrical about its maximum.²³ Its shape depends on the

Fig. 3. Comparison of observed and calculated values of the half width at half maximum of the reflection curve from calcite.

intensity of the bundle of parallel rays passing through the slits and making an angle α with the central ray in a vertical plane relative to that of the bundle of rays proceeding parallel to the central ray. This will be referred to as the variation of intensity with vertical divergence of the beam. If the widths of the horizontal slits are h_1 and h_2 , ($h_2 \geq h_1$), and the distance between them is L ,

$$\phi = (h_1 + h_2)/2L. \quad (13)$$

ϕ calculated from Eq. (13) gives the upper limit of α . If we neglect variations of intensity in the focal spot itself, we may assume that the intensity of a parallel bundle of rays is proportional to its cross-section area. This gives

$$I_\alpha = I_0 \text{ for } 0 < \alpha < (h_2 - h_1)/2L \quad (14)$$

$$I_\alpha = I_0(h_1 + h_2)(1 - \alpha/\phi)/2h_1 \text{ for } h_2 - h_1/2L < \alpha < \phi. \quad (15)$$

²² Eq. (12) occurs in Schwarzschild's paper as $\frac{1}{2}(\tan\theta_1 \pm \tan\theta_2)\phi^2$. It does not, of course, express the entire geometric width if the crystal faces and axes are not vertical. The percentage contribution to the geometric width from lack of verticality is much less in anti-parallel than in parallel positions due to the preponderating influence of the natural line breadths. In our experiments it was found by trial that using the cathetometer and horizontal slits we could set the crystals so nearly vertical that the minimum width was obtained at once in anti-parallel positions, although, as has been previously stated, this was not true in parallel positions. For this reason we do not include a term involving verticality corrections in Eq. (12)

²³ See Schwarzschild, reference 11, p. 166, Fig. 3b curve D. This curve corresponds to a function $I_\alpha = I_0(\phi - \alpha)$, or to horizontal slits of equal width.

In the preceding equations, I_α is the intensity of a bundle of parallel rays having a vertical angular divergence α ; I_0 is the intensity of the bundle of rays parallel to the central ray. Due to geometric causes alone, as crystal B is rotated from the position in which the central ray makes the angle of best reflection for a certain wave-length, other vertically divergent rays also can make this glancing angle and be reflected. If ξ is the angular deviation of crystal B from the position of reflection for the central ray, and α the vertical divergence of the bundle of rays making the correct angle for reflection at ξ ,

$$\xi = \frac{1}{2}D\lambda\alpha^2 \quad (16)$$

We wish to find the value of ξ at which this geometric rocking curve comes to half maximum. If we set $I_\alpha/I_0 = \frac{1}{2}$ in Eq. (16) and solve for $\alpha_{1/2}$ we find

$$\alpha_{1/2} = h_2\phi/(h_1 + h_2) \quad (17)$$

and substitution in Eq. (16) gives

$$\xi_{1/2} = \frac{1}{2}D\lambda\phi^2 \left\{ \frac{h_2}{h_2 + h_1} \right\}^2. \quad (18)$$

In correcting our results for geometric width in anti-parallel positions we have subtracted the values of $\xi_{1/2}$ calculated from Eq. (18) from our observed full widths at half maximum.

The temperature correction. In their paper on the natural widths of x-ray lines Ehrenberg and von Susich noted effects on the widths of the rocking curves in anti-parallel positions which they ascribed to a change in temperature of the crystals while the readings were being taken. It is easily shown that

$$d\theta_B/dT = -a\lambda D \quad (19)$$

where $d\theta_B$ is the angular range on crystal B corresponding to a temperature change dT . The negative sign has the same interpretation as that previously given.¹⁰ a is the linear expansion coefficient of calcite in a direction perpendicular to the cleavage planes,²⁴ which is 1.04×10^{-5} . For the reflection of $\text{MoK}\alpha_1$ in the (1, 1) position Eq. (19) gives $d\theta_B/dT = -0.51$ seconds of arc

per degree centigrade. During the readings in the anti-parallel positions, the thermometer was frequently read. The change of temperature during the observations was never over 0.5°C . Accordingly we have made no temperature corrections to our results.

We have investigated the half widths at half maximum of the rocking curves for $\text{MoK}\alpha_1$ for as many positions of the instrument as were conveniently possible with the intensity available. The results are shown in Table V.

The values of W_λ in column 10 of Table V are in general averages of several trials, the number of trials being given in column 9. In taking the averages we have weighted our results according to our estimate of their reliability. Some of the curves taken are shown in Fig. 4.

Fig. 4. Observed rocking curves in anti-parallel positions for $\text{MoK}\alpha_1$ at 50 k.v. Ordinates are proportional to ionization currents, abscissae to angular settings of crystal B . The vertical scale is not the same for all the curves.

We have investigated the half width at half maximum of $\text{MoK}\alpha_1$ as a function of voltage from the excitation voltage up to 50 k.v. If part of the observed width is due to satellites arising from multiply ionized states of the atom the width should depend on the voltage. The results are given in Table VI. The details given in Table V are omitted, although all corrections were made.

TABLE VI. Variation of width of $\text{MoK}\alpha_1$ with voltage. All observations in (1,1) position.

Corresponding energy width 3.92 volts.

DISCUSSION OF RESULTS IN ANTI-PARALLEL POSITIONS

We shall first discuss the results given in Table V. It is seen that in positions in which D varies from 35.748 to 143.34 seconds per X. U. the half width at half maximum W_λ varies from 0.155 X. U. (if we disregard the single observation at (2, -1)) to 0.135 X. U. or a variation of about 13 percent. This variation is not random, however; there is a distinct trend toward lower values of W_λ with higher values of D . A systematic error is therefore indicated. We are not certain where this systematic error lies, but offer the following hypotheses (1). The actual shape of the lines differs from the Gaussian error curve shape sufficiently to make Eq. (2) inapplicable; (2) The effect is due to the finite size of the focal spot.

It is possible to calculate the size of focal spot which would explain the effect. Due to the fact that during the measurement of a line, crystal A is left stationary, the radiation reflected by B at various values of ζ must come from different parts of the target. This effect is increased for higher values of D (broader curves) and by the fact that the radiation was taken at a glancing angle of 8° from the target face. Let us assume that the adjustments have been correctly made and that therefore when crystal B is reflecting the tip of the peak for a line, the radiation reflected comes from the most intense part of the focal spot. As B is rocked to either side of this position, the radiation reflected will have a different initial intensity if the focal spot is finite in extent. We have calculated that if the distribution of intensity in the focal spot in the particular tube used is such that at a distance of 0.43 mm from the center of the spot the intensity has fallen to $\frac{1}{2}$ that at the center, a 10 percent decrease in rocking curve width in the (2, 2) position can be explained. This corresponds to a diameter of 0.86 mm for the most intense part of the focal spot. The region of discoloration of the target appeared to be about 2.5 mm in diameter so that this explanation does not seem obviously impossible. If in later work it is found that this decrease of wave-length width with increasing D persists when a broad focus tube is used and rays taken at a large glancing angle from the target this explanation must be abandoned.

From Table VI we conclude that there is no significant variation of the width of $\text{MoK}\alpha_1$ from 25 kv to 50 kv. The excitation voltage is 19.945 kv, but from intensity considerations it was not possible to take measurements below 25 kv. This indicates that the observed width is not due to satellites.

We obtained no evidence of satellites of $\text{MoK}\alpha_1$ or α_2 from our experiments.²⁵

Table VII indicates that the width of $\text{MoK}\alpha_2$ is slightly greater than $\text{MoK}\alpha_1$. The observed difference between the widths of the two lines is however close to the experimental error and we cannot positively assert that there is a difference in width.

The half width at half maximum to be expected from the classical theory of an oscillating electron damped by the electromagnetic radiation emitted is²⁶

$$\Delta\lambda = \frac{2\pi e^2}{3mc^2} \quad (20)$$

where e is the electronic charge in e.s.u., m the electronic mass and c the velocity of light. Eq. (20) gives $\Delta\lambda = 5.9 \times 10^{-13}$ cm. Our measured value of W_λ for $\text{MoK}\alpha_1$ is 1.47×10^{-12} or 2.5 times as large. If we call τ the time required for the vibrations of the electron to decrease to $1/e$ of their initial amplitude,

$$\tau = \frac{3mc\lambda^2}{4\pi^2 e^2} = \frac{\lambda^2}{2\pi c} \frac{1}{\Delta\lambda} \quad (21)$$

Using $\Delta\lambda = 1.47 \times 10^{-12}$ we find $\tau = 1.8 \times 10^{-16}$ seconds, which gives the order of magnitude of the life of a molybdenum atom excited to the K state.

Ehrenberg and Mark,³ using diamond crystals, found $W_\lambda = 0.204$ X. U. for $\text{MoK}\alpha_1$ and 0.199 for $\text{MoK}\alpha_2$. Ehrenberg and von Susich⁴ found, using calcite, $W_\lambda = 0.19$ X. U. for $\text{MoK}\alpha_1$. These observations were made using only the (1, 1) and (1, -1) positions.

Davis and Purks²⁵ observed the rocking curves in the (2, 2) and (3, 3) positions but did not give a definite value to the line width as they interpreted their curves as being composed of satellites. The present results may be considered as an extension of the work of Ehrenberg and Mark and Ehrenberg and von Susich. Their results are confirmed in the sense that a line width in excess of the classically predicted value was found. The lower value found here may be partially due to the limitation of the vertical divergence of the x-ray beam.

THE VIBRATIONAL QUANTUM ANALYSIS OF THE
BLUE-GREEN BANDS OF MAGNESIUM OXIDE

By P. N. GHOSH, P. C. MAHANTI AND B. C. MUKHERJEE

UNIVERSITY COLLEGE OF SCIENCE AND TECHNOLOGY, CALCUTTA

(Received March 14, 1930)

ABSTRACT

The paper deals with the assignment of the vibration quantum numbers of the violet degrading system of the magnesium oxide bands. The frequencies of vibration for infinitesimal amplitude are found to be 716 cm^{-1} and 751 cm^{-1} for the upper (initial) and lower (final) states respectively. The heat of dissociation as calculated from the extrapolation of the $\omega^2:n$ curve is nearly 5.8 volts.

INTRODUCTION

A REVIEW of the studies of the band spectrum of magnesium oxide has been given by Kayser¹ till the year 1910. Since then there has been no further investigation of the bands which are found to lie in the red, green and ultraviolet regions.

Lecoq² was the first to observe the bands of MgO in the green region. The bands lying in this as well as in the two other regions have been measured by Eder,³ Brooks,⁴ Olmstedt⁵ and others. They excited these bands either by sparking through a solution of magnesium chloride, or by burning magnesium ribbon in air, or by burning the salts in an oxy-hydrogen flame or by arcing or sparking between magnesium electrodes in oxygen at reduced pressure.

The necessity of the presence of oxygen in the production of these bands has been shown by Dewar⁶ and also by Brooks.⁴ These bands were found to come out in the presence of air and CO₂ but would completely disappear when nitrogen or hydrogen was substituted. Even when the sparking between the magnesium electrodes was continued for a long time in the atmosphere of CO₂, these bands would gradually become fainter and finally disappear.

By using a new method of excitation, we have obtained the bands lying in the blue and green regions but the bands in the ultraviolet region observed by Olmstedt did not come out.

So far no relations, either empirical or theoretical, have been found among the various heads of the magnesium oxide bands. The object of the present paper is to obtain the vibrational quantum analysis of the bands com-

posing the blue-green system. The rotational structure of these bands shall be treated in a later communication.

EXPERIMENTAL

A quartz spectrograph (Model E 1 of Adam Hilger) of the Littrow type has been used in the investigation. The burning of magnesium ribbon in air or in an atmosphere of oxygen is certainly the most natural way of exciting the oxide bands for they come out only during the combination of magnesium with oxygen. But the magnesium ribbon while so burning forms a flocculent white oxide which glows in the light and becomes a source of continuous radiation. To avoid this, a mixture of powdered magnesium metal and nitrate of magnesium in suitable proportions was used. This mixture, on being ignited, produces an explosive flash and quickly disperses away the flocculent oxide. In this case it was found that the spectrum showed a larger number of bands than when magnesium ribbon was simply burned in air or in the atmosphere of oxygen. The heat generated during the flash was enough to melt a platinum wire (about a millimeter in thickness) which was used as the sparking arrangement. The flash so produced was focussed by a quartz lens on the slit of the spectrograph and the number of flashes required for

Fig. 1.

an exposure depended on the sensitiveness of the photographic plate in the region in which the bands were photographed. From a preliminary observation, these bands were found to lie between the regions $\lambda 5210$ and $\lambda 4700$. Ilford Special Process Panchromatic Plates were used which gave the best results in these regions.

The comparison lines for calculating the wave-lengths were obtained from a Pfund iron arc. They were photographed on either side of the bands. The standard wave-lengths used were those of Meggers, Kiess and Burns. Actual measurements of the band-heads were done on a Hilger comparator. On account of a general diffuse character of some of the bands and high magnifying power of the comparator used, difficulties were encountered in the correct location and measurement of the weak bands. It is, however, very well known that it is the identification and location of the "null" or "zero" line in an individual band, which is of more importance than that of its head or edge, in arranging the bands into various n' and n'' progressions. Unless the line structure of a band be studied under sufficient dispersion, the "null" line can hardly be located. Thus the frequency of the head may be taken to fit the various progressions. This, however, will produce some error. R. S. Mulliken⁷ is in favour of setting the cross-wire of the comparator on the point

⁷ R. S. Mulliken, *Phys. Rev.* 26, 2 (1925).

of maximum blackening for each band as it reduces the uncertainty in locating a band-head. This procedure has been adopted by us in the measurements of the bands where possible. No where within the range of our measurements could we find a band in which the head could be distinguished from the "null" line either by a gap in the shading or even by a mere lightening—so the method of indirectly calculating the null lines from the observed bands could not be applied.

ANALYSIS OF MgO BANDS

A visual inspection of the plate indicates that the bands near about λ 5211 have been resolved inspite of the low dispersion of the quartz spectrograph in this region. They have, however, been identified to be the hydride bands of magnesium. Considerable difficulty was, therefore, met with in locating the oxide bands lying in this region. It is, however, found that the bands at λ 5007 come out very easily, even when magnesium ribbon is simply burned in air. This fact seems to be in agreement with the intensity measurements and with the excellent reproduction of Eder and Valenta ("Atlas typischer Spektren," Wien, 1928). Hence they were taken as the O-sequence.

WAVE-LENGTH DATA

The results of the present measurements together with the data of the previous investigators are given in the following table.

TABLE I.

		Authors			Previous investigators

8	7	4761.78	20,994	0.00			

To start with, the band at λ 5007.13 was taken as the 0-0 band and the rest of the band system was then arranged into the Deslandre's progressions according to the criterion of Heurlinger and Kratzer for the assignment of the vibrational quantum numbers. The vibrational isotopic effect was looked for but no evidence of it was obtained.

The equation in terms of the parameters n' and n'' capable of representing the position of the measured heads is given below.

$$\nu_n = 19,967 + (751n' - 3.06n'^2) - (716n'' - 5.96n''^2).$$

CALCULATION OF THE HEAT OF DISSOCIATION

Having made the assignment of the vibration quantum numbers for the system of bands, the average values of each ΔG_n , i.e., ω^n for the two progressions were calculated and plotted as a function of n . The interval between successive vibrational levels in the lower electronic state is zero when $n' = 125$, i.e. when $751 - 6n' = 0$. The area on the $\omega^n:n$ diagram therefore gives 5.80 volts, which is the heat of dissociation of MgO(gas) into Mg(gas) and O(gas).

DISCUSSION

Mecke,⁸ Mulliken,⁹ Birge¹⁰ and Hund¹¹ have shown that the band spectra of diatomic molecules bear a simple systematic relationship with the line spectra of atoms having similar outer electronic configuration. In the case of these it has been definitely proved by Dewar and by Brooks as well that the presence of oxygen is essential to produce these bands. Their emitter, may therefore be legitimately assumed as the oxide of magnesium. The band spectra of MgO will then resemble the line spectra of argon since they have the same outer electronic configuration. The ground state is therefore a singlet 1S -state in both cases, and in the excited states, one would get singlets and triplets. Hence the MgO bands would be singlets and triplets in character.

There, however, remains the other possibility that the emitter of these bands may be MgO^+ . If so, the band spectra would resemble the line spectra of ionized argon atom or of the normal chlorine atom. In either case, they would be doublet in structure.

But in the region in which these bands lie, the quartz spectrograph has a low dispersion and hence the separation of the bands into doublets or triplets could not be detected. We, therefore, reserve our opinion about the nature of the emitter till the line analysis of each individual band is made.

Our best thanks are due to Professor Birge for kindly sending us his monograph for the rapid calculation of the least squares solution of a polynomial, which has been of great use in our investigation.

THE ZEEMAN EFFECT IN THE OH BANDS

BY GERALD M. ALMY

JEFFERSON PHYSICAL LABORATORY, HARVARD UNIVERSITY

(Received April 19, 1930)

ABSTRACT

Apparatus and experimental procedure. The Zeeman effect in the $^2\Sigma \rightarrow ^2\Pi$ OH bands in the near ultraviolet has been photographed with a 21-foot grating at 7 field strengths, varying from 5000 gauss to 34000 gauss. Up to 22000 gauss a discharge in water vapor was used as the source. Two types of quartz tubes were employed, one viewed laterally, the other end-on and placed between rectangular pole-faces. At high fields the Back-box arc, operating in water vapor, was employed.

Nature of the OH bands. The structure of the bands is briefly reviewed. New data on the satellite lines are presented, from which the ρ -type doubling in the $^2\Sigma$ states for which $v=0$, and 1, is found to be $0.216 (K + \frac{1}{2})$. Wave-number data on the hitherto unobserved $^{PP}P_{21}$ branch are also given. The agreement between the calculated and observed wave numbers, as well as the Zeeman effect, establishes the identity of this branch.

Theoretical calculation of the Zeeman patterns in OH. Hill's theory of the Zeeman effect in doublet states is applied to OH. In the $^2\Pi$ state the molecule behaves in the field as though quite rigid, symmetrical patterns being produced. The exact treatment of a $^2\Sigma$ molecular state, is given here for the first time. This state gives rise to large magnetic energy patterns which are shown in diagrams, as are also the resulting Zeeman spectrum patterns. The variety of ordering of the magnetic levels in the two states involved is the cause of strange patterns, consisting, for all lines except those near the origin, of a narrow concentrated part and a wide diffuse part.

Results and comparison with the theory. The results of observations on the Zeeman patterns are given in tables and diagrams and quantitatively compared with the theoretical expectations. The lines are treated in three groups, (1) lines near the origin, whose fine structure is resolved, (2) lines of intermediate J'' whose patterns were completely observed, (3) lines of larger J'' . The agreement with the theory is satisfactory.

INTRODUCTION

THE theory of the effect of a magnetic field on molecular spectra of the doublet type has been discussed in a recent paper by Hill.¹ At the same time the observations of Crawford and the writer² on the Zeeman effect in the $^2\Pi \rightarrow ^2\Sigma$ MgH band at 5211A were correlated quantitatively with the theory with generally satisfactory results. In the present paper the Zeeman effect in the $^2\Sigma \rightarrow ^2\Pi$ OH bands in the near ultraviolet is similarly treated, particular attention being paid to the (0,0) band at 3064A.

From a spectroscopic point of view the OH molecule differs from the MgH in two essential respects. First, the $^2\Pi$ state in OH is distinctly more rigid, or nearer case (a), as is indicated by the greater doublet separation in

¹ E. L. Hill, Phys. Rev. **34**, 1507 (1929).

² G. M. Almy and F. H. Crawford, Phys. Rev. **34**, 1517 (1929).

the bands;³ second, the $^2\Sigma$ state in OH is obviously a doublet state (ρ -type doubling) for it gives rise to observable satellite branches accompanying the main branches. These satellites permit definite measurements of the magnitude of the doubling.⁴ This definite knowledge of the $^2\Sigma$ state enables one to predict quantitatively how it will be affected by the magnetic field. As a result, the appearance of the OH bands in the field can be more definitely calculated than the MgH, especially for the higher rotational lines. Hence the agreement with the theory is more significant than in the case of MgH.

The Zeeman effect in OH has been extensively investigated by Fortrat.⁵ His report included a qualitative description of the Zeeman patterns as well as numerical data on displacements from the no-field positions. He made observations at fields of about 5000, 20000, and 40000 gauss on the six branches of each of the bands, (0,0) at 3064Å and (0,1) at 3122Å. He reported that the effect was the same in perpendicular and parallel polarizations. His measurements of displacements (obtained by reference to iron lines) showed odd fluctuations which he thought greater than the experimental error. He did not discuss the resolvable fine structure of the patterns near the origin, except the doublet from the first line in the P_1 and Q_1 branches, nor did he give any data on the unresolved parts of the patterns. Moreover, he did not publish measurements on the weak $^{RR}R_{21}$ branch beyond the head of the band, which furnishes the most certain data on widths of patterns. It is probable that much of this information was to be found on Fortrat's plates but that in the absence of a theory to guide the work it was not recognized as useful. In view of the rather better experimental conditions at hand, it was thought worth while to repeat the investigation of OH. Information was secured on most of the points left in doubt by Fortrat's paper.

The present paper deals, in the first section, with the experimental procedure employed in photographing the Zeeman effect in the OH bands. In the second section, in which the nature of the states giving rise to the bands is discussed, some new data on the satellite branches and a hitherto unobserved non-satellite branch ($^{PP}P_{12}$) are given. The third section contains a discussion of the theoretical behaviour of the two states in the field, according to Hill's results, and the last, a detailed comparison of the observed and theoretical patterns.

³ The position which a molecular state occupies in the range from case (a) to case (b) is specified by its "coupling constant," λ . For normal case (a) λ is $+\infty$, for inverted case (a), $-\infty$. For case (b) λ is 0 or $+4$. Hence the $^2\Pi$ state in OH ($\lambda \approx -6.9$) is considerably more removed from the nearer case (b) than in MgH ($\lambda \approx +5.7$). For the theory of multiplet molecular states, see E. L. Hill and J. H. van Vleck, Phys. Rev. **32**, 250, (1928).

⁴ In order to account for the observed doublet widths in MgH at large rotational speeds, it is necessary to assume a considerable ρ -type doubling in the $^2\Sigma$ state. No satellites appear, however, as might be expected, since their theoretical intensity near case (b) is very low. Hence one has no way of determining uniquely the amount of the ρ -type doubling. It was assumed to be zero in the work on the Zeeman effect, which led, of course, to a discrepancy between the observed and theoretical patterns. The discrepancy is discussed in Footnote 13.

APPARATUS AND EXPERIMENTAL PROCEDURE

The apparatus used in this work, except for the light sources, was that employed in previous work in this laboratory on the Zeeman effect in bands.^{2,6} Two types of source were used, an uncondensed discharge in water vapor and the Back-box arc, operating in water vapor at low pressure. The spectrum from the former is freer from impurities but the tubes employed could not be used at very high fields.

Two discharge tubes were used. The first one, made of quartz, had a capillary 4 mm in internal diameter and 5 cm in length. It was mounted vertically between the flat-tipped conical polepieces of the electromagnet. A stream of water vapor from a bulb containing freshly boiled, distilled water was pumped continuously through the tube, the flow being controlled, as suggested by Jack,⁷ by means of a 1 mm capillary tube, about 10 cm long, in the inlet of the tube. With a $\frac{1}{2}$ -kw transformer, a discharge could not be forced through the tube at fields exceeding about 20000 gauss. It was necessary to cool the tube with an air blast. The OH spectrum produced was very weak. A 20-hour exposure just under 20000 gauss gave a spectrum of excellent definition and purity, though of only fair intensity. A similar exposure was required to get the no-field comparison spectrum.

The difficulty of faintness of source was overcome by using a tube which could be viewed end-on, between polepieces with rather large rectangular faces (3×13.5 cm). The polepieces, which were made in the laboratory shop, were designed in accordance with the theory of polepieces given by Du Bois,⁸ in such a way as to give the largest field consistent with the necessary homogeneity. The maximum field attainable with a pole separation of one cm was

Fig. 1. Construction of the end-on quartz discharge tube. The rectangle shows the size and relative position of the pole-faces. The capillary between the side tubes was flattened, as shown in the section, in order to concentrate the discharge.

about 24000 gauss. That the field was satisfactorily uniform was shown by the sharpness of the Hg atomic line Zeeman patterns, obtained with Hg in the discharge tube. The construction of the discharge tube and its position in the magnetic field is shown in Fig. 1. The tube was made of quartz. The window on the end was fastened with deKhotinsky cement. The whole tube was cooled with a blast of cold air, and water was allowed to drop slowly on a bit of cotton wrapped around the tube just back of the window. The water

vapor was supplied as before and a more powerful transformer used. With this arrangement the intensity was increased at least ten-fold over that previously obtained.

With the end-on tube, usable photographs were taken at the following fields; 4900 gauss, 1 set of plates; 12900 gauss, 2 sets of plates; 18000–22000 gauss, 4 sets of plates. Two of the exposures near 20000 gauss were extended to 24 hours to bring out the weak RR_{21} branch lying beyond the head of the band at 3064Å. At lower fields this branch was obtained satisfactorily in much less time (7 hours at 12900 gauss).

At high field strengths the Back-box with brass electrodes was used. Water vapor was pumped through the box, the pressure being less than 1 cm Hg. A satisfactory photograph was obtained in about 8 hours, with a field of 33600 gauss. The RR_{21} branch was not obtained.

The most intense spectra were obtained in the second order of the 21-foot grating, where the dispersion is 0.93Å per mm. The third order was usable in some cases. Photographs were taken of the three bands, 3064Å, 2811Å, 3122Å. A no-field comparison spectrum of the bands and the iron arc spectrum were photographed on each set of plates. Eastman Speedway plates were used. The patterns were measured with the aid of a Wolz comparator.

The field strengths were determined, when a discharge tube was the source, from the Zeeman patterns of the Hg atomic lines at 4047Å and 4358Å. These were obtained by introducing a drop of mercury into the tube and exposing a properly placed plate for a few minutes. When the Back-box was used the field was determined from the Zn triplet, 4680Å, 4722Å, 4811Å, whose Zeeman patterns were photographed in a few minutes with brass electrodes in the box.

NATURE OF THE OH BANDS

The OH bands consist of six strong branches forming three branches of doublets, several satellite branches, and two weak branches arising from extraordinary transitions in which K changes by two units instead of one. Mulliken⁹ has discussed the structure of the bands and given a diagram showing the arrangement of levels in both states as well as the transitions which produce the first line in each branch.

The $^2\Pi$ state is inverted, having a coupling constant (λ , or Mulliken's $\Delta E/B$) equal to -6.9 . The doublet character of the main branches arises from the fact that there are two energy levels associated with each value of K in the $^2\Pi$ state. These states, whose J values are $K \pm \frac{1}{2}$, correspond to the two possible orientations of S and K . The doublet difference decreases from about 125 cm^{-1} at the origin to about 30 cm^{-1} at $K'' = 20$. Each level also shows appreciable Λ -type doubling which, however, does not enter into a consideration of the Zeeman effect.¹

The $^2\Sigma$ state shows a pronounced ρ -type doubling which increases linearly with K . As in the $^2\Pi$ state there are two levels associated with each value of K , whose J values are $K \pm \frac{1}{2}$. The origin of this doubling, considered

⁹ R. S. Mulliken, Phys. Rev. **32**, 388 (1928).

especially by Van Vleck,¹⁰ lies presumably in a combination of (1) a magnetic moment due the rotating nuclei themselves, and (2) a rotational distortion of the electronic motions, also resulting in a magnetic moment along the axis of rotation. Both should produce effects proportional to $K + \frac{1}{2}$. This doubling gives rise to the satellite branches accompanying the main branches. These satellites result from transitions in which ΔJ is not equal to ΔK , as is true for the main branches. The results of several investigations of these satellites have been discussed by Mulliken, who concludes that the width of the ρ -type doublet is $0.22 K$, for the lowest vibrational state.

Since the satellites in the (1,0) band at 2811A have not been reported, and because some uncertainty was expressed by Mulliken in his value of the ρ -doubling constant (0.22), it may be worth while to include here measurements on the satellites, made on the comparison spectra. Table I gives

TABLE I. Displacements in cm^{-1} of satellite lines from main branch lines, arranged according to the value of K in the $^2\Sigma$ state. These displacements are the amounts of the ρ -type doubling in this state. The mean displacements are plotted in Fig. 2 from which the best value of the doublet constant may be obtained.

the displacements of the satellites from the main branch lines. The (0,0) band at 3064A furnishes the data on the lowest vibrational state ($^2\Sigma^{(0)}$), the (1,0) band at 2811A on the next higher ($^2\Sigma^{(1)}$). The average values of these displacements are plotted against K in Fig. 2. The data indicate, though none too conclusively, that the ρ -doubling is proportional to $K + \frac{1}{2}$, rather than K , agreeing with Van Vleck's prediction. Within experimental error the doubling in either vibrational state is equal to $0.216 (K + \frac{1}{2})$.

¹⁰ J. H. Van Vleck, Phys. Rev. 33, 467 (1929).

A search was also made for the ${}^{PP}P_{12}$ branch of the (0,0) band which Mulliken predicts should be somewhat stronger than the ${}^{RR}R_{21}$ branch. It is situated in the midst of the bands at 3064A and 3122A and observation

Fig. 2. Average displacement of satellites in the (1, 0) band (above), and the (0,0) band, plotted against K . The ordinate thus gives the amount of ρ -type doubling in the ${}^2\Sigma$ state involved in each band. From the intercept of the solid, averaging line on the vertical axis it appears that the displacements are proportional to $K + \frac{1}{2}$, rather than K , and that for both states it is about $0.216(K + \frac{1}{2})$.

is difficult. As can be seen from Mulliken's energy level diagram the positions can be calculated by the relation:

$${}^{PP}P_{12}(J) = Q_2(J) - \Delta_2 F_2'(J-1) + 0.216(J-1)$$

where

$$\Delta_2 F_2'(J-1) = F_2'(J) - F_2'(J-2)$$

and 0.216 is the ρ -type doubling constant. $\Delta_2 F_2'$ was obtained from Mulliken's data on the ${}^{RR}R_{21}$ branch and $Q_2(J)$ from Fortrat's table of wave numbers. The results of these calculations appear in Table II together with the observed wave numbers of what are believed to be the lines of this branch. The agreement is good. This assignment is substantiated by the Zeeman effect of these lines, which will be discussed later. The observed intensities in this branch are about the same as those of the ${}^{RR}R_{21}$ branch and decrease rapidly with increasing J .

THEORETICAL CALCULATION OF THE ZEEMAN PATTERNS IN OH

The theory of the Zeeman effect in doublet bands has been discussed in terms of the quantum mechanics by Hill.¹ He has obtained an expression in closed form for the magnetic energy of ${}^2\Pi$, ${}^2\Delta$, . . . molecular states ranging from case (a) to case (b). Qualitatively, the predicted behavior in

TABLE II. Wave numbers of ${}^{PP}P_{12}(J)$. When a line coincides with a main branch line the latter is put in parentheses. The intensity scale is arbitrary.

J	Calculated cm^{-1}	Observed cm^{-1}	Intensity (Obs.)
$1\frac{1}{2}$	32253.29	$(P_2(2\frac{1}{2}))$

the field of the ${}^2\Pi$ state of OH is that of a rigid molecule. Each level (J, K) breaks up into $2J+1$ magnetic sublevels, symmetrically placed about the no-field energy. Their positions are quantitatively given by Hill's Eq. (12):¹¹

$$W(\Lambda, K, J, M) = B \left\{ (J + \frac{1}{2})^2 - \Lambda^2 + \beta(\Lambda^2 + \frac{1}{2}) \right. \\ \left. \pm \frac{1}{2} [(2J+1)^2(1-\beta)^2 + \Lambda^2(\lambda + \beta)(\lambda - 4 + 5\beta)]^{1/2} \right\} \quad (1)$$

where the two signs are to be associated with the two states for which $J = K \mp \frac{1}{2}$, $B = h/8\pi^2 cI$, and $\beta = (\Delta\nu_n/B) M/J(J+1)$.

In the paper referred to, Hill treated the ${}^2\Sigma$ state as if it consisted of two coincident levels, neglecting the ρ -type doubling. Such a state should become, in the field, a doublet of twice normal separation, arising from the energy of the spin in the field. This procedure was justifiable in the case of MgH, since its bands have no satellites from which the ρ -type doubling can be estimated.⁴ In OH, however, the ${}^2\Sigma$ state possesses, as has been discussed, a ρ -type doubling equal to $0.216(K + \frac{1}{2})$. At a field of 20000 gauss ($\Delta\nu_n = 0.94 \text{ cm}^{-1}$) the ρ -type doubling is considerably less at the origin than $\Delta\nu_n$, but it increases linearly with K , becoming considerably greater than $\Delta\nu_n$ rather early in the band. Near the origin, therefore, we may expect a molecular Paschen-Back effect, with the spin parallel or anti-parallel to the field, giving a doublet of twice normal width. But since the interaction energy which gives rise to the ρ -type doubling still remains, each member of this twice normal doublet should be "spread out" to approximately the ρ -type doublet width, the pattern consisting of $2J+1$ closely spaced levels. On the other hand, as K increases, and the ρ -type doublet width becomes much greater than $\Delta\nu_n$, S and K tend to preserve their orientation when in the field. Each member of the no-field doublet splits into $2J+1$ magnetic levels. Their separations from the no-field position run from about $+\Delta\nu_n$

¹¹ The OH molecule is sufficiently rigid that the δ term in Hill's complete Eq. (22) is negligible. This reduces (22) to (12). In Eq. (12) the terms in the square of the field also turn out to be negligible so that the Zeeman energy level pattern for the ${}^2\Pi$ state is sensibly symmetrical about the no-field position. In the calculations on MgH Hill's Eq. (22) had to be used.

to $-\Delta\nu_n$, since the magnetic energy is largely that of spin and field, with that of nuclear rotation and field making little contribution.

Precisely this behavior is predicted in the following quantitative treatment of the $^2\Sigma$ state. This treatment is due to Dr. Hill, and I owe him thanks for permission to set it down here. Since the p -type doubling is a small effect, compared with other interactions in the molecule, we may treat the motion in the $^2\Sigma$ state as case (b) (i.e., K and S precess regularly about J), perturbed by the magnetic field. Assuming that the perturbation energy is due to the interaction of S and H , it has the form,

$$H_1 = 2\Delta\nu_n(S \cdot H). \quad (2)$$

The matrix elements of this perturbation function may be written:

$$\begin{aligned} H_1(K_1, M; K_1, M) &= \Delta\nu_n \frac{M}{K + \frac{1}{2}} = \Delta\nu_n \alpha, \quad \text{where } \alpha = \frac{M}{K + \frac{1}{2}} \\ H_1(K_1, M; K_2, M) &= H_1(K_2, M; K_1, M) = \Delta\nu_n(1 - \alpha^2)^{1/2} \\ H_1(K_2, M; K_2, M) &= -\alpha\Delta\nu_n \end{aligned}$$

where K_1 corresponds to $J = K + \frac{1}{2}$, K_2 to $J = K - \frac{1}{2}$. Let $W(K_1) - W(K_2) = \nu_0$ (energy expressed in cm^{-1}).¹² The energy determinant is,

$$\begin{vmatrix} -\frac{\nu_0}{2} - \alpha\Delta\nu_n - W & \Delta\nu_n(1 - \alpha^2)^{1/2} \\ \Delta\nu_n(1 - \alpha^2)^{1/2} & \frac{\nu_0}{2} + \alpha\Delta\nu_n - W \end{vmatrix} = 0,$$

where the origin for W is the mid-position of the no-field doublets. The solution of this determinant is,

$$W = \pm \frac{1}{2} \{ \nu_0^2 + 4\alpha\nu_0\Delta\nu_n + 4\Delta\nu_n^2 \}^{1/2} \quad (3)$$

where the upper sign goes with $J = K + \frac{1}{2}$, the lower with $J = K - \frac{1}{2}$. From (3) the magnetic energy levels may be calculated. The two extreme levels in the K_1 state need separate treatment, since for them, $M = K + \frac{1}{2}$, and the non-diagonal terms vanish. Since the upper left term in the determinant is associated with the K_2 state, only the single lower right term remains. Hence the energies for these two extreme magnetic levels of the K_1 state are simply,

$$W = \frac{\nu_0}{2} \pm \Delta\nu_n. \quad (4)$$

Calculations at 12900, 20000, and 33600 gauss of the magnetic energy levels in the two states of OH have been carried through by means of Eqs. (1)

¹² In the $^2\Sigma$ states of some molecules $W(K_1)$ is less than $W(K_2)$, in which case the appropriate change in the sign of ν_0 must be made. The assignment of the two roots of Eq. (3) to the two no-field levels is also changed.

and (3). In the $^2\Pi$ state the values, $\lambda = -6.9$, $B = 18.47$, given by Mulliken, were used. In the $^2\Sigma$ state the ρ -type doubling (ν_0 in Eq. (3)) was supposed to be $0.22 K$. As shown above, the subsequent more careful consideration

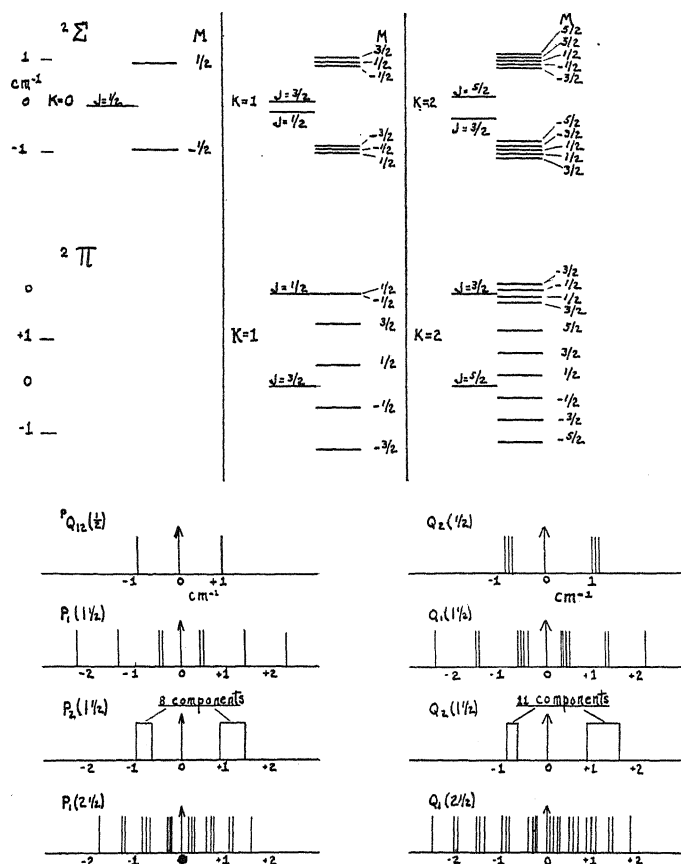

Fig. 3. Magnetic energy levels at 20000 gauss in OH $^2\Sigma$ and $^2\Pi$ states of low values of K , and some of the resulting Zeeman patterns. In each group of energy levels the no-field energies are shown at the left, the energies in the field at the right. In the Zeeman patterns the grouping in clusters is due to the fact that M may change by 0 or ± 1 . Hence, since the spacing is quite close in the $^2\Sigma$ state, three lines may fall close together. These groups are not resolvable at attainable fields, but appear as broadened lines on the plates, their intensities roughly proportional to the number in the group. Parts of all of these patterns (except $P_2(1\frac{1}{2})$ and $Q_2(1\frac{1}{2})$) are observed as resolved (Table III). In the $Q_1(2\frac{1}{2})$ pattern, for example, the five low-frequency groups are resolved at 33600 gauss, while the high-frequency part appears as a broad faint band, consistent with the fairly uniform distribution of components in this figure. All intervals are to scale except the $^2\Sigma \rightarrow ^2\Pi$ interval and the $^2\Pi$ no-field doublet interval.

of the satellites indicates that this doubling is, more precisely, $0.216 (K + \frac{1}{2})$. However, since the change would make differences of much less than 0.1 cm^{-1} in any of the computed patterns, it was not thought worth while to repeat the calculations.

The magnetic energy levels in both states for a field of 20000 gauss are plotted in Figs. 3 and 4. Fig. 3 shows the fine structure in the two states for low values of K , and, below, the Zeeman patterns of some of the early lines, when all permissible transitions ($\Delta M = \pm 1, 0$) are considered. Fig. 4 shows the magnetic energy of the extreme levels ($M = \pm J$) in each state, plotted as a function of K . The fictitious level, $M = 0$, serves merely to locate the center of the number of levels, but, since J is half integral, does not correspond to a real level. In the $^2\Sigma$ state the magnetic energy is calculated with reference to the center of the no-field doublets. The energy separations

Fig. 4. Magnetic energies at 20000 gauss of the $^2\Sigma$ and $^2\Pi$ states of OH, plotted as a function of K . The levels omitted are quite uniformly spaced between the center "levels" ($M = 0$) and the extreme levels ($M = \pm J$). The broken lines show the no-field $^2\Sigma$ levels, the distance between them being the amount of the ρ -type doubling. The Zeeman patterns in Fig. 6 are obtained by considering the transitions between the groups of this figure, taking into account the proper changes in K and M during the transition.

of the latter are given by the distance between the broken lines. Due to the peculiar behavior near the origin of the level for which $M = -(K + \frac{1}{2})$ the levels $M = \pm(K - \frac{1}{2})$ in the upper group are also shown.

In a consideration of the Zeeman spectrum patterns resulting from this arrangement of energy levels, the order of these levels is very significant. Thus, in the group A (Fig. 4) of the $^2\Sigma$ state the level, $M = K + \frac{1}{2}$ is at the top whereas in group B the level $M = -(K - \frac{1}{2})$ is at the top. This is to be expected for large values of K since in A the spin is parallel to the nuclear rotation ($J = K + \frac{1}{2}$), and thus parallel to the field when $M = +J$. In B, on the other hand, the spin is anti-parallel to K , and parallel to the field when

$M = -J$. These states are highest in their respective groups because the magnetic energy is mostly due to the interaction of spin and field. The calculations show that this ordering of energy levels holds continuously to low values of K , where, however, S is to be thought of as quantized independently in the field (molecular Paschen-Back effect).

Similar considerations as to the arrangement of the energy levels apply to the ${}^2\Pi$ state. The difference in the two groups, for which $J = K \pm \frac{1}{2}$, is shown in Fig. 4, C and D . In C the spin is anti-parallel to K , and the state for which $M = -(K - \frac{1}{2})$ has the greatest energy. In D , spin and K are parallel and the state for which $M = K + \frac{1}{2}$ has the greatest energy.

Fig. 5. Zeeman patterns of the R branches in the OH bands at 20000 gauss. The values of J'' are so arranged that the intersection of a horizontal line with the curves gives the outline of a pattern of a no-field R doublet. Two things may be particularly noted: (1) the great difference in width, except near the origin, of the two parts of the pattern of a line, due to the arrangement of magnetic levels in the two states (cf. Fig. 4 and text), (2) the appearance, at intermediate values of J'' , of the "center line" ($M' = M'' = 0$) outside of what would ordinarily be the extreme components. The circles show the observed positions of the narrow intense parts, the two-headed arrows the widths of the observable broad faint parts.

From the energy level diagram of Fig. 4 the outlines of the Zeeman spectrum patterns may be obtained. As an example, the patterns of the R_1 and R_2 branches in a field of 20000 gauss are shown in Fig. 5. Displacement from the no-field position is plotted horizontally and J'' , vertically. The extreme components and the center of the number of components ($M' = M'' = 0$) of any line are the intersections of the curves shown with a horizontal line at the corresponding value of J'' . The curious effect of one wide and one narrow part of each pattern is due to the arrangement of energy levels in the two states, just discussed. Thus the transitions $B \rightarrow C$ and $A \rightarrow D$ (cf. Fig. 4) result in close clusters of components near the no-field position, because the magnetic effect in one state undoes that in the other, when one considers the transition. But for the transitions $A \rightarrow C$ and $B \rightarrow D$ the displacements in the two states add, giving the extremely wide, and con-

sequently faint, parts of the patterns. In the narrow groups $B \rightarrow C$ and $A \rightarrow D$ it is also to be noted that, except near the origin, the center line, for which $M' = M'' = 0$, falls outside the components which would ordinarily be the extreme edges of the pattern. In other words, each of these groups folds back on itself. The components not shown fall, in all cases, fairly uniformly between the center line and the "extreme" components.¹³

In anticipation of the results to be discussed in the following section, it may be said that the circles in Fig. 5 represent the observed positions of the intense narrow parts of the patterns and the two-ended arrows the observed widths of the more diffuse parts of the patterns.

The theoretical patterns of the Q and P branches are, except for small differences in widths, like those of the R branch. The general appearance of the calculated patterns at 12900 and 33600 gauss is the same as that shown for 20000 gauss. Widths and displacements are different, of course, and roughly proportional to the field.

RESULTS AND COMPARISON WITH THE THEORY

A description of the general features of the Zeeman effect in the OH bands will be given and, where feasible, a quantitative account and comparison with the theory. The lines may be considered in three groups, (1) the lines near the origin for which the fine structure is resolved, (2) a number of intermediate lines for which complete patterns are observable, including lines in the $^{RR}R_{21}$ and $^{PP}P_{12}$ branches, and (3) the lines with larger values of J'' , for which only the intense parts of the patterns are observed. Quantitative observations were made extensively only on the (0,0) band at 3064A. Qualitative observations and a few measurements indicated that the (0,1) band at 3122A and the (1,0) band at 2811A behave in very much the same manner.

Fine structure of the lines near the origin. The calculated patterns of several lines near the origin are shown in Fig. 3. It is seen that the fine structure patterns increase rapidly in complexity as one proceeds from the origin. Only branches subscribed "1" have patterns which one might expect to resolve beyond the relatively coarse doubling to be observed in most of the patterns. The numerical description of the patterns observed and comparison with the theory is contained in Table III.

As predicted, $Q_2(\frac{1}{2})$, $R_2(\frac{1}{2})$, $^PQ(\frac{1}{2})$ become doublets of twice normal separation. The doublets of the first two of these lines are unsymmetrical with

¹³ A consideration of the ρ -type doubling would account for the discrepancies appearing in the Zeeman patterns of the high rotational doublets of MgH (Ref. 2). The Zeeman pattern of such a doublet consisted, at 16000 gauss, of an intense part filling the no-field doublet interval and on either side a somewhat fainter, narrow "wing." The central part corresponds to the broad parts of the patterns in OH (Fig. 5), though in MgH they overlapped. The wings correspond to the narrow parts of the OH patterns. (Their faintness was due to the fact that the Paschen-Back effect was setting in.) Thus both the too large width of the central part (according to the previous theory) and the too small width of the wings, as well as the too large no-field doublet width (Cf. Footnote 4), would be accounted for by a consideration like the above for OH of the ρ -type doubling in the $^2\Sigma$ state.

TABLE III. *Fine structure of lines near the origin. Values given are displacements in cm^{-1} from the no-field position of the line in question. The question mark indicates that the pattern overlaps with another, the identity of the component being uncertain.*

respect to the no-field position. Such asymmetry, which appears throughout the band, is due to the fact that the Zeeman energy levels in the $^2\Sigma$ states are symmetrical with respect to the mid-points of the p -type doublet levels, while a no-field line arises from a level displaced from a mid-point by $0.108 (K + \frac{1}{2})$. The agreement between theory and observation for these lines is not too good. Measurement is difficult in the Q_2 and R_2 doublets because of the prominence of the satellite line in the no-field spectrum of each. It is nearly as intense as the no-field line and barely resolved from it.

No more patterns are resolved in the branches with subscript "2". But the more open patterns of the early lines of the branches with subscript "1" are resolved, where observable. The agreement with theory is generally good.

The intensities fall off rapidly as one proceeds outward from the components nearest the no-field line. This corresponds to the decreasing number of members of the close groups in the theoretical pattern. Data on the first line of the $^{RR}R_{21}$ branch is also given, though the pattern is so faint as to be barely observable on the plates. This pattern is noteworthy because of the unusually large shift of the whole pattern with respect to symmetry about the no-field position. This shift is due to the fact that the ρ -type doubling in the $^2\Sigma$ state for this line is larger than in other lines with the same final J .

Patterns of lines of intermediate J ". Several of the lines of intermediate J " are so situated that the complete patterns may be observed. The appearance of these patterns is just what would be expected from Fig. 5. Thus the branches with subscript "2" consist of two separated parts, one (the low-frequency) fairly sharp, intense, and less displaced than the other, which is wide and faint. On the other hand, the pattern of a line with subscript "1" consists of two contiguous parts, the high-frequency part being intense, fairly sharply defined, and narrower than the fainter low-frequency part. The fainter part of each type of pattern becomes rapidly too weak to observe as one proceeds out in the band, though on one plate at 20500 gauss the complete patterns of $Q_2(12\frac{1}{2})$ and $Q_1(12\frac{1}{2})$ could be observed. The numerical description of these patterns is contained in Table IV. Some are reproduced in Fig. 6.

In this group should be included the observable lines of the $^{RR}R_{21}$ branch. This branch, being beyond the head of the band, offers excellent opportunity

TABLE IV. Quantitative description of patterns of lines with intermediate J ". Only patterns which could be fairly completely observed are included. Measurements are given to the nearest 0.05 cm^{-1} .

Notes to Table IV. 1. The data at 20000 gauss are the average of measurements on 4 sets of plates between 18200 and 20700 gauss, the measurements being adjusted to 20000 gauss, assuming the effects proportional to the field in this range.

2. Since the width of a no-field line, as determined by the blackened portion of the plate, is about 0.5 cm^{-1} , measured widths of less than 1 cm^{-1} , say, have little meaning. In a well-exposed part of a pattern, the observed width might easily be 0.5 cm^{-1} greater than the actual width, or range of wave number, of the part. The negative parts of the Q_2 patterns, however are definitely wider than expected from the theory.

3. In both $P_2(6\frac{1}{2})$ and $Q_2(6\frac{1}{2})$ the observed high-frequency part at 20000 gauss is abnormally wide.

TABLE V. Quantitative description of the Zeeman patterns of the $^{RR}R_{21}$ branch, and comparison with the theory. The values at 20000 gauss are figured to the nearest 0.05 cm^{-1} . Observations at 18200 and 20500 were adjusted to 20000 gauss, assuming that the effect was proportional to the field, and averaged.

Fig. 6. Reproductions of a part of the 3064A band, at two fields, together with the no-field comparison spectra. The patterns at the lower field are labelled with the usual line notation, and those at the higher field can be identified by comparison. The effects, such as doubling, broadening, and displacement are seen to be roughly proportional to the field. As representative patterns, $P_2(3\frac{1}{2})$, $Q_1(6\frac{1}{2})$, $Q_2(6\frac{1}{2})$, $R_1(20\frac{1}{2})$, $R_2(\frac{1}{2})$ might be suggested. Some satellites can be seen in the no-field spectrum, e.g. in $P_2(3\frac{1}{2})$, $P_2(4\frac{1}{2})$, $P_2(6\frac{1}{2})$, on the high frequency side of the main branch line. There are a great many apparently spurious lines, especially on the high field plate.

for observation, but is very weak. Only 6 or 7 lines were obtained with sufficient intensity to measure accurately. The Zeeman pattern of each of these consists of a broad sharp-edged pattern which is divided into two parts, a broad low-frequency part and a sharper high-frequency part whose sharpness increases with increasing J'' . This is exactly the calculated behavior. The two parts have about the same maximum intensity, in contrast to the

TABLE VI. Zeeman patterns of $^{PP}P_{12}$ branch.

Field	J''	Total width (cm ⁻¹)		Position of negative edge with respect to no-field position (cm ⁻¹)	
		Obs.	Calc.	Obs.	Calc.
12900	$3\frac{1}{2}$	2.15	2.4	-1.3	-1.3
	$4\frac{1}{2}$	2.25	2.7	-1.4	-1.45
20000	$3\frac{1}{2}$	3.4	3.75	-1.7	-1.95
	$4\frac{1}{2}$	3.4	4.1	-1.8	-2.15

patterns of the main branch lines. In the latter the intensity of the concentrated part is much greater than that of the wider part, as one would expect. The results of observation and the comparison with theory are contained in Table V.

Of the lines ascribed to the $^{PP}P_{12}$ branch only two have Zeeman patterns sufficiently intense and in the clear to permit definite measurements. These

Fig. 7. Displacements of the narrow intense parts of the patterns of Q and R branches. The solid curves give the calculated displacements as estimated from plots like Fig. 5. The crosses and circles are the observed displacements.

two, $J'' = 3\frac{1}{2}$ and $J'' = 4\frac{1}{2}$, have been observed at 12900 and 20500 gauss. The total width and position with respect to no-field of these patterns is in fair agreement with the theory (Table VI). The intensity distribution, however, is surprising. For the calculations indicate a fairly uniform distribution of components from edge to edge of the pattern, while the observed pattern consists of two parts, a low-frequency narrow part and a high-fre-

quency wider part, with possibly a faint band between. Other lines assigned to this branch apparently have the characteristic wide patterns, but they are partly obscured by other lines. Since there are no other lines in this spectral region which show such width of pattern, the Zeeman effect substantiates the assignment of these lines to the $^{PP}P_{12}$ branch.

Lines with large values of J'' . The Zeeman patterns of lines with large values of J'' theoretically consist of the concentrated slightly displaced part and the wide diffuse part (Fig. 5). The latter is too weak to photograph. The intense sharp part, however, may be followed apparently as far as the band itself. Hence the Zeeman spectrum looks almost like the no-field spectrum, except for a slight broadening and a small displacement of each line, positive for those branches subscribed "1", negative for those subscribed "2". The displacements of these intense parts in the Q and R branches is plotted in Fig. 7. The P branches behave similarly. The solid curves show the calculated displacements. The behavior of the R branches at 20000 gauss is also shown in Fig. 5. Several patterns of large J'' are reproduced in Fig. 6.

I am glad to express my gratitude to Professor E. C. Kemble for suggesting this problem, to Dr. F. H. Crawford for advice and criticism throughout the work, and to Dr. E. L. Hill for many discussions of the application of the theory of the Zeeman effect. I am also very grateful to the laboratory technicians, particularly Mr. H. W. Leighton, for assistance in the manufacture of apparatus. It should also be mentioned that a large part of the apparatus used in this work was acquired through the generosity of the Milton Fund of Harvard University.

THE ZEEMAN EFFECT IN THE RED CaH BANDS

BY WILLIAM W. WATSON AND WILLIAM BENDER

SLOANE PHYSICS LABORATORY, YALE UNIVERSITY

(Received May 1, 1930)

ABSTRACT

The Zeeman effect in the red ${}^2\Pi \rightarrow {}^2\Sigma$ and ${}^2\Sigma \rightarrow {}^2\Sigma$ CaH bands, together with new satellite branches in the ${}^2\Pi \rightarrow {}^2\Sigma$ system, are reported. Field strengths up to 30,000 gauss were employed, the dispersion of the large concave grating in a parallel light mounting being about 2.1 Å per mm.

Satellite series in the ${}^2\Pi \rightarrow {}^2\Sigma$ bands.—The ${}^0P_{12}$ satellite branches are measured for both the A and A' bands. These frequencies together with certain combination relations fix the hitherto uncertain J numbering in the Q branches, and hence the size of the Λ -type doubling. This doubling is very large (70 cm^{-1} at $K=34\frac{1}{2}$) and of opposite sign to that usually found in other bands.

Zeeman effect in the ${}^2\Pi \rightarrow {}^2\Sigma$ bands.—General agreement with the pattern blocks predicted by Hill's theoretical formulas for the lower K' states is found. Intensity variations with increasing field strength are described. For $K' > 19$, where the no-field spin doublet components come together and cross over, uncoupling effects occur. Only the transitions from anti-parallel S and K in the ${}^2\Pi$ state to parallel S and H in the ${}^2\Sigma$ state, and from parallel S and K to antiparallel S and H persist. The displacements of these components are proportional to H^2 . At 30,000 gauss the high K components in the P_1 branch broaden out and go rapidly to zero intensity, but the P_2 field components remain narrow and strong. With complete uncoupling by this "strong field," these components are probably the transitions from parallel S and H in the ${}^2\Pi$ state to parallel S and H in the ${}^2\Sigma$ state. For the highest K levels, these high-field P_2 components are displaced farther from the no-field position and become more diffuse, suggestive of an approach to Hund's case d .

Zeeman effect in the ${}^2\Sigma \rightarrow {}^2\Sigma$ bands.—Contrary to the usual findings for bands of this type, broad and prominent Zeeman patterns here occur for $K' > 8$ which are quite similar to those found in a ${}^2\Pi$ state. The explanation is probably that an appreciable magnetic moment is created in the upper $4s\sigma^2 3d\sigma^2 {}^2\Sigma$ state by the increasing component of L along the rotational axis.

INTRODUCTION

A THEORETICAL treatment of the Zeeman effect in doublet band spectra has recently been published by E. L. Hill,¹ and the formula for the magnetic field patterns have been nicely verified by Almy and Crawford² for the case of the MgH ${}^2\Pi \rightarrow {}^2\Sigma$ band system. This theory considers molecules which can be classed under Hund's cases (a) and (b) or for cases intermediate between (a) and (b), neglects "rho-type" doubling, and considers the only uncoupling effect to be that on the electron spin. There are examples of diatomic molecules, however, where the rho-type doubling becomes very large, and where the coupling of the electronic orbital angular momentum to the rotational axis would be accompanied by a magnetic

¹ E. L. Hill, Phys. Rev. **34**, 1507 (1929).

² G. M. Almy and F. H. Crawford, Phys. Rev. **34**, 1517 (1929).

moment in that direction. In the $\lambda 6389^2\Sigma \rightarrow ^2\Sigma$ and $\lambda 7000^2\Pi \rightarrow ^2\Sigma$ CaH bands, for which these effects become very large, the Zeeman effect predicted by Hill's theory is to be expected, then, for the lower rotational states, but for the highest rotational states new magnetic field patterns should be found. Measurements of this perturbing effect of an external field should increase our knowledge of the dynamics of molecules exhibiting such a very large ρ -type and Λ -type doubling.

The analysis of Hulthén,³ together with Mulliken's⁴ discussion of these data, demonstrate the marked distortion increasing with the rotation in these CaH bands. In the upper electronic state of the $^2\Sigma \rightarrow ^2\Sigma$ band the orientation energy of the spin S with respect to the nuclear rotation axis, as measured by the separation of the F_1 and F_2 terms, is exceptionally large, the rotational doublets being separated even at the origin of the band by 1.3 cm^{-1} . Also the usual relation for $^2\Sigma$ states, $F_1 > F_2$, is reversed in this case. In the $^2\Pi$ state of the $\lambda 7000$ band the Λ -type doubling is very large (see below), thereby indicating a large L_{perp} (component of orbital angular momentum L perpendicular to the electric axis of the molecule), and the usual $^2\Pi$ state relation, $F_2(J) > F_1(J+1)$, which does hold for low J values is reversed for $J > 19\frac{1}{2}$. The ρ -type doubling in the common lower $^2\Sigma$ state is small, as in most $^2\Sigma$ states.

EXPERIMENTAL PROCEDURE

Our source was an intermittent d.c. arc in a modified Back chamber mounted on the pole faces of a large water-cooled Weiss electromagnet. The moving electrode was a small block of metallic calcium mounted on a tungsten wire, while the fixed electrode was a thin copper strip insulated from the pole face by a piece of mica. The arc was struck in a hydrogen atmosphere at from 5 to 10 cm pressure, and since the arc chamber was not absolutely vacuum tight, a stream of hydrogen gas from a tank was pumped slowly through the apparatus during the exposures. It was necessary to renew the calcium electrode at frequent intervals during each run. The bands were photographed in the second order of a large concave grating mounted in parallel light, the dispersion being approximately 2.1 \AA per mm.

The $\lambda 6389$ band was photographed with Eastman panchromatic plates hypersensitized by an ammonia bath. Plates were taken with field strengths of 14,000, 24,600 and 29,950 gauss with no polarizing prism in the path, and at 29,950 gauss in the perpendicular and parallel polarizations separately, with the exposure times up to 12 hours when the Nicol prism was used. The $\lambda 7000$ band was recorded on Eastman 40 and panchromatic plates dyed with dicyanin. Field strengths of 10,500 and 30,000 gauss were used, the times of actual exposure on the slit running to 18 hours. On every plate in addition to the field exposure a no-field comparison and an iron arc spectrum were photographed. The strength of the magnetic field was determined by measurements of the patterns of the Zn triplet $\lambda\lambda 4680, 4722$, and 4811 .

NEW SERIES AND MAGNITUDE OF Λ -TYPE DOUBLING IN ${}^2\Pi \rightarrow {}^2\Sigma$ BAND

The J values assigned by Hulthén³ to the lines in the P and R branches of the $\lambda 7000$ band are correct when reduced by $\frac{1}{2}$ unit in order to agree with the quantum mechanics numbering. But since it is apparent from Hulthén's data that the ordinary PQR combination relation does not even hold approximately, and since no (1, 0) or (0, 1) band seems to be available for combination checking purposes, the J numbering in the Q branches has been heretofore undetermined. Now our spectrograms indicate that all the satellite series to be expected in a ${}^2\Pi_{ab}$ state⁵ are present and with fair intensity in this band. In particular the ${}^0P_{12}$ satellite branch⁶ proceeds to the red from the P branch head in a region clear of other lines. The frequencies of the lines in this branch can be calculated from the relation⁷

$${}^0P_{12}(J) = Q_1(J-1) + [F_1''(J-1) - F_2''(J-2)] - [F_2''(J) - F_2''(J-2)]_{(1)} \\ = Q_1(J-1) + 0.045(J - 1\frac{1}{2}) - \Delta_2 F_2''(J-1).$$

The second term on the right side of this equation involves the empirical rule for the separation of the spin components in the lower state of these bands,⁵ while the $\Delta_2 F_2''$ values can be taken directly from Hulthén's tables. The proper Q_1 frequencies to so combine with these F'' differences as to give the observed satellite branch lines can be thus uniquely determined, and the important point is that this fixes the J numbering of the Q_1 branch and hence the exact course of the Λ -type doubling in the F_1' levels. Table I

⁵ Cf. R. S. Mulliken, Phys. Rev. 32, 388 (1928) for a detailed account of the various possible branches in ${}^2\Pi \rightarrow {}^2\Sigma$ transitions.

⁶ We are using, throughout, the notation recommended by R. S. Mulliken in his forthcoming article in this journal on standardized notation for description of molecular spectra. This branch would be designated formerly as ${}^PP_{12}$.

⁷ Compare level diagram in ref. 5. Note particularly that the ${}^0P_{12}$ and Q_1 transitions are from the same A sublevels in the upper state.

gives the wave-numbers of the observed ${}^0P_{12}$ lines for both the (0, 0) and (1, 1) bands together with their calculated values from Eq. (1). The agreement of the observed and calculated frequencies can only be produced by increasing Hulthén's J numbering in the Q_1 branch of the (0, 0) band (his A band) by $1\frac{1}{2}$ units, and in the Q_1 branch of the (1, 1) band (his A' band) by $\frac{1}{2}$ unit. Two new Q_1 lines should be added to Hulthén's tabulation for the A band; $Q_1(\frac{1}{2})$ 14393.31 and $Q_1(1\frac{1}{2})$ 14396.71. These are clearly present and of good intensity on our plates. Because of the confusion of stronger lines in the short wave-length side of these bands, the accurate measurement of the corresponding ${}^5R_{21}$ is rendered difficult. Fragments of this branch have been located, however, and seem to indicate similarly that Hulthén's J numbering in the Q_2 branch should also be raised $1\frac{1}{2}$ units. In computing the magnitude of the Λ -type doubling in the F_1' terms we use the relation

$$\begin{aligned} & [R_1(J) - Q_1(J)] - [Q_1(J+1) - P_1(J+1)] \\ &= F_{1B}'(J+1) - F_{1A}'(J) - F_{1A}'(J+1) + F_{1B}'(J) \\ &\cong F_{1B}'(J+\frac{1}{2}) - F_{1A}'(J+\frac{1}{2}). \end{aligned} \quad (2)$$

Table II gives in condensed form the course of this doubling, showing that for the lowest J levels the doubling increases in the usual fashion;⁸ but that at $J=6\frac{1}{2}$ the separation of these sublevels begins to decrease, becomes

TABLE II. Λ -type doubling in F_1' levels of (0,0) ${}^2\Pi \rightarrow {}^2\Sigma$ band calculated from Eq. (2).

J	$F_{1B}'(J+\frac{1}{2}) - F_{1A}'(J+\frac{1}{2})$	J	$F_{1B}'(J+\frac{1}{2}) - F_{1A}'(J+\frac{1}{2})$
$1\frac{1}{2}$	+2.04	$11\frac{1}{2}$	-0.54

$10\frac{1}{2}$	+0.53		

zero at $J=11\frac{1}{2}$, and increases to very large negative values for the highest rotational levels. The F_2' levels proceed apparently in much the same way, although usually⁸ F_2 levels show an almost negligible Λ -type doubling.

This large rotational doubling in the Π state is evidence for a very considerable growth in L_{perp} . There is reason therefore for supposing that the effect of an external magnetic field on these high rotational levels would be a variation of that for cases a to b .

THE ZEEMAN EFFECT IN THE ${}^2\Pi \rightarrow {}^2\Sigma$ BAND

We will consider the effect of the magnetic field first for the lines of low and intermediate K values, and then for the high rotation lines. For the lines in the first group the CaH molecule is intermediate between case a and case b , and Hill's theory should give a good description of the observed patterns. Since the ρ -type doubling is small in the lower ${}^2\Sigma$ state, the only effect of the field in this state should be to uncouple the spin S from its weak coupling with K , so that these levels all become sharp doublets of separation

⁸ J. H. Van Vleck, Phys. Rev. **33**, 467 (1929). R. S. Mulliken, Phys. Rev. **33**, 507 (1929).

$2\Delta\nu_{\text{norm}}$. In general one must make a detailed computation with Hill's equation (22), the constants for our $^2\Pi$ state being $B=4.3\text{ cm}^{-1}$, $\lambda=+19\text{ cm}^{-1}$, $\Lambda=1$. Since for no line have we observed the resolved magnetic fine structure due to all the possible values of M , the magnetic quantum number, it is only necessary to calculate the position and overall widths of the blocks of unresolved components in the patterns by using $M=+J$, 0, and $-J$. These patterns we have calculated for $K'=3$, 10, and 18. For $K'=18$, and even for $K'=10$, Hill's energy equation considerably overestimates the width of the spin doublet interval, since it does not consider ρ -type doubling, and therefore complete quantitative agreement with the observations is not to be expected. The details of the comparison, together with some observations on lines with approximately these K' values are presented in Table III. Figs. 1 and 2 show graphically this comparison for $K'=3$ and 10.

TABLE III. Comparison of observed and calculated patterns for low and intermediate values of K in $^2\Pi \rightarrow ^2\Sigma$ band.

(In this and the other tables + indicates field radiation to the higher frequency side, - to the lower frequency side, of the no-field position.)

	$H=30,000$ gauss, $\Delta\nu_n=1.41$. Calculated pattern wide diffuse doublet, approx. symmetrical about no-field position; roughly in agreement with obs. $P_1(4\frac{1}{2})$ pattern. - components inside edge at -0.89 ; obs. -0.94 . Violet block's outermost edge at $+1.93$; obs. $+2.06$. Other two edges obscured. Q_1 lines also become diffuse doublets but the intensity distribution is very different: the two blocks are of equal intensity, whereas at the lower field strength the "wings" are more intense; maximum intensity in each block is near the inner edge, nearest the no-field position. Red component's maximum at -0.72 , violet's at $+0.79$, whereas predicted inside edges are -0.89 and $+0.85$ cm ⁻¹ .																										
$P_1(11\frac{1}{2}), (12\frac{1}{2})$ $(13\frac{1}{2})$ $Q_1(10\frac{1}{2}), (13\frac{1}{2})$ $P_2(9\frac{1}{2}), (10\frac{1}{2}), (11\frac{1}{2})$ $Q_2(13\frac{1}{2})$	$K'=9$ to 14 $H=10,500$. Calculated patterns are doublets. F_1 states: calculated inside edge of red component at -0.08 for $K'=10$; obs. -0.09 -0.08 , -0.14 for $P_1(11\frac{1}{2})$, $P_1(12\frac{1}{2})$, and $Q_1(10\frac{1}{2})$ respectively. Width of red components: calc., 0.78 ; obs., 0.39 , 0.35 , and 0.30 respectively—i.e., obs. blocks much narrower than calculated width. P_1 and R_1 violet components of negligible intensity, but in $Q_1(10\frac{1}{2})$ the violet component is weaker than the red component but is present starting at the red component and extending to $+0.51$, against the theoretical max. displacement $+0.90$. F_2 states: Predicted doublets are approximately symmetrical with respect to no-field line, have components narrower, 0.48 cm ⁻¹ , and separated by 0.98 cm ⁻¹ between centers for $K'=10$. Observed patterns in good agreement with theory. Violet or "wing" components much stronger than red components and narrower than predicted.																										

TABLE III (continued).

	K'	Observed F_2 Patterns		
		Doub. width	Component widths	
P_2	9	0.85	-0.37	+0.28
Q_2	14	0.79	-0.46	+0.31

$H=30,000$. F_1 states: Lines should become broad symmetrical doublets in field according to theory. P_1 and R_1 patterns not present; probably too weak and diffuse. Q_1 lines become strong broad doublets, narrowing with increasing K , and whose inside edges nearest the no-field line are much the stronger parts of the patterns. For $K'=10$ these maxima are at -0.50 and $+0.55$ as against computed inside edges for the blocks at -0.28 and $+0.30$. The red "wing" components are just as intense as the violet components.

F_2 states: Calculated field doublets are symmetrical, have inside edges farther from no-field position, and have narrower component blocks. All in agreement with observations, but obs. components much narrower than predicted, hence quite intense; also two components are equally strong.

P_2 component separations from no-field line.

K'	Calc.	Obs. -	Obs. +
9		1.14 to 1.62	1.08 to 1.37
10	0.74 to 2.08	1.15 to 1.45	1.05 to 1.34
11		1.17 to 1.57	0.98 to 1.31

$K'=18$

$P_1(19\frac{1}{2})$
 $Q_1(18\frac{1}{2})$
 $P_2(18\frac{1}{2})$
 $R_2(16\frac{1}{2})$

$H=10,500$. According to theory all lines become doublets in the field; the F_1 patterns with very narrow components separated by 0.96 . Actually only the red "wing" components can be seen; in $P_1(19\frac{1}{2})$ from -0.08 to -0.43 ; in $Q_1(18\frac{1}{2})$ from $+0.01$ to -0.29 , although theory has this component at -0.48 .

F_2 patterns are calculated to be more diffuse doublets with but 0.21 cm^{-1} between inside edges and center of components at -0.48 and $+0.50$. For $P_2(18\frac{1}{2})$ only violet component observed from $+0.07$ to $+0.38$. $R_2(16\frac{1}{2})$ becomes a doublet with strong violet component from $+0.16$ to $+0.46$ and very weak red component at -0.27 . Theory predicts no-field spin doublet separation 15.8 cm^{-1} , whereas experimentally it is but 2.5 cm^{-1} .

$H=30,000$. Theory predicts widely separated doublets (2.82 cm^{-1}) with components narrow for F_1 patterns. These are not observed. No P_1R_1 field radiation is apparent and the Q_1 pattern is broad and diffused into adjacent patterns. F_2 patterns predicted to be broad diffuse doublets with inside edges at -0.32 and $+0.35$ and centers at -1.30 and $+1.52$ for the red and violet components respectively.

Observed F_2 patterns for $K'=18$

$P_2(18\frac{1}{2})$	-0.86 to -1.30	+0.94 to +1.67
$R_2(16\frac{1}{2})$	-0.86 to -1.30	+1.22 to +1.61

Both components intense and considerably narrower than the computed widths.

Some of the more striking features of the observed patterns should be emphasized. In agreement with the theory, all of these lines apparently become doublets in the field, each component of the doublet of course being in reality a block of $2J+1$ unresolved lines, but the observed doublet width is always less than that predicted. This smaller width may be caused by the relative faintness of the outer portions of the patterns. At $10,500$ gauss, for all except the very lowest K' values, the intensity is almost entirely in the red components for the P_1 , Q_1 , R_1 patterns and in the violet components for

the P_2 , Q_2 , R_2 patterns. These are the transitions from parallel S and K in the $^2\Pi$ state to the $M_s = +\frac{1}{2}$ level in the $^2\Sigma$ state and anti-parallel S and K to $M_s = -\frac{1}{2}$ respectively, and correspond to the "wings" of Almy and Crawford's

Fig. 1. Calculated splitting of the energy levels and the resulting Zeeman patterns for lines with $K'=3$ from Hill's theoretical equation (ref. 1). Of the observed lines, $P_1(4\frac{1}{2})$ and $R_1(2\frac{1}{2})$ have $K'=3$, while for $Q_1(2\frac{1}{2})$, $K'=2$ and $P_1(5\frac{1}{2})$ has $K'=4$. The corresponding P_2 , Q_2 , R_2 lines are too weak to observe. Since at 10,500 gauss the field components are narrow, only a measurement of the center of the component in each case was made. At 30,000 gauss due to overlapping patterns only the measurements given on the $P_1(4\frac{1}{2})$ line pattern could be made, but the observations indicate widths for the blocks approximately in agreement with the predictions.

MgH patterns.² The components arising from the other two possible transitions⁹ we shall refer to as the "inside" components. At 30,000 gauss, however, both components are equally strong for all the patterns measured (P_2 , R_2 ,

Fig. 2. Comparison of calculated and observed patterns for lines with $K'=10$. The $P_1(11\frac{1}{2})$, $Q_1(10\frac{1}{2})$ and $P_2(10\frac{1}{2})$ lines all have $K'=10$. For $P_2(9\frac{1}{2})$, $K'=9$, while for $Q_2(13\frac{1}{2})$ $K'=14$. At 10,500 gauss the "outside" components are much stronger (indicated by solid black) than the inside (shaded) components. At 30,000 gauss the P_2 components are narrower than predicted, the Q_1 components are strongest at their edges nearest the no-field line position, and both components are in all cases of equal intensity.

Q_1), thus indicating that, because the no-field spin doublet separation is still considerably greater than $\Delta\nu_n$, the coupling of S in the $^2\Pi$ state has not been

⁹ Cf. the excellent diagrams illustrating the relation between the possible transitions and the components in ref. 2.

broken down by the field. The intense concentration of the patterns of the Q_1 lines as contrasted with the apparent absence of field radiation for the P_1 and R_1 lines, however, is difficult to explain. The enlargement of a portion of this band in Fig. 3 illustrates some of these pattern changes.

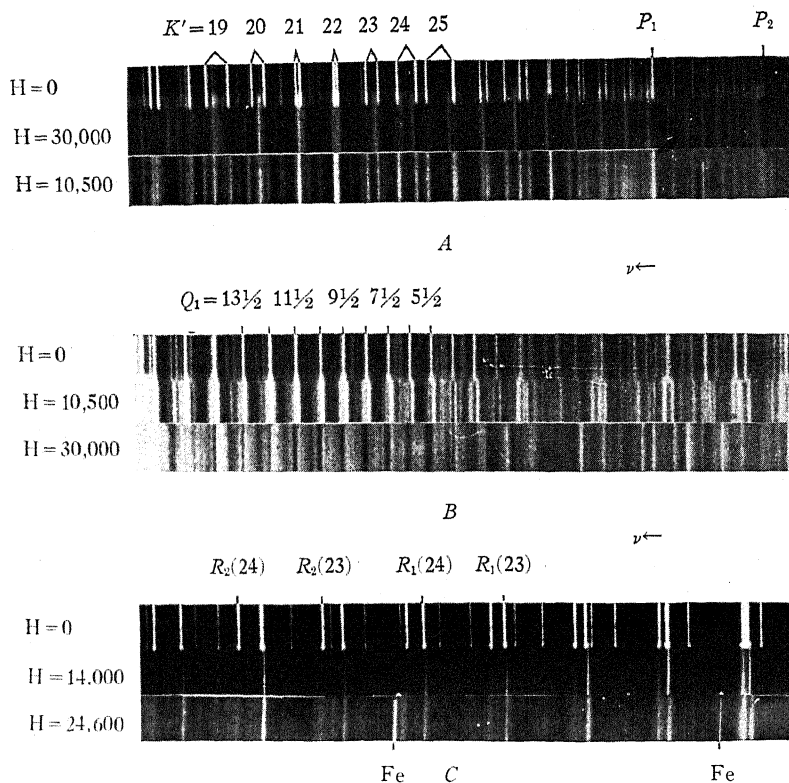

Fig. 3. Enlargements 9 times. A shows the "cross-over" region in the P branches of the $^2\Pi \rightarrow ^2\Sigma$ band. It is evident that for $K' > 24$ both the P_1 and P_2 lines for $H = 10,500$ gauss have "inside" component blocks equally strong, but that for $H = 30,000$ gauss the P_1 field radiation has broadened out and become of negligible intensity, although the P_2 components are strong. In the reproduction P_1 and P_2 denote the heads of the two branches in the no-field strip. In B note the greater intensity of the field components on the long wave length side for $H = 10,500$ gauss as compared to the equal intensity of the two field components for $H = 30,000$ gauss. In the latter case the greater intensity of the field blocks at their inside edges is evident. C gives some of the patterns for high K values in the $^2\Sigma \rightarrow ^2\Sigma$ band. The R_2 line patterns and the weak components of the R_1 lines on the high frequency side are of insufficient intensity to be brought out well in the reproduction. The breadth of the no-field lines in C is due to over exposure.

For $K' \geq 19$ where the no-field spin doublet components come close together and then cross over, making $F_1'(J+1) > F_2'(J)$, prominent and interesting "second-order" or Paschen-Back effects appear. These effects are summarized in Table IV and are illustrated in Fig. 3A for the P_1 , P_2 lines only. That a "strong field" uncoupling of S is here taking place is evidenced by first, the fact that the wing components decrease to zero intensity

TABLE IV. Magnetic field patterns at and beyond the cross-over in the P branch spin doublets in the $^2\Pi \rightarrow ^2\Sigma$ band.

K'	10,500 gauss. $\Delta\nu_n = 0.49 \text{ cm}^{-1}$
19	Practically all the intensity in the "wings". $P_1(20\frac{1}{2})$ wing at -0.28 , $P_2(19\frac{1}{2})$ wing at $+0.33$. Very little shading between the lines.
20	Now wings are weaker and the other two "inside" components have appeared. Reckoning from the P_2 line: P_1 wing at -2.07 , P_1 no-field, -1.64 ; inside components fused from -1.36 to -0.44 , P_2 wing $+0.51$.
21	Wings have disappeared. P_1 no-field at -0.57 , strong field component -0.52 to -0.29 , weaker fused field radiation from strong component to $+0.13$.
22	No-field lines have now crossed over. Field pattern one strong broad block approximately width of original spin doublet separation, 0.51 . No wings.
23	Fused inside components now separated because spin doublet separation is greater. P_2 no-field at 0.0 , P_2 component at $+0.07$, P_1 component $+1.45$, P_1 no-field $+1.54$. These P_1 and P_2 field components are equally strong. No wings. Succeeding P_1 and P_2 lines to the ends of the branches similarly affected.
	30,000 gauss. $\Delta\nu_n = 1.41 \text{ cm}^{-1}$
19	Reckoning all separations from the P_2 no-field line position in each pattern: Weak shading in field starts at P_1 no-field, -2.83 , and goes to strong band component starting at -0.91 and ending -0.41 , P_2 wing from $+1.74$ to $+2.20$.
20	Weak shading from -1.82 to strong component starting at -1.00 and ending -0.65 . P_1 no-field position is -1.64 . No evidence now of P_2 wing.
21	Rather strong shading begins sharply at -1.08 and extends to the strong, narrower field component at -0.24 . P_1 no-field position is -0.57 . No wings.
22	Lines have crossed. Strongest field line and $P_2(22\frac{1}{2})$ position at 0.00 , with field radiation extending rather intense to a strong edge at $+0.85$. P_1 position is $+0.51$. No wings.
23	Weaker fused field radiation starts at -0.35 and extends to $+1.94$. Edges of this block are well defined. Strong field component at $+0.45$ superposed. P_1 position is $+1.54$.
24	Strong field component at $+0.54$ with weaker field radiation solid from here to $+2.88$. P_1 position is $+2.50$.
25	Strong field component at $+0.74$. Broad weak field radiation for the P_1 from $+1.75$ to $+4.47$. P_1 position is $+3.53$. From here on to the P_1 head, the P_1 field radiation is very diffuse and weak causing the whole background to be slightly blackened. The strong P_2 field component blocks continue out to the P_2 head, the displacements from the no-field positions for the next four lines being $+0.65$, $+0.69$, $+0.75$ and $+0.73$, or about $\frac{1}{2}\Delta\nu_n$. For the last lines near the head, the displacements are a little greater, averaging $+0.80 \text{ cm}^{-1}$ for $K' = 36, 37, 38$, and the components are becoming definitely broader and more diffuse.

and the inside components come in strong as the spin doublet separation goes to zero. This is to be interpreted as due to the uncoupling of S from its interaction with the internal field directed along the rotational axis in the molecule, the F_2 state in which S and K are anti-parallel being replaced by the parallel orientation of S and the field H , while the F_1 state or parallel S and K is replaced by the state in which S lies anti-parallel to H .¹⁰ S and K are then separately quantized with respect to the field, giving the quantum numbers M_S and M_K . Since only the inside components representing transitions for which $M_S = 0$ occur for all levels of higher K , we infer that this uncoupling is complete. Second, the displacement of the strong P_2 field components seems to be almost exactly proportional to H^2 rather than to H as in the usual first-order Zeeman effects.

The difference between the patterns of the P_1 and P_2 lines at 30,000 gauss in this uncoupling process is striking. The one inside field component

¹⁰ Reference 1, p. 1513.

of the P_2 lines is rather narrow and intense, whereas the field radiation associated with the P_1 lines in the interval from $K'=20$ to 25 becomes increasingly broader and weaker, and for $K' > 25$ is too weak to detect. Apparently the transition from parallel S and H in the $^2\Pi$ state is very much more probable when the field is "strong" than that from the anti-parallel S and H , indicating an instability of this anti-parallel orientation.

Also to be especially noticed are the increasing separation and increasing diffuseness of these high field P_2 components for the highest K levels. This would seem to be related to the exceptionally large Λ -type doubling and consequent relatively large L_{perp} . The electric axis of the molecule at these highest rotational levels is probably becoming less effective in orienting the L , with the result that Λ is no longer a good quantum number. There is a close approach to the case d type of coupling, and the resulting changes in the magnetic moment are reflected in the broadening of these last field patterns.

THE ZEEMAN EFFECT IN THE $^2\Sigma \rightarrow ^2\Sigma$ BAND

Neglecting p -type doubling, $^2\Sigma \rightarrow ^2\Sigma$ bands should exhibit no first order Zeeman effect, for the field merely completely uncouples the spin S in both states, and with $\Delta M_S = 0$ accurately holding, no displacement of the spectrum lines is to be expected. The very pronounced p -type doubling in the $\lambda 6389$ CaH band, however, indicates a considerable energy of orientation of S with respect to an internal field directed along the rotational axis in the

TABLE V. Summary of magnetic field measurements in the $\lambda 6389$ $^2\Sigma \rightarrow ^2\Sigma$ CaH band.
($H_1 = 14,000$ gauss, $\Delta\nu_n = 0.66$. $H_2 = 24,600$ gauss, $\Delta\nu_n = 1.16$. $H_3 = 29,950$ gauss, $\Delta\nu_n = 1.41$)

K' 1 to 7	Measurements and Remarks		
	P_1 and R_1 lines (parallel S) unaffected by field $R_2(1\frac{1}{2})$ becomes a doublet in field, components at -0.35 and $+0.55$ for H_2 and -0.36 and $+0.88$ for H_3		
	Other R_2 lines are affected by field but patterns are confused with other radiation P_2 lines are doubled in field:		
K'	H_1	H_2	H_3

For $K'' > 8$ all of the R_1 and R_2 lines have the patterns as given below for a few samples:			
	R_1	R_2	
12	H_1 -0.60 to -0.25 and shades to +0.93	H_2 -1.34 to -0.20 and +0.28 to +0.91 + and - components same strength	H_3 -1.74 to -0.25 and +0.42 to ? These single blocks shading to the violet from the no-field position constitute the full R_2 pattern
15	-comp. at -0.44 no + comp.	-1.15 to -0.19 strong, and +0.37 to ? weak	
21	-comp. at -0.35 no + comp.	-1.05 to -0.25 strong, and +0.49 to ? very weak	-1.29 to -0.29 strong, and +0.34 to ? weak 0.00 to +1.49 ($K' = 23$:) 0.00 to +0.64
25	-comp. at -0.34 no + comp.	-0.91 to -0.47 strong, with +0.36 to ? very broad and weak	-1.24 to -0.37 strong, with + comp. very weak 0.00 to +1.50 ($K' = 24$:) 0.00 to +0.58

upper electronic state. One might anticipate a rather large and unique Zeeman effect in this band, then, and so there is. In Table V we list briefly some of our measurements, and in Fig. 3C an enlargement of a portion of one of the spectrograms illustrates the principal pattern types obtained. The measurements are confined mostly to the R branch lines, since the overlapping of the patterns from the rather closely packed lines in the P branches makes their analysis hopeless at this dispersion.

It will be noticed that the P_1 and R_1 lines of low K values are unaffected by the field, but that the P_2 and R_2 lines become rather broad doublets. At about the level $K'=8$ the field patterns change, and take on a form which they retain out to the highest K level observed. The R_1 lines (parallel S and K) become rather diffuse doublets, the red and violet components being at first of about the same intensity, and with the outer edge of each component at about $\Delta\nu_n$ displacement from the no-field position. As K increases, however, the violet component becomes much weaker and the red component becomes narrower and somewhat stronger. The characteristic pattern for all the corresponding R_2 lines (anti-parallel S and K), on the other hand, is just one block of unresolved lines, shading from the no-field position toward higher frequency for an interval of about $\Delta\nu_n$. All patterns appear in both polarizations, although the widths and intensities are perhaps different on the two plates.

These patterns for the higher rotational levels are quite similar to those found in a $^2\Pi$ state for which there is a normal magnetic moment associated with the component of L in the direction of the electric axis. In the upper $^2\Sigma$ electronic state of this $^2\Sigma \rightarrow ^2\Sigma$ band there is a large magnetic interaction energy between S and an internal field directed along the nuclear rotational axis. This field must be due to a component of L in this direction, the order of magnitude of this component being at least a full unit of angular momentum, for one can interpret these patterns as being the superposition of the pattern due to the symmetrical top on a partial uncoupling of the spin S . The width of the blocks of lines forming the components in the patterns decreases with increasing K , as they should. And the strength of the $-$ components for the R_1 lines and the $+$ components for the R_2 lines is just as found in the $^2\Pi \rightarrow ^2\Sigma$ band, for these components originate in the "wing" transitions which we have discussed above.

It is not probable that this magnetic moment in this $^2\Sigma$ state could be due to nuclear rotation, for then one would expect similar very large p -type doubling in all $^2\Sigma$ states of this and like molecules. Now there is other reason to believe that the outer electron configuration in this $^2\Sigma$ state¹¹ is $4s\sigma^23d\sigma$, this level being derived from the low-lying $3D$ level of the Ca atom. Since $L=2$ (due to the d electron) and the effect of the electric axis is small ($\lambda=\sigma=0$), there is a good chance that the component of L along the perpendicular axis can become large. The accompanying magnetic moment and rather large coupling energy with the S then account for the Zeeman patterns observed.

THE INFRARED ABSORPTION OF SOME ORGANIC LIQUIDS
UNDER HIGH RESOLUTIONBY R. BOWLING BARNES
JOHNS HOPKINS UNIVERSITY

(Received April 30, 1930)

ABSTRACT

For the purpose of comparing the Raman effect with infrared absorption spectra, the following organic liquids have been measured from 3.1μ to 3.6μ : benzene, toluene, ortho-, meta- and para-xylene, ethyl-, butyl-, monochlor-, and monobromobenzene. The spectrometer employed an echelette grating, which had 3600 lines per inch, and which concentrated the energy of a Nernst filament into the region which was investigated. The dispersion of the instrument was such that with the slits each 0.25 mm in width, one "slit width" was approximately 25\AA . The calibration was obtained in terms of the positions of the 5461 line from an auxiliary Hg arc, and the wave-lengths as given are considered accurate to $\pm 0.003\mu$. In every case the bands in this region, due to the C-H vibration, which have hitherto been reported only under low dispersion have been resolved into many component parts. The 3.25μ band of benzene was resolved into three equally strong components lying at 3.231 , 3.253 and 3.291μ respectively. The shifts of these bands caused by the various substitutions were studied, and in no case was a shift of over 0.01μ found.

DURING the past two years much has been said concerning a new method of infrared analysis, the Raman effect. Much importance is attached to it, for it offers a very convenient mode of attacking many problems of molecular structure. However, its usefulness depends upon the accuracy of its theoretical interpretation, and the manner in which this latter agrees with experimental evidence. As a direct result of this, all work previously done in the infrared has taken on an added importance, that of furnishing means of investigating and testing the theory of this effect.

The technique of the Raman effect has developed so rapidly that the photographs taken now, are all made under high resolution and hence show considerable detail. These results must be compared with such infrared measurements as may be found in the literature, and since these latter wave-lengths are usually known to a rather low degree of accuracy, such comparisons are not fair and in most cases can be only qualitative. So, in order to obtain any quantitative checks between the two phenomena, it seems necessary that many absorption measurements be made with the highest resolution obtainable.

The complete theory of the Raman effect is contained in the theory of dispersion as outlined by Kramers as early as 1925. Further calculations by Dirac,¹ based upon the more recent form of quantum mechanics lead to the same results as those stated in the papers by Kramers and Heisenberg.²

¹ Dirac, Proc. Roy. Soc. A114, 710 (1927).

² Kramers and W. Heisenberg, Zeits. f. Physik 31, 681 (1925).

Here we learn that the intensity of a Raman line is determined in an entirely different manner from that of an absorption line. Between any two energy levels, say A_1 and A_2 , the presence or absence of an absorption line is completely determined by the value of the transition coefficient (a_{12}). However, in the expression for the intensity of the Raman line, this coefficient does not enter, but in its place the transition coefficients to a third level, say B , which can combine with both A_1 and A_2 . Thus it is possible to have, between A_1 and A_2 , either an absorption line or a Raman line, or both, depending on the values of the transition coefficients (a_{12}), (a_{1b}) and (a_{2b}). Further, in case both exist, the intensities are to be entirely independent of each other. That this interpretation is correct, cannot be doubted in view of the beautiful manner in which it agrees (in the case of the simple molecules) with the experimental results obtained by Rasetti, McLennan and McLeod and Wood. In HCl, Wood finds that the so called "missing line" occurs as a rather strong Raman line. It was shown by Kemble and Hill³ that this was in perfect ac-

TABLE I. STRUCTURAL FORMULAE OF COMPOUNDS STUDIED

cord with the theory. In the case of more complex molecules further corroboration comes from the work of Coblenz⁴ on CCl_4 , and of many other experimenters.

It seems well to emphasize here, the fact that one must not expect to find a one-to-one correspondence between absorption and Raman spectra. In spite of the many theoretical papers on the question regarding the difference between the two, experimentalists frequently refer to the fact that absorption lines "predicted" by the Raman effect do not appear in absorption measurements. Only if we know the energy diagram for a given substance, can we really predict from the Raman spectra just what lines shall occur in the absorption spectra. And in the case of the complex molecule usually studied by Raman investigators, these energy schemes are entirely unknown.

³ Kemble and Hill, Proc. Nat. Acad. Sci. **15**, 387 (1929).

⁴ W. W. Coblenz, Bull. Amer. Phys. Soc. **4**, No. 2 (1929).

It is out of the question therefore to expect, as is very frequently done, that strong Raman lines will be found corresponding to each of the intense absorption lines, and vice versa.

It is clear then, that infrared measurements which can state wave-lengths with the same degree of accuracy as those on Raman photographs, will be of great interest. And so, as a step in this direction, we offer here a study of the C-H vibration in the case of the following nine organic liquids whose structural formulae are given in Table I: benzene, toluene, ortho-, meta- and para-xylene, ethyl- butyl-, monochlor-, and monobrom-benzene.⁵ It is hoped that these results will be useful in connection with the Raman study of the same compounds made by Wood,⁶ for his plates show that this band is in every case quite complex in its structure.

Fig. 1. Plan of apparatus.

APPARATUS

A plan of the grating spectrometer, which was used is given in Fig. 1. Radiation from a Nernst glower, operated on a 110-volt storage battery at 0.35 amp., was focussed upon the absorption cell, *C*. After passing through this, it was focussed upon *S*₁, the first slit. *M*₃ then collimated the beam and directed it to *G*, the eschelette grating. The diffracted beam was then focussed upon *S*₂, after which it was finally concentrated upon the thermopile *T*, by the mirror *M*₅.

Attention is called to several novel features included in this spectrometer. In the major part of these investigations a new type absorption cell was used,

⁵ R. B. Barnes, *Nature* **124**, 300 (1929), *Bull. Amer. Phys. Soc.* **5**, 10 (1930).

⁶ R. W. Wood, *Phil. Mag.* **7**, 858 (1929).

instead of the customary one of rock-salt. As is shown in Fig. 2(b), this cell consisted of a brass cup so designed that the layer of the liquid to be examined would be contained between the two microscope cover glasses, b and b' . This thickness could be varied at will, and very easily measured, for a metal "thickness gauge" could be temporarily inserted between the plates, while the horizontal tubes were being sealed in place with sodium silicate. Such a cell has a high uniform transparency in this region, and eliminates the inconveniences caused by evaporation of the solution and fogging of salt plates. The use and design of this new cell was suggested by Dr. Pfund.

The grating was a chromium plated echelette⁷ ruled in this laboratory, and concentrated most of the energy in the desired region. Having 3600 lines

Fig. 2. Absorption cell and thermocouple mounting.

per inch, and being 3 inches wide, it had a theoretical resolving power of over 10,000, as compared with about 170 for a 3-inch salt prism, the type usually used in this region. Since a grating, however, superposes orders, the effect of the second order 1.5μ radiation had to be determined. A water cell, which had zero transmission beyond 3μ was used. This had a transparency of about 70 percent at 1.5 to 2.0μ . By making measurements with and without this shutter in place, the second order effect was readily detected and due allowance made for it in the calculations.

The thermocouple was a compensating one made of Hutchings alloys.⁸ This was used in series with a high-sensitivity Leeds and Northrup galvanometer of 5 sec. period. The scale distance was about 5 m, and the deflections

⁷ R. W. Wood, *Phil. Mag.* 7, 742 (1929).

⁸ A. H. Pfund, *J.O.S.A.* 15, 69 (1927).

were read to 0.5 mm. By means of the arrangement shown in Fig. 2(a) a double deflection method, somewhat analogous to that used by Pfund,⁹ was employed. By raising the weight, W , the radiation was focussed upon the lower junction of the thermocouple instead of the upper junction, and a deflection in the opposite direction was obtained. Readings were taken of deflections to the right, left and again to the right, thus eliminating the troublesome zero shift and at the same time realizing a double sensitivity and a greater accuracy.

The calibration was obtained by placing a mercury arc in front of S_1 and observing the positions of the grating as the first eight orders of the 5461 line fell upon S_2 . The grating settings were determined by observing the image of a lamp filament, reflected by a small mirror which rotated with the grating. By plotting the grating settings against the respective wave-lengths a perfectly straight calibration curve was obtained. Before and after each set of absorption measurements were made, this was checked at two points. In no case did the image of the filament fail to fall at its appointed place by as much as 0.5 mm, where a distance of 1 mm indicated a change of wave-length of 0.0028μ . The accuracy of the calibration was therefore better than 0.0014μ .

For each setting of the spectrometer we recorded a set of galvanometer deflections, C , for the radiation passing through the absorption cell; a set for transmission through an empty cell, E ; and finally a set while the water shutter H , was in place. By dividing $(C-H)$ by $(E-H)$ we obtained directly the percentage transmission for the wave-length indicated by the grating setting.

RESULTS AND DISCUSSION

The wave-lengths as stated below are believed to be accurate to less than $\pm 0.003\mu$. Throughout most of the work the two slits were kept at a separation of 0.25 mm. The mercury yellow lines in the 6th order were separated on the face of S_2 by 1.2 mm, which indicated that the "slit-width" must have been very nearly 0.0025μ . Except in regions where a more careful check upon the location of some particular band was desired, readings were taken at intervals of 0.0070μ . Even when these intervals were halved, the author realizes that much of the band structure has been missed.

Fig. 3 shows a comparison of the absorption of benzene and four methyl substitutions. In Fig. 4 we have compared benzene with ethyl-, butyl-, chlor- and brom-benzene. In these curves we have plotted as ordinates the percentage transmission, and while the numerical values are not given, as the curves are each based upon a different zero line, the percentages run in each curve from about 95% to 25 or 30%. The structural formulae of the various compounds, showing the position of the C-H linkages, are given in Table I. Table II gives a list of all the observed bands. The samples used in every case are the same as those used by Dr. Wood in his Raman work, and are of a very high degree of purity.

* Bands due to the absorption of water vapor in the atmosphere. More recent investigations, in which better resolution was obtained, have revealed the fact that several of the bands listed in Table II, and which occur in Figs 3 and 4 as very small minima, are due to atmospheric absorption. It is possible also, that in regions where the C-H bands are of about the same intensity as the water-vapor bands, there may be some little uncertainty as to the exact locations of the former due to imperfect resolution. However, in the cases of the stronger C-H bands which I discussed above, this effect plays a negligible role. A complete account of this more recent work is very soon to be published.

In this series of benzene derivatives, we have an excellent opportunity to study and observe the effects of various substitutions and of molecular arrangement and symmetry in causing a shift in the frequency of particular bands. Since benzene is the parent of all of the compounds studied we call especial attention to its characteristic bands.

The C-H band of benzene is always reported at 3.25 μ in the literature.¹⁰ In this work we have it clearly resolved into three components of approximately the same intensity lying at 3.231 μ , 3.253 μ and 3.291 μ respectively. We shall follow these bands throughout all of these compounds. Benzene shows other weaker bands as can be seen from Table II. In this discussion however, we shall deal only with the strongest bands in each of the compounds.

In the case of toluene, we find in the literature¹⁰ a single band at 3.34 μ , indicating a shift, due to the substitution of the methyl group of 0.09 μ . From curve (b) of Fig. 3 it can be seen that this is not at all the case. All three of the benzene C-H vibrations persist, each having been shifted by 0.007 μ only, and are found at 3.238 μ , 3.261 μ and 3.298 μ respectively. The intensities of the two bands of shorter wave-length have been noticeably decreased, while the band at 3.291 μ is still quite strong. The vibrations of the C-H within the methyl group have apparently introduced rather strong bands at 3.276, 3.343, 3.428 and 3.478 μ besides other weaker ones. These facts suggest that the presence of the other two H atoms in the CH₃ group makes possible several modes of C-H vibration other than those possible in benzene.

In the xylenes we find many interesting changes. Orthoxylene is very unsymmetrical with respect to benzene, and so we expect the substitution

¹⁰ W. W. Coblentz, *Astrophys. J.* 20, 207 (1924); *Carnegie Inst. of Wash.* No. 35, 1 (1905).

to have a greater effect on the benzene vibrations than in the case of toluene. In the meta form, the effect should be smaller, and in paraxylene we would expect it to be nearly the same as that in toluene, or possibly less. By examining curves (c), (d), and (e) of Fig. 3 this is seen to be the case. In orthoxylene there is only one band which closely checks the benzene vibrations, the 3.253μ band occurring here at 3.261μ again. In paraxylene on the

Fig. 3. Absorption curves. (a) benzene (b) toluene (c) orthoxylene (d) metaxylene (e) paraxylene. Thickness, 0.05 mm.

other hand, we find the 3.231μ and the 3.291μ bands recurring with no shift at all.

Since the strong 3.426μ band of toluene, does not appear in orthoxylene, while it does in the meta- and para- forms, we are inclined to look for a mutual effect of the two neighboring CH_3 groups. We find bands at 3.313μ , 3.396μ and 3.486μ occurring almost exactly in all three forms of xylene, while they are entirely absent in toluene, or to say the least, they occur in entirely new locations, again seeming to point to a mutual effect of the two groups.

The cases of ethyl- and butyl- benzene are somewhat similar. In each, we find the three benzene bands each shifted by 0.007μ . Their intensity changes are relatively the same as in the case of toluene. Just as we expected, the other bands, occurring in these two compounds, which are apparently due to the C-H vibrations within the ethyl- and butyl groups, are found at

Fig. 4. Absorption curves. Thickness 0.05 mm. (a) benzene (b) ethyl benzene (c) n-butyl benzene (d) monochlor benzene (e) mono-brombenzene.

entirely different wave-lengths in the two cases. This is probably due to a different mutual effect in the two cases.

It is interesting to note that in methyl-, ethyl- and butyl-benzene, whose molecular weights are respectively 92, 106 and 134, the vibrations of the C-H bond in the benzene radical, have been shifted by the same amounts, namely

0.007μ . It must be remembered that 0.007μ is the interval between the spectrometer readings and so the actual shift might even be slightly less than that indicated.

In chlor- and brom- benzene we have a different type of substitution-namely, a single heavy atom instead of a group of C's and H's. Here, the 3.23μ band is absent entirely; the 3.253μ band occurs in each; the 3.291μ vibration appears in each at 3.298μ , and for the first time has its intensity very greatly decreased. Literature¹⁰ gives for each one single band at 3.25μ , with that for brom-benzene being much the stronger of the two, in close agreement with these results.

CONCLUSIONS

If we notice in every case the combined effect of the intensity changes and of the new vibrations introduced by the substitutions, we find that the result is just that necessary to cause the center of the absorption region to agree nicely with the wave-lengths given in the lower resolving power work recorded in literature.¹⁰

Apparently we can follow a particular band through the series of substitutions, noting the shifts and intensity changes which it suffers. We can see the mutual effect of the neighboring atoms upon the C-H radicals, and we can note distinct changes, dependent upon the symmetry of the molecule, as we progress for instance from benzene through toluene, ortho- and metaxylene to paraxylene.

It is thought that from these results, supplemented by further experimental data on temperature effects which we are at present assembling, we shall be able to work out the energy levels of these compounds.

The author wishes to express his sincere appreciation to Dr. Pfund, Dr. Herzfeld, and Professor Wood, who have been very helpful in aiding this work.

QUANTUM KINETICS AND THE PLANCK EQUATION

BY GILBERT N. LEWIS

DEPARTMENT OF CHEMISTRY, UNIVERSITY OF CALIFORNIA

(Received May 13, 1930)

ABSTRACT

With the same system that Einstein employed, the Planck equation should issue directly from kinetic principles without the aid of the theory of induced emission. The three fundamental laws of physico-chemical kinetics are (1) the law of entire equilibrium, (2) the law of the duality of elementary processes (or the equality of direct and reverse transition probabilities), (3) the law of equal *a priori* probabilities. It is shown that all three follow from the law of the symmetry of time, and furthermore, that the first and third of these laws are both derivable from the second.

From one of these laws, from the equation of Boltzmann, and from the number of quantum positions in a Hohlraum within a given range of frequency, the equation of Planck is immediately derived. Finally, there is a brief discussion of the more general case of thermal equilibrium in a Hohlraum when the number of photons is permanently or temporarily restricted, resulting in a state of *gray* rather than of *black* radiation.

IN THE justly famous paper in which Einstein¹ derived the Planck equation, he first introduced that coefficient of induced emission which has played so large a part in recent physics. Without in any way minimizing the value of this conception, which indeed seems necessary to an understanding of radiation from the standpoint of field-theory, one may doubt whether it was necessary, or even legitimate, to combine this method of treatment with a totally different method based upon the kinetics of light quanta, or photons; especially as Einstein's treatment seems to be incompatible with the principle of the symmetry of time, which we shall discuss presently.

It should be possible to obtain the laws of radiation by methods of two distinct types. Let us not risk misunderstanding by calling these the method of the wave and the method of the particle. Let us rather say that the first has its analogy in classical electromagnetics, in which a radiating particle is conceived to be immersed in, and in equilibrium with, a field, while the second has its analogy in the classical methods of kinetic theory, such as that of Guldberg and Waage, whereby the radiating atoms may be regarded as reacting with the atoms of light. Einstein borrowed from both types, but we shall see that it is possible by the second type of method alone to obtain, in a remarkably simple way, Planck's law of radiation, without otherwise departing from Einstein's procedure.

THE LAWS OF QUANTUM KINETICS DERIVED FROM THE SYMMETRY OF TIME

In a paper which is being published in *Science*, I show what remarkable conclusions may be drawn from the simple law, that in the domain of physical

¹ Einstein, *Phys. Zeits.* 18, 121 (1917).

science it is impossible to distinguish between past and future. If this law had been recognized, many of the errors of classical physics would have been avoided, such as the doctrine of Clausius that entropy tends toward a maximum, the theory that energy is radiated in a continuous expanding spherical shell, and the associated use of the retarded potentials. To present problems the law of the symmetry of time finds its most interesting applications in the study of quantum transitions, into which all physico-chemical processes may be resolved.

In discussing thermal equilibrium a special assumption has sometimes been employed which is not derivable from thermodynamics. It has been called the principle of detailed balancing, or of microscopic reversibility, or of entire equilibrium, and has usually been regarded as of useful, but limited, applicability. However, in the paper² in which I spoke of it as the principle of entire equilibrium, I proposed that it be regarded as a universal law, valid throughout physics and chemistry. This view was unacceptable to many physicists on the ground that the principle could not apply to cases in which radiation is involved. I think it will be apparent as we proceed that these very cases illustrate in a most satisfactory manner the value and the scope of the principle.

We may regard a physico-chemical system as passing through a succession of well defined quantum states for the whole system, which may be numbered (each degenerate state being separately listed). If the succession of these several quantum states is followed over a period of time long enough to be representative, we say that we are dealing with an equilibrium, and we may inquire how frequently one of these quantum states is reached; how long, on the average, it lasts, and what the chance is of a transition to any other given state.

The law of entire equilibrium demands that on the average the transition from state j to state k will occur just as often as the transition from k to j , or in other words, that the chance of going from j to k is equal to the reverse chance. The chance of going from j to k is equal to the chance p_j that the system is in the state j , multiplied by the intrinsic probability ϕ_{jk} that when it is in state j it will go over in unit time to state k . The law of entire equilibrium then states that,

$$p_j \phi_{jk} = p_k \phi_{kj}. \quad (1)$$

The reason that I felt convinced of the universality of the law of entire equilibrium was that it is directly derivable from the principle of symmetry in time. If it should fail at any point it would be the only known case in the whole of physical science in which time appears as unsymmetrical. The argument is simple: If in any system we should find $p_j \phi_{jk} > p_k \phi_{kj}$, $p_k \phi_{kl} > p_l \phi_{lk}$, $p_l \phi_{lj} > p_j \phi_{jl}$, we might still have equilibrium, but it would be of a cyclic character. We could state as a law for this system that the succession of states is chiefly in the direction $jkljk \dots$. Now reversing time, we should be obliged to describe the chief sequence as $jlkjl \dots$, a different law.

² G. N. Lewis, Proc. Nat. Acad. Sci. 11, 179, 422 (1925).

I shall not enter here upon the somewhat more difficult but equally binding, proof, which I give in my other paper, that the law of the symmetry of time also requires the equality of the intrinsic transition probabilities in two directions, namely,

$$\phi_{jk} = \phi_{kj}. \quad (2)$$

This, the most fundamental law of quantum kinetics, has hitherto received no name, except in so far as it has occasionally been confused with the law expressed in Eq. (1). It may be called the law of the duality of elementary processes, in order to indicate that the transition from j to k , and the transition from k to j , are not two separate physical entities, but the same entity regarded from two points of view.

By combining Eqs. (1) and (2), we find

$$p_i = p_k. \quad (3)$$

This is the principle known as the equality of *a priori* probabilities. These three equations, all of which may be derived from the law of the symmetry of time, underlie the whole theory of physico-chemical kinetics.

Both of the other two laws may be obtained from the law of duality, in the following manner. If we say that the probability of finding a system in a given state is determined by the probability of entering that state, and by the probability of leaving it, this means that all the p 's are determined when all the ϕ 's are given. The equations which suffice for such determination are evidently the ones which express the fact that in the long run the system enters as often as it leaves a given state. Thus,

$$\begin{aligned} p_1\phi_{12} + p_1\phi_{13} + \cdots p_1\phi_{1N} &= p_2\phi_{21} + p_3\phi_{31} + \cdots p_N\phi_{N1} \\ p_N\phi_{N1} + p_N\phi_{N2} + \cdots p_N\phi_{N(N-1)} &= p_1\phi_{1N} + p_2\phi_{2N} + \cdots p_{(N-1)}\phi_{(N-1)N} \end{aligned}$$

Of these N equations the last may obviously be derived algebraically from the remainder, but since the system must always be in one of the states, we have the further equation,

$$p_1 + p_2 + \cdots p_N = 1.$$

We therefore still have N equations, and these must be independent if the p 's are determined by the equations. Hence the solution is unique. Now, employing Eq. (2), we see that a solution, and therefore the only solution, is obtained by making the p 's equal. Thus we obtain Eq. (3) from Eq. (2), and from these Eq. (1) follows.

THE DERIVATION OF THE PLANCK EQUATION

Let us consider the same system that was discussed by Einstein, namely a Hohlraum of volume V , and temperature T , in which there is a single atom which may exist in the two quantum states A and B , the energy of the latter being greater in the amount $h\nu$. In systems of this simple character it is possible to express the quantum state of the whole system by describing separately the quantum states of its several parts. Thus we may completely describe this system by saying whether the atom is in state A or B , and by giving

the complete quantum state of the radiation. The latter may also be simplified by setting up a set of skeleton quantum positions, or cells, and giving the number of photons in each skeleton position, or cell.

The number dn of these cells lying within a given energy range $h\nu$ has now been obtained by several very different methods, all of which lead to the same result, namely,

$$dn = \frac{8\pi V\nu^2}{c^3} d\nu. \quad (4)$$

By making V indefinitely large, dn can be kept large, however small the range $d\nu$. Indeed, the Planck equation, to which Eq. (4) leads, is strictly valid only for a Hohlraum of infinite volume.

A completely specified individual state of the system is given when we know whether the atom is in state A or B , and when we know the number of photons in each of the skeleton positions or cells. The relative probability that the atom will be in state B or A , we shall assume, with Einstein, to be given by the following equation (although later we shall further consider its validity).

$$\frac{p_B}{p_A} = e^{-h\nu/kT} \quad (5)$$

From Eqs. (4) and (5), and with one of the preceding equations, we may obtain in a variety of ways the equation for black-body radiation. The very simple method which I shall give here I owe in part to a kind communication from Professor L. Brillouin, who has consistently maintained the applicability of the fundamental laws of kinetics to radiative processes.

Let us pick out one particular cell, Q , which corresponds to the energy emitted by state B . Let us then consider a process by which the atom changes from B to A , while the number of photons in cell Q changes from an initial value, m , to $m+1$, all the remaining radiation being unchanged. This may be expressed as

$$B, Q_m \rightarrow A, Q_{m+1}.$$

Calling the two complete states I and II, we have from Equation (3)

$$p_I = p_{II}.$$

The probability p_I is equal to the probability p_B , that the atom will be in state B , multiplied by the independent probability q_m , that cell Q has m photons; so also for the second state, and we may write

$$p_B q_m = p_A q_{m+1}. \quad (6)$$

Combining this equation with Eq. (5) we now have a result which concerns the radiation alone, and tells the relative probability of having $m+1$ and m photons in a given cell, namely,

$$\frac{q_{m+1}}{q_m} = e^{-h\nu/kT}.$$

If then q_0 represents the chance that cell Q has no photons, q , the chance that it has one, and so on,

$$q_0 + q_1 + q_2 + \dots = 1 = q_0(1 + e^{-h\nu/kT} + e^{-2h\nu/kT} + \dots). \quad (7)$$

If the cell Q has no photons, it has zero energy, with one photon it has the energy $h\nu$, with two photons $2h\nu$, so that \bar{E} , the probable energy of the cell, is

$$\bar{E} = q_0 h\nu (e^{-h\nu/kT} + 2e^{-2h\nu/kT} + \dots).$$

Eliminating q_0 by means of the previous equation,

$$\bar{E} = \frac{h\nu(e^{-h\nu/kT} + 2e^{-2h\nu/kT} + \dots)}{(1 + e^{-h\nu/kT} + e^{-2h\nu/kT} + \dots)}, \quad (8)$$

and by carrying out the indicated division we find,

$$\bar{E} = h\nu(e^{-h\nu/kT} + e^{-2h\nu/kT} + \dots) = \frac{h\nu}{e^{h\nu/kT} - 1}. \quad (9)$$

Multiplying \bar{E} by the number of cells lying in the range $d\nu$, from Eq. (4), we find the energy dE lying within this range,

$$dE = \frac{8\pi V h\nu^3 d\nu}{c^3} \frac{1}{e^{h\nu/kT} - 1}. \quad (10)$$

In this straightforward derivation of the Planck equation from simple kinetic principles there is no suggestion of "induced emission," which, I should like to repeat, may appear as a very real phenomenon when the same system is studied from the standpoint of field-theory, but is not a consideration that properly belongs to the kinetic mode of treatment.

Both Eq. (5) and Eq. (10) represent states of thermal equilibrium in the presence of an unlimited supply of photons. It is, however, perfectly possible to find processes by which photons interchange energies, and thus establish thermal distribution with respect to frequencies, without changing the number of photons. In case the concentration of photons of each frequency is less than that of black radiation, we may speak of *gray* radiation. Such a distribution I regard as a true and permanent case of equilibrium. Others who deny this will still admit that such a state may persist for a long time. Such equilibria, whether permanent or temporary, are susceptible to thermodynamic treatment.

In the presence of such a gray equilibrium of radiation, the atom at a given temperature will be less often in state B than when black radiation is present, and we may correct Eq. (5) by writing

$$\frac{\dot{p}_B}{\dot{p}_A} = \gamma e^{-h\nu/kT}, \quad (11)$$

where γ may be a function of temperature as well as of the number of photons per unit volume. Using this equation in place of Eq. (5), we obtain the expression for the distribution of energy in gray radiation, which I have previously derived more rigorously,³ namely,

$$dE = \frac{8\pi V h\nu^3 d\nu}{c^3} \frac{1}{(1/\gamma)e^{h\nu/kT} - 1} \quad (12)$$

A CONTRIBUTION TO THE QUANTUM MECHANICAL
THEORY OF RADIOACTIVITY AND THE DISSOCIA-
TION BY ROTATION OF DIATOMIC MOLECULESBY OSCAR KNEFLER RICE¹

INSTITUT FÜR THEORETISCHE PHYSIK DER UNIVERSITÄT, LEIPZIG

(Received February 26, 1930)

ABSTRACT

In the recent theory of radioactive decay, and also, as is shown, in the theory of dissociation of a diatomic molecule by the acquisition of rotational energy, there occurs a potential energy curve which has the following shape, as we go, say, from left to right. At the left the potential energy is very high, it then comes down to a minimum, increases to a maximum, and again falls off to an asymptotic value. The problems connected with such a curve are of two types. First, we may be given a particle in the region near the minimum, in an energy level which lies below the maximum, and wish to find the chance that it appear by a quantum mechanical process in the region on the other side of the maximum. Second, we wish to find how the "discrete states" in the neighborhood of the minimum are "broadened" by the continuum on the other side of the maximum. To solve these problems we first find the stationary eigenfunctions. By means of them the width and shape of the "broadened discrete levels" are found immediately. We then use these eigenfunctions to set up a wave packet, or, rather, we show how nature may set up a wave packet, which enables us to solve the first of the problems mentioned. The result justifies the use of complex eigenvalues for the solution of the problem.

INTRODUCTION

THE theory of radioactive decay, recently proposed by Gurney and Condon,² and independently by Gamow³ makes use of a potential energy curve of the type shown in Fig. 1 (solid curve), the wave equation being of the form

$$d^2\psi/dx^2 + (8\pi^2M/h^2)(E - U)\psi = 0. \quad (1)$$

The alpha-particle is supposed to be originally in some energy level such as E between x_2 and x_3 . There is then a finite probability of its appearing to the right of x_1 which gives the chance of disintegration of the radioactive atom.

Curves of much the same general characteristics also occur in the case of molecules, and can be used to explain the phenomenon of dissociation by rotation; i.e. one can use them to show how rotational energy can cause a diatomic molecule to dissociate. This explanation was given by Oldenberg,⁴ but as his work was not put into quantum mechanical form, and as a little more information may be obtained when this is done, it seems worth while to devote a paragraph to indicating how this may be done.

⁴ Oldenberg, *Zeits. f. Physik* **56**, 563 (1929).

One begins with the wave equation of a rotating and oscillating diatomic molecule, and, in the usual way, separates out the variables which give the orientation of the molecule. One thus obtains a wave equation in r , the dis-

Fig. 1.

tance between the two nuclei. If we let $F=rR$, where R is the part of the eigenfunction which depends on r , this equation is⁵

$$d^2F/dr^2 - j(j+1)F/r^2 + (8\pi^2M/h^2)(E - U_0)F = 0$$

where j is the rotational quantum number, M the reduced mass, E the eigenvalue, and U_0 the potential energy, which is a function of r . The term $j(j+1)/r^2$ when multiplied by $h^2/8\pi^2M$ acts exactly like an addition to the potential energy⁶ and we may replace $U_0 + (h^2/8\pi^2M)j(j+1)/r^2$ by an effective potential energy U , getting an equation like (1). When $j=0$ the curve has the usual form of the potential energy curve for a molecule (lower dotted curve in Fig. 1). As j increases the curves become like the solid curve of Fig. 1, and finally when j is quite large they are like the upper dotted curve of Fig. 1, the valley becoming shallower and finally disappearing altogether.⁷ Now, as we shall see, we can in a certain sense speak of discrete states in the valley, corresponding to an oscillation of the molecule in this region, and we see that the number of discrete states in the valley grows less and less until at last there are no more. Thus if a molecule is in a certain vibrational state, this state will disappear, and the molecule will dissociate, if j exceeds a certain value. This is the phenomenon observed in the case of mercury hydride, and the explanation does not differ greatly from that given by Oldenberg.

For energy levels such as E between the top of the mountain and the level of the plain, the problems which occur in the case of radioactivity will have an analog in the case of molecules. In the case of radioactivity what we observe is that a system starting in the valley goes through the mountain and appears in the plain. In the case of molecular spectra we actually observe another phenomenon. We find that the discrete states in the valley will be broadened

⁶ See Gamow and Houtermans, *Zeits. f. Physik* 52, 509 (1928).

⁷ The curves of Fig. 1 are quite schematic. For curves drawn to scale see Oldenberg, *l.c.*

in the same sense as in the case of predissociation,⁸ and one in fact observes diffuse rotation lines.

The problem which concerns the rate at which particles appear on the plain, and which, as noted, is of particular interest in the case of radioactivity, has been considered by a number of investigators. In the original papers of Gurney and Condon, and Gamow, no attempt was made to put this calculation on a rigorous basis. Numerous articles have appeared since, attempting to do this.⁹ Among the various methods used the introduction of complex eigenvalues offers to my mind the most elegant solution of this problem which has appeared so far. This very ingenious procedure gives very reasonable results. Still the idea of a complex eigenvalue is a rather unusual one. The method also includes the assumption that the decomposition is proceeding in just the same way as if it had been going on for an infinite length of time. This is also not an unreasonable assumption but it can be avoided; at the same time the use of complex eigenfunctions can be justified, and new light thrown on the significance of the whole process by the method we propose to use.

METHOD OF ATTACK

First of all we shall consider the entire system to be enclosed in a large box, to avoid the necessity of considering a continuum. Then we shall find the stationary eigenfunctions. In general it will be found that the part of the eigenfunction on the plain will be great compared to that in the valley. As we pass through certain energies, however, the relative size of the part inside will increase, reach a maximum and fall off again. To avoid circumlocution we shall refer to these energies as "discrete levels." They will in general occur near an energy where we would expect a discrete level to be if the curve rose continuously to the right of the valley. Since there is a finite energy range over which the part of the eigenfunction in the valley has a relatively large size these discrete levels are "broadened."

We wish now to investigate how our system can appear in a "discrete state," and what it means to say that we start out with our system in the valley, and calculate the probability that it will get out on the plain. To do this we suppose that the system was originally in some real discrete state which might or might not be part of the system of states belonging to the potential energy curve of Fig. 1, but from which no escape from the valley into the plain is possible. We will call the eigenfunction of this state ψ_0 and its energy E_0 . Now our system is subjected to a perturbation which causes it to appear in one of the states belonging to the curve of Fig. 1. There is a cer-

tain probability that it will land in some one of these states, of energy E , say, which is near some discrete energy, E_d . The eigenfunction of energy E (not including the exponential time factor) will be called $\psi(E)$. The wave packet which is formed by systems jumping from the state to the states $\psi(E)$ will be of the form

$$\psi = \sum a(E)\psi(E) \exp(-2\pi iEt/h)$$

where $a(E)$ is a constant coefficient for any E , and the sum is taken over all allowable values of E , which form a continuous set within the limits allowed by the box.

As a typical example, we shall consider the case where the perturbation which sets up the wave packet ψ for us is due to the action of monochromatic light,¹⁰ of a frequency somewhere near $E_d - E_0$ which difference we will suppose great¹¹ compared to the "breadth" of the discrete state at E_d . Now we have said that we will have the wave packet produced by monochromatic light. But if light is to be strictly monochromatic we have to shine it in for an infinitely long time. There would be no sense in making any calculation for a process which occurs after such an excitation. In fact there would be no process to calculate. The system after the excitation by light would simply be in one of the stationary states $\psi(E)$. We can, however, shine in light of a given frequency for a short time. It is of particular interest to have it shine in for so short a time that any of the states $\psi(E)$ over a considerable range of energies in the neighborhood of E_d may be excited, and short enough so that no appreciable difference in phase of the exponential factor for the various states $\psi(E)$ in the expression for ψ can arise.¹² The matrix component of the perturbation for the excitation by light from state ψ_0 to a state $\psi(E)$ is proportional to the matrix component,¹³ $P_{0E} = \int_0^\infty \psi_0 P \psi(E) dx$, where P is the electrical polarization expressed as a function of x . The $\psi(E)$ must be normalized. $a(E)$ will be proportional to P_{0E} and to find out how P_{0E} depends on E we must make a certain assumption regarding the integral which gives it. We assume that all appreciable contributions to this integral come from the range

¹⁰ Rice, Phys. Rev. **34**, 1454 (1929).

¹¹ The assumption that $E_d - E_1$ should be great compared to the width of the discrete state at E_d was also made in the previous work, Ref. 9, but it was forgotten to mention it explicitly there. This assumption was necessary to show that a_n in Eq. (5) of that article is proportional to P_{n0} ; it makes $E_n - E_0$ practically independent of E_n' over the important range of E_n' .

¹² As in the case previously considered (Ref. 10, see p. 1458) it seems safe to replace this condition by the statement that the time of illumination must be short compared to the time of decomposition, i.e. in this case the average life of a particle in the valley before it escapes into the plain. If the time of illumination is so short that more than one discrete state is excited the various decompositions from the various states may all be treated separately provided the energy between two discrete states is great compared to the breadth of a discrete state, a condition which must be fulfilled anyhow. This will also presumably be the case, if the perturbation is due to any other cause, provided it lasts for such a short time that no appreciable decomposition takes place in this time. The point is, as we shall see, that the wave packet starts in the neighborhood of the valley, and if the time of the perturbation is short enough, it will not, during that time, get out of the valley.

¹³ Dirac, Proc. Roy. Soc. **A112**, 674 (1926).

of x in the valley, because ψ_0 is supposed to have appreciable values only in the valley. In the immediate neighborhood of any given discrete level in the valley, the shape of the part of $\psi(E)$ which is in the valley or the amplitude of the part in the plain will not vary greatly with the energy over a small energy range, but the ratio which we call B , of the magnitude of the valley part of $\psi(E)$ (for some definite value of x , say x^1) to the amplitude of the plain part will vary greatly with the energy. Let us designate the maximum of B as B_1 . Then B/B_1 (which does not depend on x^1) is equal to the ratio¹⁴ P_{0E}/P_{0E_1} because the normalization makes all $\psi(E)$ alike in the plain.^{14a} The coefficient $a(E)$ is proportional to P_{0E} hence to P_{0E}/P_{0E_1} , hence to B/B_1 . Therefore, neglecting a constant factor, ψ becomes

$$\psi = \sum (B/B_1) \psi(E) \exp(-2\pi i E t / \hbar) \quad (2)$$

where the summation is over all allowable values of E . Now it will later be seen that this equation results in the total amount of material in the plain at $t=0$ being zero or almost so, but as time goes on, matter appears in the plain, and the amount of material in the valley suffers an exponential decrease.

If E_0 is greater than E_d so that the wave packet is set up by emission of light the above will also hold.

CALCULATION OF THE STATIONARY EIGENFUNCTION

If ψ now is the stationary eigenfunction for some definite energy E , it has been shown that for regions when $|E - U|$ is not too small, and the slope of the U vs. x curve not too great, that the solutions of the wave equation can be written in the form¹⁵ (disregarding constant factors)

$$\psi = \begin{matrix} \sin \\ (E - U)^{-1/4} \text{ or } \left\{ \kappa \int (E - U)^{1/2} dx \right\} \\ \cos \end{matrix} \quad (3)$$

for $U < E$, and

$$\psi = (U - E)^{-1/4} \exp \left\{ \pm \kappa \int (U - E)^{1/2} dx \right\} \quad (4)$$

for $U > E$, where $\kappa = (8\pi^2 M / \hbar^2)^{1/2}$.

In the immediate neighborhood of such a point as x_1 these solutions do not hold. The question now arises as to what happens if we start with some given solution in the mountain to the left of x_1 , and go through x_1 into the plain. On the assumption that the side of the mountain is long and straight, Kramers¹⁶ has shown that, if we start with the solution

$$(U - E)^{-1/4} \exp \left\{ -\kappa \int_x^{x_1} (U - E)^{1/2} dx \right\}$$

far to the left of x_1 , after going through x_1 and getting far to the right the solution has become

¹⁴ E_d is not a well defined energy and we could take it as that value of the energy for which B is a maximum. We prefer, however, to designate the latter energy as E_1 .

^{14a} The matter of normalization is explained in more detail after Eq. (17). See also Ref. 8, p. 749.

¹⁵ See, e.g., Nordheim, *Zeits. f. Physik* **46**, 842 (1927).

¹⁶ Kramers, *Zeits. f. Physik* **39**, 828 (1926).

$$2(E-U)^{-1/4} \cos \left\{ \kappa \int_{x_1}^x (E-U)^{1/2} dx - \pi/4 \right\}.$$

This means that the particular solution of the differential equation which has the one form to the left of x_1 has the other form to the right. We express this by using the following notation:

$$(U-E)^{-1/4} \exp \left\{ -\kappa \int_x^{x_1} (U-E)^{1/2} dx \right\} \xleftrightarrow{x_1} 2(E-U)^{-1/4} \cos \left\{ \kappa \int_{x_1}^x (E-U)^{1/2} dx - \frac{\pi}{4} \right\} \quad (5)$$

Putting in the limits is equivalent to evaluating the constant of integration, the integral being a function of x . Kramers and Ittman¹⁷ also point out that

$$(U-E)^{-1/4} \exp \left\{ \kappa \int_x^{x_1} (U-E)^{1/2} dx \right\} \xleftrightarrow{x_1} -(E-U)^{-1/4} \sin \left\{ \kappa \int_{x_1}^x (E-U)^{1/2} dx - \frac{\pi}{4} \right\} \quad (6)$$

Zwaan¹⁸ points out that the relation (5) holds whether the side of mountain is long and straight or not, if we can go from a region where the approximations of the type (4) hold to a region where the approximations of the type (3) hold, *via* a path in the complex plane along which the solutions are of the general type $(E-U)^{-1/4} \exp \left\{ i\kappa \int_{x_1}^x (E-U)^{1/2} dx \right\}$ and which crosses the curve along which argument of $\int_{x_1}^x (E-U)^{1/2} dx$ is $\pi/2$ at a point where the absolute value of $\int_{x_1}^x (E-U)^{1/2} dx$ is large.¹⁹

In similar manner we also have

$$2(E-U)^{-1/4} \cos \left\{ \kappa \int_x^{x_2} (E-U)^{1/2} dx - \frac{\pi}{4} \right\} \xleftrightarrow{x_2} (U-E)^{-1/4} \exp \left\{ -\kappa \int_{x_2}^x (U-E)^{1/2} dx \right\} \quad (7)$$

and

$$-(E-U)^{-1/4} \sin \left\{ \kappa \int_x^{x_2} (E-U)^{1/2} dx - \frac{\pi}{4} \right\} \xleftrightarrow{x_2} (U-E)^{-1/4} \exp \left\{ \kappa \int_{x_2}^x (U-E)^{1/2} dx \right\}. \quad (8)$$

Now if we multiply the left hand side of expression (5) by the factor $\exp \left\{ \kappa \int_{x_2}^{x_1} (U-E)^{1/2} dx \right\}$ which we will call $\theta/2$ we see that it coincides exactly with the right hand side of expression (8). Likewise if we multiply the left

¹⁷ Kramers and Ittman, *Zeits f. Physik* 58 222 (1929)

¹⁸ Zwaan: *Intensitäten im Ca-Funkenspektrum*, Thesis, Utrecht (1929), p. 35. I am indebted to Dr. F. Bloch for calling my attention to this work.

¹⁹ Kramers and Ittman state that (6) can be derived in the same way.

hand side of (6) by $2\theta^{-1}$ it coincides with the right hand side of (7). Thus we have established a connection between the solutions to the left of x_2 and to the right of x_1 . We see, in fact, that

$$-(E-U)^{-1/4} \sin \left\{ \kappa \int_x^{x_2} (E-U)^{1/2} dx - \frac{\pi}{4} \right\} \\ \longleftrightarrow_{x_2 \text{ and } x_1} \theta(E-U)^{-1/4} \cos \left\{ \kappa \int_{x_1}^x (E-U)^{1/2} dx - \frac{\pi}{4} \right\} \quad (9)$$

and

$$(E-U)^{-1/4} \cos \left\{ \kappa \int_x^{x_2} (E-U)^{1/2} dx - \frac{\pi}{4} \right\} \\ \longleftrightarrow_{x_2 \text{ and } x_1} -\theta^{-1}(E-U)^{-1/4} \sin \left\{ \kappa \int_{x_1}^x (E-U)^{1/2} dx - \frac{\pi}{4} \right\}. \quad (10)$$

The actual eigenfunction in the valley must consist of a linear combination of the left hand sides of (9) and (10). If the eigenfunction in the valley is

$$(E-U)^{-1/4} \left[\cos \left\{ \kappa \int_x^{x_2} (E-U)^{1/2} dx - \frac{\pi}{4} \right\} \right. \\ \left. + b \sin \left\{ \kappa \int_x^{x_2} (E-U)^{1/2} dx - \frac{\pi}{4} \right\} \right] \quad (11)$$

the same eigenfunction in the plain is

$$-(E-U)^{-1/4} \left[\theta^{-1} \sin \left\{ \kappa \int_x^{x_1} (E-U)^{1/2} dx - \frac{\pi}{4} \right\} \right. \\ \left. + b \theta \cos \left\{ \kappa \int_{x_1}^x (E-U)^{1/2} dx - \frac{\pi}{4} \right\} \right] \quad (12)$$

THE SHAPE OF THE BROADENED DISCRETE STATE

In order that the solution of the wave equation should be an eigenfunction it must satisfy a certain condition to the left of x_3 . It is probably good enough to assume that to the left of x_3 the solution must decrease exponentially in absolute value as we go to the left,¹⁶ and the solution to the left of x_3 will therefore be of the form $(U-E)^{-1/4} \exp \left\{ -\kappa \int_x^{x_3} (U-E)^{1/2} dx \right\}$. Now

$$(U-E)^{-1/4} \exp \left\{ -\kappa \int_x^{x_3} (U-E)^{1/2} dx \right\} \\ \longleftrightarrow_{x_3} 2(E-U)^{-1/4} \cos \left\{ \kappa \int_{x_3}^x (E-U)^{1/2} dx - \frac{\pi}{4} \right\} \quad (13)$$

(11) must be the same as the right hand side of (13), and it can be made the same as follows. We can easily at any time adjust the amplitude of (11) or (13) so that they will be the same. But we have to adjust the phase of (11)

so that it will coincide with (13). This is done by choosing the value of b . At some energy, say for example at E_1 , the value of b will be zero. Then under the mountain we have only the decreasing exponential. The value E_1 will therefore be approximately the same as an eigenvalue of the wave equation if the curve for U increased indefinitely to the right. Kramers¹⁶ has shown that the condition that E_1 should be the energy of such a discrete state is

$$\kappa \int_x^{x_2} (E_1 - U)^{1/2} dx = n\pi \quad (14)$$

when $n = 1/2, 3/2, 5/2, \dots$. The phase of the right hand side of (13) (starting from x) is less than that of the first term of (11), at some E not too distant from E_1 , by

$$\kappa \int_{x_1}^{x_2} (E - U)^{1/2} dx - \kappa \int_{x_1}^{x_2} (E_1 - U)^{1/2} dx. \quad (15)$$

The amount that the phase of (11) is less than that of its first term is $\tan^{-1}b$. Thus, since (13) and (11) must be alike,

$$b = \tan \left\{ \kappa \int_{x_1}^{x_2} (E - U)^{1/2} dx - \kappa \int_{x_1}^{x_2} (E_1 - U)^{1/2} dx \right\}. \quad (16)$$

Now if the breadth of the "broadened discrete state" is to be narrow compared to the distance between two discrete states, it means that over the "width" of the discrete state (15) must be small compared to π . We assume it so small that we may write

$$\begin{aligned} b &= \kappa \int_{x_1}^{x_2} (E - U)^{1/2} dx - \kappa \int_{x_1}^{x_2} (E_1 - U)^{1/2} dx \\ &= (E - E_1) \frac{\partial}{\partial E} \kappa \int_{x_1}^{x_2} (E - U)^{1/2} dx \end{aligned} \quad (17)$$

which we set $= b'(E - E_1)$. The derivative is taken for $E = E_1$. It is important to note that b' is positive.

We now wish to find how the value of b affects the relative size of the eigenfunction in the valley and on the plain. For large values of x we know that U takes on some asymptotic value, which we can without loss of generality take as 0. Then (12) also has an asymptotic form. In the limiting case when the box is large this part of (12) will determine the normalization, as the integral of ψ^2 over the plain can always, by taking the plain long enough, be made large compared to the integral across the valley. We make $\int_0^\infty \psi^2 dx = 1$. The amplitude of the sinusoidal function represented by (12) is (for large values of x where $U=0$) equal to $(\theta^{-2} + b^2 \theta^2)^{1/2} E^{-1/4}$. To satisfy the normalization conditions the amplitude must be $(2/x_\infty)^{1/2}$ where x_∞ is the largest possible value²⁰ of x . To normalize we therefore multiply (12) by $(\theta^{-2} + b^2 \theta^2)^{-1/2} E^{1/4}$

²⁰ Giving x a largest value allows in an idealized way for the fact that the system is in a box.

$(2/x_\infty)^{1/2}$. Now (11) must also be multiplied by the same thing, so its amplitude becomes $(1+b^2)^{1/2}(E-U)^{-1/4}(\theta^{-2}+b^2\theta^2)^{-1/2}E^{1/4}(2/x_\infty)^{1/2}$. But if b is small so that (17) holds, then it will also be negligible compared to 1. So the amplitude of (11) becomes

$$(E-U)^{-1/4}(\theta^{-2}+b^2\theta^2)^{-1/2}E^{1/4}(2/x_\infty)^{1/2}.$$

If we divide this expression by its value when $E=E_1$, and hence $b=0$, we get an expression which will no longer depend on the particular value of x between x_2 and x_3 , and which will in fact be just equal to the quantity B/B_1 which appeared in Eq. (2). We thus find (assuming that E and θ do not vary appreciably over the range of E included in a broadened discrete state):

$$B/B_1 = (1+b^2\theta^4)^{-1/2} = [1+b'^2(E-E_1)^2\theta^4]^{-1/2}. \quad (18)$$

The shape of the broadened discrete state is found by plotting

$$(B/B_1)^2 = [1+b'^2(E-E_1)^2\theta^4]^{-1} \quad (19)$$

against E . The width w of the state we may define as the energy over which $(B/B_1)^2$ has the value $\frac{1}{2}$ or greater, or twice the absolute value of $E-E_1$ for which $(B/B_1)^2 = \frac{1}{2}$. Thus

$$w = 2/b'\theta^2. \quad (20)$$

THE SETTING-UP OF THE WAVE PACKET; THE RATE OF DECAY; PROOF OF ASSUMPTION OF COMPLEX EIGENVALUES

For a very large box the summation in Eq. (2) can be replaced by an integration, which is surely allowable, as it will be seen that the integrand has no singular points. Eq. (2) thus becomes

$$\psi = \int_{-\infty}^{\infty} (B/B_1)\psi(E) \exp(-2\pi i Et/h) dE/\epsilon \quad (21)$$

where ϵ is the distance between energy levels, and is equal to $2\pi E^{1/2}/\kappa x_\infty$ where x_∞ is the largest possible value of x . It is only possible to integrate thus from ∞ to $-\infty$ because only a small range of E 's contributes appreciably. To find ψ for $x \gg x_1$ we substitute for $\psi(E)$ in (21) the expression (12) with $U=0$ which must however be multiplied, as noted, by $(\theta^{-2}+b^2\theta^2)^{-1/2}E^{1/4}(2/x_\infty)^{1/2} = \theta(B/B_1)E^{1/4}(2/x_\infty)^{1/2}$. To find $\psi(E)$ for $x_3 < x < x_2$ we use (11) multiplied by the same thing. We will, however, find it convenient to multiply (11) and (12) through by $-\theta(B/B_1)E^{1/4}\epsilon$, instead, which is permissible for the following reasons: ψ itself is not normalized, and we can always further multiply or divide (11) and (12) by any factor which does not depend on E . And in the range of values of E which contribute importantly in the integral (21) we may regard ϵ as constant. $E^{1/4}$, $(E-U)^{1/4}$, and θ are also practically constant. So (11) gives, when thus multiplied and substituted in (21) remembering (17) and (19):

$$\psi = -\frac{E_1^{1/4} \theta}{(E_1 - U)^{1/4}} \left[\int_{-\infty}^{\infty} \frac{\cos \left\{ \kappa \int_x^{x_2} (E - U)^{1/2} dx - \frac{\pi}{4} \right\} \exp(-2\pi i E t / h)}{1 + b'^2 \theta^4 (E - E_1)^2} dE \right. \\ \left. + \int_{-\infty}^{\infty} \frac{b'(E - E_1) \sin \left\{ \kappa \int_x^{x_2} (E - U)^{1/2} dx - \frac{\pi}{4} \right\} \exp(-2\pi i E t / h)}{1 + b'^2 \theta^4 (E - E_1)^2} dE \right] \quad (22)$$

For great values of x we can substitute $\kappa E^{1/2} x + \zeta$ for $\kappa \int_x^{x_2} (E - U)^{1/2} dx - \pi/4$ in (12). We simply let ζ be the difference between these two expressions, this difference being constant for large values of x . Then we multiply (12) by the same expression as we multiplied (11) by, and get

$$\psi = \int_{-\infty}^{\infty} \frac{[\sin \{ \kappa E^{1/2} x + \zeta \} + \theta^2 b'(E - E_1) \cos \{ \kappa E^{1/2} x + \zeta \}] \exp(-2\pi i E t / h)}{1 + b'^2 \theta^4 (E - E_1)^2} dE \quad (23)$$

We assume that the important range of E in this integral is so small that ζ is the same for all the states in this range. We now proceed to evaluate (23).

We substitute $(E - E_1) + E_1$ for E , and $E_1^{1/2} + (E - E_1)/2E_1^{1/2}$ for $E^{1/2}$, as this is allowable for the small values of $E - E_1$ which contribute to the integral. The latter substitution gives the cosine and the sine of the sum of the two angles $\kappa E_1^{1/2} x + \zeta$ and $(\kappa/2E_1^{1/2})(E - E_1)x$. These are reduced by the usual trigonometric formulas. We also write $\exp(-2\pi i E t / h) = \exp(-2\pi i E_1 t / h) [\cos \{ 2\pi(E - E_1)t/h \} - i \sin \{ 2\pi(E - E_1)t/h \}]$. One thus gets a number of parts of the integral which drop out because they are antisymmetrical about the point $E - E_1 = 0$. The rest of the expression becomes

$$\psi = \exp(-2\pi i E_1 t / h) \left[\int_{-\infty}^{\infty} \frac{\sin \{ \kappa E_1^{1/2} x + \zeta \} \cos \{ (\kappa/2E_1^{1/2})(E - E_1)x \} \cos \{ 2\pi(E - E_1)t/h \}}{1 + b'^2 \theta^4 (E - E_1)^2} d(E - E_1) \right. \\ - b' \theta^2 \int_{-\infty}^{\infty} \frac{(E - E_1) \sin \{ \kappa E_1^{1/2} x + \zeta \} \sin \{ (\kappa/2E_1^{1/2})(E - E_1)x \} \cos \{ 2\pi(E - E_1)t/h \}}{1 + b'^2 \theta^4 (E - E_1)^2} d(E - E_1) \\ - i \int_{-\infty}^{\infty} \frac{\cos \{ \kappa E_1^{1/2} x + \zeta \} \sin \{ (\kappa/2E_1^{1/2})(E - E_1)x \} \sin \{ 2\pi(E - E_1)t/h \}}{1 + b'^2 \theta^4 (E - E_1)^2} d(E - E_1) \\ \left. - i b' \theta^2 \int_{-\infty}^{\infty} \frac{(E - E_1) \cos \{ \kappa E_1^{1/2} x + \zeta \} \cos \{ (\kappa/2E_1^{1/2})(E - E_1)x \} \sin \{ 2\pi(E - E_1)t/h \}}{1 + b'^2 \theta^4 (E - E_1)^2} d(E - E_1) \right]$$

The four integrals we shall designate respectively as I_1, I_2, I_3, I_4 . Another trigonometric reduction gives $I_1 = \frac{1}{2} [\sin \{ \kappa E_1^{1/2} x + \zeta \}] (I_1^+ + I_1^-)$ and $I_2 = \frac{1}{2} [\sin \{ \kappa E_1^{1/2} x + \zeta \}] (I_2^+ + I_2^-)$, where

$$I_1^{\pm} = \int_{-\infty}^{\infty} \frac{\cos \{ [(\kappa/2E_1^{1/2})x \pm 2\pi t/h](E - E_1) \}}{1 + b'^2 \theta^4 (E - E_1)^2} d(E - E_1)$$

and

$$I_2^{\pm} = \int_{-\infty}^{\infty} \frac{(E - E_1) \sin \{ [(\kappa/2E_1^{1/2})x \pm 2\pi t/h](E - E_1) \}}{1 + b'^2 \theta^4 (E - E_1)^2} d(E - E_1)$$

I_1^+ and I_1^- are to be found from Pierce's Tables²¹ and I_2^+ and I_2^- can readily be found by differentiating I_1^+ and I_1^- with respect to the proper parameter $(\kappa/2E_1)^{1/2}x \pm 2\pi t/h$. Now it will be found (as b' is positive) that the contributions from I_1^+ and I_2^+ cancel each other in the expression for ψ , as do also the contributions from I_1^- and I_2^- when $(\kappa/2E_1)^{1/2}x > 2\pi h/t$. When, however, $(\kappa/2E_1)^{1/2}x < 2\pi h/t$ the latter add. We can treat I_3 and I_4 in a similar way. So ψ is zero for $(\kappa/2E_1)^{1/2}x > 2\pi h/t$ and for $(\kappa/2E_1)^{1/2}x < 2\pi h/t$ we have

$$\begin{aligned} \psi &= (\pi/b'\theta^2) [\sin(\kappa E_1^{1/2}x + \zeta) - i \cos(\kappa E_1^{1/2}x + \zeta)] \\ &\quad \exp \left\{ [(\kappa/2E_1)^{1/2}x - 2\pi t/h]/b'\theta^2 \right\} \exp(-2\pi i E_1 t/h) \\ &= (\pi/b'\theta^2) \exp \left\{ i(\kappa E_1^{1/2}x - 2\pi E_1 t/h - \pi/2 + \zeta) \right\} \exp \left\{ [(\kappa/2E_1)^{1/2}x - 2\pi t/h]/b'\theta^2 \right\} \end{aligned} \quad (24)$$

We see that this represents a wave going in the positive direction with the particle velocity $(2E_1/M)^{1/2}$, and with an amplitude determined by the second exponential factor for values of x up to the place where $(\kappa/2E_1)^{1/2}x = 2\pi t/h$ after which it breaks off. The wave shows an exponential decrease with time and just the proper exponential increase with distance to insure that the amount of matter in the wave is conserved. This is exactly like the outward going wave of Kudar's,⁹ which resulted from the use of complex eigenvalues, except that his did not break off, but continued out to infinity in space and negative infinity in time.

We shall now evaluate (22). The sine and cosine of $\kappa \int_x^{x_2} (E - U)^{1/2} dx - \pi/4$ are roughly periodic functions of E , but we know that in the important range of E the functions have gone through a small fraction of a period, as we are considering a discrete state that is narrow compared to the distance between two discrete states. We can therefore consider the sine and cosine terms as constant factors in the integration of (22). We write $\exp(-2\pi i E t/h)$ in sine and cosine form, as before, substitute in (22), note that some of the parts of the resulting integral drop out because of antisymmetry of the part of the integrand about $E - E_1 = 0$, integrate the remaining terms, which involve integrals of the type already met with, and get

$$\begin{aligned} \psi &= - [\exp(-2\pi i E_1 t/h)] [(E_1^{1/4}\theta)/(E_1 - U)^{1/4}] \\ &\quad [(\pi/b'\theta^2) \cos \left\{ \kappa \int_x^{x_2} (E_1 - U)^{1/2} dx - \pi/4 \right\} \exp(-2\pi t/hb'\theta^2) \\ &\quad - i(\pi/b'\theta^4) \sin \left\{ \kappa \int_x^{x_2} (E_1 - U)^{1/2} dx - \pi/4 \right\} \exp(-2\pi t/hb'\theta^2)]. \end{aligned} \quad (25)$$

Since the distance between two discrete states is by (17) and (14) of the order of $1/b'$ and since, if w is to be small compared with this, θ^2 must, by (20), be large compared to 1, the last term in the expression (25) is negligible, and we are left with

$$\begin{aligned} \psi &= - [\exp(-2\pi i E_1 t/h)] E_1^{1/4} \theta (E_1 - U)^{-1/4} (\pi/b'\theta^2) \\ &\quad \cos \left\{ \kappa \int_x^{x_2} (E_1 - U)^{1/2} dx - \pi/4 \right\} \exp(-2\pi t/hb'\theta^2), \end{aligned} \quad (26)$$

²¹ Pierce, "A short Table of Integrals," Ginn and Co., Formula 490.

a standing wave, except for the exponential decrement with time. Actually, if we consider terms of higher order, the wave function in the valley will not be expected to be merely a standing wave with exponential decrement with time.

Now if the mountain is not too thick through (i.e. if $x_1 - x_2$ is not too great)²² we may find the expression for ψ in the mountain the same way as we found it for ψ in the valley. We simply assume that $\exp\{\kappa \int_{x_2}^x (U - E)^{1/2} dx\}$ does not vary over the effective range of $E - E_1$, and this is, in fact included in the assumption we have already made that θ does not vary appreciably over this range. The integrations are then readily performed. We get an expression which again contains the factor $\exp(-2\pi i E_1 t / h - 2\pi t / h b' \theta^2)$. Also just to the right of x_1 , (23) does not give an exact expression for ψ . The difference between the true value of ψ and that given by (23) will, however, not be appreciably different from 0 for any great distance to the right of x_1 , and for this range we may also assume that $\kappa \int_{x_1}^x (E - U)^{1/2} dx$ does not vary appreciably with E over the range w , or at least that it is a linear function of $E - E_1$. In either case it is easily seen that the expression for ψ will contain the factor $\exp(-2\pi i E_1 t / h - 2\pi t / h b' \theta^2)$. Thus we see that the assumption of a complex eigenvalue is at least approximately correct, and that the smaller w is the better the approximation is. It also depends on the relations (9) and (10). It is also, of course, necessary that t should not be too small.

The rate of decay, γ , of ψ^2 is of course given by twice the real factor of t in this exponential time factor. We have²³

$$\begin{aligned} \gamma &= 4\pi / h b' \theta^2 \\ &= \frac{\pi}{h} \left(\frac{\partial}{\partial E} \kappa \int_{x_2}^{x_1} (E - U)^{1/2} dx \right)^{-1} \exp \left\{ -2\kappa \int_{x_2}^{x_1} (U - E)^{1/2} dx \right\}. \end{aligned} \quad (27)$$

It is seen from (20) that

$$w / \gamma = h / 2\pi \quad (28)$$

the same relation that held in the case of predissociation, where we have a different type of interaction between discrete and continuous states.²⁴

GENERALIZATION OF THE RESULTS

Our results so far are somewhat unsatisfactory inasmuch as the general validity of the relations (5), (6), (7) and (8) depends upon the properties of $E - U$ considered a function of x when x is a complex variable, which are a little hard to investigate in a general way, or upon the assumption that the

²² In order for the discrete state not to be too broad, θ must be great. The condition just cited states that a sufficient portion of this greatness must be caused by the height rather than the breadth of the mountain. If the mountain and the valley are of somewhat the same width the required condition will be sufficiently well fulfilled.

²³ This expression agrees with that of Kudar, *Zeits. f. Physik* **53**, 99 (1929) also that of Fowler and Wilson, *l.c.*, in the exponential part, but not in the factor. The difference is probably due to the fact that Kudar and Fowler and Wilson considered a type of potential energy curve to which Kramer's approximation method could hardly apply.

²⁴ Ref. 10, p. 1457.

mountain-sides are long and straight. We may, however, show that the general character of the results depends only on the broadening of the discrete state being sufficiently small so that any given solution of the wave equation does not change its general character in that range. For then we may assume that a particular solution in the plain (far to the right of x_1) is connected with a particular type of solution in the mountain and in the valley. Thus the two solutions $E^{-1/4} \frac{\cos}{\sin}(\kappa E^{1/2}x + \zeta)$ are connected with solutions in the mountain and valley which do not change much over the range of energies in the width of the discrete state. This will be true no matter what value we choose for ζ . Let us choose ζ so that if $E=E_1$ the eigenfunction in the plain becomes $E^{-1/4} \sin(\kappa E^{1/2}x + \zeta)$. For any other value of E the eigenfunction in the plain is

$$[E^{-1/4} \sin(\kappa E^{1/2}x + \zeta) + gE^{-1/4} \cos(\kappa E^{1/2}x + \zeta)]/(1 + g^2)^{1/2}. \quad (29)$$

If $E-E_1$ is small enough g can be written as a linear function of $E-E_1$ say $g'(E-E_1)$ and in general it may be expected to be of the order of $b'\theta^2(E-E_1)$ as before, but the general character of the results, and the possibility of the use of complex eigenvalues do not depend on this. (The sign of g' is important but is surely the same as that of $b'\theta^2$.) Since we assume that the range of $E-E_1$ is so small that the shape of the eigenfunction in the valley is not affected we see that $(B/B_1)^2$ is given by $1/[1+g'^2(E-E_1)^2]$, hence all our previous results follow with g' substituted for $b'\theta^2$. Except, therefore, for this substitution we see that our results depend only on general properties of the solutions of the wave function, and not on their specific form.

I wish to thank Professor W. Heisenberg and Dr. F. Bloch for discussing this problem with me. I am informed by Dr. Bloch that much the same thing has been worked out independently by Professor Kramers, though without indicating, as is done here, how the wave packet is probably formed in nature.

PERTURBATIONS IN MOLECULES AND THE THEORY OF PREDISSOCIATION AND DIFFUSE SPECTRA. II

BY OSCAR KNEFLER RICE¹

INSTITUT FÜR THEORETISCHE PHYSIK DER UNIVERSITÄT, LEIPZIG

(Received March 8, 1930)

ABSTRACT

Further consideration is given to the problems which arise when the continuum of one electronic state of a diatomic molecule occurs in the same range as the discrete states of another electronic state. In the finding of electronic states and the potential curves which go with them certain approximations must be made; a better approximation can then be obtained by quantum mechanical perturbation theory. The discrete states are broadened, and this will appear, inasmuch as spectral lines involving these states are broadened. In this paper the shape of the broadened spectral lines is found, certain properties of the perturbation matrix are considered, and a wave packet is set up or rather one such as would be set up by nature is used to give all the details of a radiationless transition from a discrete state to the overlying continuum.

SHAPE OF A SPECTRAL LINE IN CASES OF PREDISSOCIATION

THE simple result obtained in the preceding paper² for the shape of the absorption line in the case of radioactive decay and other similar processes, suggests that it would be well to try to obtain an explicit result for the shape of the line in the case of predissociation, for purposes of comparison. The shape of line could of course be calculated from the expressions in the first paper with the above title³ (hereafter referred to as (I)), but it turns out that these can be somewhat simplified.

In this paper it was shown that the absorption coefficient over a broadened spectral line (see Abstract above) as a function of $E - E_1$ (called $-E$ in (I)) where E is the energy of the light absorbed and E_1 the energy of the center of the line, is proportional to K^2 , where

$$K^2 = \left(\frac{1}{(\epsilon/2 + \beta)^2} + \frac{1}{(3\epsilon/2 + \beta)^2} + \dots + \frac{1}{(\epsilon/2 - \beta)^2} + \frac{1}{(3\epsilon/2 - \beta)^2} + \dots \right)^{-1} \quad (1)$$

where ϵ is the distance between unperturbed continuous levels⁴ (the system being in a box) and where β is a parameter given by the equation⁵

¹ National Research Fellow.

² Rice, Phys. Rev. preceding paper in this issue.

³ Rice, Phys. Rev. **33**, 748 (1929).

⁴ ϵ can of course be varied arbitrarily by varying the size of the box, but in any given problem can be regarded as a constant. None of the results depend on it in any essential particular, and it will always cancel out of expressions for things which are experimentally determinable. Nevertheless it has been found very convenient to treat the system as if contained in a box, so the continuous levels really become a very close-spaced set of discrete ones, and we shall continue to do so.

⁵ (I), Eq. (26), since $v_{ed} = v_{de}$ (see Rice, Phys. Rev., **34**, 1459 (1929), especially footnote 19).

$$E - E_1 = -2\beta A v_{ed}^2 \quad (2)$$

where $A = (\pi/2\epsilon\beta) [2 \cot(2\pi\beta/\epsilon) - \cot(\pi\beta/\epsilon)]$ and v_{ed} is the component of the perturbation matrix giving the interaction between the discrete level and the continuous levels. Now A is easily reduced to the form $-(\pi/2\epsilon\beta) \tan(\pi\beta/\epsilon)$, hence (2) becomes

$$E - E_1 = (v_{ed}^2 \pi / \epsilon) \tan(\pi\beta/\epsilon) \quad (3)$$

Eq. (1) can also be further reduced as follows. A was originally expressed as an infinite series,⁶

$$\left(\frac{1}{\beta^2 - (\epsilon/2)^2} + \frac{1}{\beta^2 - (3\epsilon/2)^2} + \dots \right)$$

which is equal to

$$\frac{1}{2\beta} \left(\frac{1}{\epsilon/2 + \beta} + \frac{1}{3\epsilon/2 + \beta} + \dots - \frac{1}{\epsilon/2 - \beta} - \frac{1}{3\epsilon/2 - \beta} - \dots \right).$$

From this and (1) we see that K^{-2} is equal to $-2d(\beta A)/d\beta = (\pi/\epsilon)^2 \sec^2(\pi\beta/\epsilon)$. Disregarding the constant factor, the absorption coefficient is given as a function of β/ϵ by $(K\pi/\epsilon)^2 = [\sec^2(\pi\beta/\epsilon)]^{-1} = [1 + \tan^2(\pi\beta/\epsilon)]^{-1}$. By (3) this becomes

$$(K\pi/\epsilon)^2 = 1/[1 + 4(E - E_1)^2 w^{-2}] \quad (4)$$

where $w = 2\pi v_{ed}^2/\epsilon$ is the width of the line. Hence the shape of the broadened discrete line is the same in the case of predissociation as in the case of radioactive decay or dissociation by rotation.

SOME PROPERTIES OF THE EIGENFUNCTIONS AND PERTURBATIONS

In previous work on the rate of predissociation⁷ it has never as yet been possible to follow the wave of dissociating molecules in the same way as in the preceding paper we have followed the wave of departing alpha particles in the case of radioactivity or the dissociating molecules in the case of dissociation by rotation. We are now in a position to do this in the case of predissociation. First we must consider certain properties of the eigenfunctions and perturbations involved.

To get the unperturbed eigenfunctions we first hold the distance, r , between the nuclei fixed, and solve the wave equation for the electrons and the rotation of the nuclei. We can write this equation in the following form

$$(H_\Theta - U_m)\Theta_m = 0 \quad (5)$$

H_Θ is the Hamiltonian⁸ with respect to the electrons and the rotation, Θ_m

⁶ See (I), Eq. (23), and text just after (23).

⁷ Wentzel, *Phys. Zeits.* 29, 333 (1928); Kronig, *Zeits. f. Physik* 50, 360 (1928); Rice, *Phys. Rev.* 34, 1451 (1929).

⁸ We use the following system of coordinates. We refer everything to a set of axes which pass through the center of gravity of the system as a whole. But in the case of the nuclei we use

is an eigenfunction, U_m an eigenvalue with quantum numbers designated collectively as m . We then set up arbitrarily the following wave equation for a function $F_{m,k}$ of r :

$$\begin{aligned} d^2 F_{m,k}/dr^2 + \kappa^2 (E_{m,k} - U_m) F_{m,k} &= 0 \\ \kappa^2 &= 8\pi^2 M/h^2 \end{aligned} \quad (6)$$

where M is the reduced mass, h Planck's constant $E_{m,k}$ an eigenvalue of (6), U_m being the eigenvalue (a function of r) previously found from (5).

instead of the six rectangular coordinates, the three coordinates of the center of gravity of the nuclei, the two coordinates ϕ and θ giving the direction of the line joining the nuclei, and r . The coordinates of the center of gravity of the two nuclei are counted among the electronic and rotational coordinates. Now if r is so large that interaction between the two atoms forming the molecule is negligible (a case which will later be of importance) then the potential energy function for any given ϕ and θ will depend on $x_1 - \alpha r l$, $y_1 - \alpha r m$, $z_1 - \alpha r n$, $x_2 - \alpha r l$, \dots , where l , m , and n are the direction cosines of the line joining the nuclei, α is a constant depending on the relative masses of the two nuclei and on which nucleus the electron in question is (αr being the distance to the given nucleus from the center of gravity of the nuclei), and $x_1, y_1, z_1, x_2, \dots$, are the coordinates of the electrons, and also on the coordinates of the center of gravity of the nuclei, but not otherwise on r than as noted above, provided the coordinates of the system have values at all probable. Therefore the eigen-function Θ_m will depend upon r only in like manner. From this we see that any function of Θ_m and its derivatives when integrated over all coordinates except r , ϕ , θ will very approximately be independent of r . For we can always substitute the variables $x_1 - \alpha r l$ for the original variables, and $d(x_1 - \alpha r l)$ for dx_1 for constant r . Further integration over ϕ and θ of course leaves the expression independent of r .

Note added in proof: Since Footnote 8 may not be clear it may be well to explain it in more detail. The reason that Θ_m involves r only in the form $x_1 - \alpha r l$ when r is large is as follows. A partial differentiation with respect to x_1 is the same as a partial differentiation with respect to $x_1 - \alpha r l$. So if in finding our eigenfunction we first hold ϕ and θ fixed as well as r we get an eigenfunction depending only on $x_1 - \alpha r l$, etc., and the coordinates of the center of gravity of the nuclei. We call this eigenfunction N and will omit subscripts. For the dependence on ϕ and θ we multiply by a spherical harmonic, Y . The NY form a complete orthogonal set in terms of which the Θ_m can be expanded. The perturbation matrix components are found in much the same way as the others (v_{ss} and v_{st}) in this paper, and are due to the fact that the terms

$$\frac{1}{r^2 \sin^2 \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial}{\partial \theta} \right) + \frac{1}{r^2 \sin^2 \theta} \frac{\partial^2}{\partial \phi^2}$$

in the Hamiltonian must operate on the whole expression NY instead of just on Y , since l , m , and n which are involved in N depend on ϕ and θ . We have

$$\partial N / \partial \theta = -\alpha r (\partial l / \partial \theta) \partial N / \partial (x_1 - \alpha r l),$$

and correspondingly for the second derivative, etc. Wherever the second partial derivatives of N with respect to $x_1 - \alpha r l$, etc., occur a factor r^2 cancels the r^{-2} in the perturbation operator, and subsequent integration over x_1 , etc., removes the dependence on r in the way discussed near the end of footnote 8. The terms in a perturbation matrix component involving only a first derivative of N will contain r to the minus first power, hence will be small for large r . Therefore, for large r , the coefficients of the of NY 's in the expression for Θ_m will not involve r and Θ_m will depend on r only as stated.

Another remark we should like to make is this. The coordinates of the actual distance of an electron to its nucleus (if X_0 , etc., are the coordinates of the center of gravity of the nuclei) are $x_1 - \alpha r l - X_0$ and the potential energy depends more directly on this quantity than on $x_1 - \alpha r l$, but this does not matter for our purposes.

As the unperturbed eigenfunction we use $\Theta_m F_{m,k}/r$. This is the usual procedure for molecules, it being generally conceded that it gives the energy levels of molecules to a good approximation.⁹

The unperturbed eigenfunction obviously obeys the equation:

$$(F_{m,k}/r)(H_\Theta - U_m)\Theta_m - \kappa^{-2}(\Theta_m/r)d^2F_{m,k}/dr^2 - (\Theta_m/r)(E_{m,k} - U_m)F_{m,k} = 0 \quad (7)$$

Since H_Θ and $E_{m,k}$ and U_m contain no derivatives with respect to r we may write

$$H_\Theta(\Theta_m F_{m,k}/r) - \kappa^{-2}(\Theta_m/r)d^2F_{m,k}/dr^2 - E_{m,k}(\Theta_m F_{m,k}/r) = 0 \quad (8)$$

The actual Hamiltonian for the system, however, is

$$H = H_\Theta - \kappa^{-2}\left(\frac{\partial^2}{\partial r^2} + \frac{2}{r}\frac{\partial}{\partial r}\right). \quad (9)$$

The actual wave equation, therefore, if it operates on $\Theta_m F_{m,k}/r$ contains the extra terms¹⁰

$$- \kappa^{-2}[(F_{m,k}/r)(\partial^2\Theta_m/\partial r^2) + (2/r)(\partial\Theta_m/\partial r)(dF_{m,k}/dr)]. \quad (10)$$

Now to get the real solution of the wave equation we can expand in terms of the $\Theta_m F_{m,k}/r$ which form an orthogonal set.¹⁰ We can treat the $\Theta_m F_{m,k}/r$ as solutions of equations like (8) and use the extra terms in setting up a perturbation matrix, (10) being considered as the result of an operator acting in a special way on $\Theta_m F_{m,k}/r$.

Now in the case of predissociation we expand the perturbed eigenfunction in terms of a $\Theta_m F_{m,k}/r$ belonging to a discrete state,¹¹ which we will call simply ψ_d , and a set of continuous ones, which belong to another electronic level, and which we designate as $\Theta_c F_{c,i}/r$ where i runs over the set of continuous states. It is to be noted that the continuous property arises from the $F_{c,i}$'s, as Θ_c for all r 's is a discrete eigenfunction of (5).

The perturbed eigenfunction, ψ'_n may thus be written as a linear function of the unperturbed, thus:¹²

$$\psi'_n = S_{dn}\psi_d + \Theta_c \sum_i S_{in} F_{c,i}/r. \quad (11)$$

For large values of r the first term of (11) gives no appreciable contribution, hence for this case

$$\psi'_n = \Theta_c \sum_i S_{in} F_{c,i}/r = \Theta_c F'_n/r \quad (12)$$

⁹ Born and Oppenheimer, Ann. d. Physik **84**, 457 (1927).

¹⁰ Perturbations of this nature were first set up in practically this form by Slater, Proc. Nat. Acad. Sci. **13**, 423 (1927), which should be seen for details. Our formulation differs only in that we have put the r part of the eigenfunction in the form $F_{m,k}/r$.

¹¹ Only one discrete state is to be considered, for we assume as throughout that any other discrete states which interact with the set of continuous states we are interested in are so far away in the term spectrum that their effect may be neglected. Also, of course we consider that the given discrete state interacts with only one set of continuous ones. See (I) pp. 751-2.

¹² (I), Eq. (29) It has been, unfortunately, necessary to change the notation somewhat.

where $F_n' = \sum_i S_{in} F_{c,i}$. The perturbed wave equation may be written

$$(H - E_n')\psi_n' = 0 \quad (13)$$

where E_n' is the corresponding eigenvalue.

This gives, for large r , using (9) and (12)

$$H\Theta(\Theta_c F_n'/r) - \kappa^{-2}(\Theta_c/r)d^2 F_n'/dr^2 - E_n'(\Theta_c F_n'/r) - \kappa^{-2}(F_n'/r)\partial^2 \Theta_c/\partial r^2 - \kappa^{-2}(2/r)(\partial \Theta_c/\partial r)(dF_n'/dr) = 0. \quad (14)$$

We now proceed to reduce (14) to an equation in F_n' . To do this we first multiply through by r , then by Θ_c and integrate over all values of the electronic and rotational coordinates. (We call the volume element $d\tau'$.) We remember that $\int \Theta_c H \Theta_c d\tau' = U_c$ and note that¹³ $2\int \Theta_c (\partial \Theta_c/\partial r) d\tau' = \int (\partial \Theta_c^2/\partial r) d\tau' = (d/dr) \int \Theta_c^2 d\tau' = d1/dr = 0$, since the Θ_m are an orthogonal set. Further we set $\kappa^{-2} \int \Theta_c (\partial^2 \Theta_c/\partial r^2) d\tau' = I_c$. Eq. (14) thus becomes

$$d^2 F_n'/dr^2 + \kappa^2(E_n' + I_c - U_c)F_n' = 0 \quad (15)$$

For large distances, r , the integral I_c must be independent of r , because for large distances r the molecule is separated into atoms which do not interact appreciably. Θ_c will always be affected the same way by a displacement, dr , regardless of what r is, provided it is large enough (see footnote 8). Eq. (15) shows us that F_n' satisfies a wave equation of the usual type for a problem of one degree of freedom, and hence is a sinusoidal function of the usual type.

CONCERNING THE PERTURBATION MATRIX AND THE PERTURBATION PROBLEM

Before we proceed further we must introduce some considerations about the perturbation matrix. The diagonal matrix component for a given continuous state is by (10) remembering that the r part of the volume element is $r^2 dr$ (we substitute c for m in (10)—also we write s for k to correspond to the notation used in previous papers—unfortunately we cannot make the correspondence complete, as in this paper it has been necessary to use two subscripts):

$$v_{ss} = -\kappa^{-2} \int_0^\infty F_{c,s}^2 dr \int \Theta_c (\partial^2 \Theta_c/\partial r^2) d\tau' - 2\kappa^{-2} \int_0^\infty F_{c,s} r (dF_{c,s}/dr) dr \int \Theta_c (\partial \Theta_c/\partial r) d\tau'$$

For the method of setting up this expression Slater's article¹⁰ can be consulted. The last term vanishes since $\int \Theta_c (\partial \Theta_c/\partial r) d\tau' = 0$ as noted above. Remembering the definition of I_c we find

$$v_{ss} = - \int_0^\infty F_{c,s}^2 I_c dr.$$

¹³ Kronig, l. c., p. 355.

Now I_c approaches a constant value for large r . Let us call this value I_{c1} . Then $I_c = I_c' + I_{c1}$ where I_c' differs from zero only for small r , and there will be of the order of I_{c1} . From the orthogonal properties of the $F_{c,s}$ we see that

$$v_{ss} = - \int_0^\infty F_{c,s}^2 I_c' dr - I_{c1}. \quad (16)$$

In similar manner, for two different continuous states s and t belonging to the same electronic-rotational state c , we get, remembering the orthogonal properties of the $F_{c,s}$

$$v_{st} = - \int_0^\infty F_{c,s} F_{c,t} I_c' dr.$$

Therefore the contributions to v_{st} come from a range in which r is small, and our previous deductions that v_{st} is small enough to be neglected are valid.¹⁴ The same deductions hold for the first term of the right of (16). Hence, very approximately

$$v_{ss} = - I_{c1} \quad (17)$$

The method of handling cases where v_{ss} is not small has already been indicated.¹⁴ In fact, it consists simply in adding v_{ss} (which is practically independent of s) to the corresponding energy $E_{c,s}$ and proceeding exactly as before. Now suppose instead of (6) we write (for the case $m=c$ and $k=s$)

$$d^2 F_{c,s} / dr^2 + \kappa^2 (E_{c,s} - U_c - v_{ss}) F_{c,s} = 0 \quad (18)$$

Then $E_{c,s} + v_{ss}$ takes the place of $E_{c,s}$ ($m=c$, $k=s$) as eigenvalue in Eq. (6). We could therefore take (18) as the unperturbed equation for the electronic-rotational state c , and otherwise disregard v_{ss} . This is the most convenient way of handling the problem, for the relations between the eigenvalues of (18) and the perturbed eigenvalues E_n' will be just the same as the relation between the eigenvalues of (6) and the E_n' *would have been* were v_{ss} actually 0, and this relationship has been deduced in the previous work.

The relationship is as follows. Between every two eigenvalues of (18) lies a value E_n' . Let us denote as $E_{c,n}$ the eigenvalue of (18) which is just above the particular value E_n' . Then from the original definition¹⁵ of the quantity β which appeared earlier in the paper

$$E_{c,n} - E_n' = \beta + \epsilon/2. \quad (19)$$

THE WAVE PACKET FOR THE DISSOCIATING MOLECULES

Now it has been shown¹⁶ that the wave packet for the dissociation from the discrete state into the overlying continuum is given by

¹⁴ (I), Appendix I. Correction, Phys. Rev. **34**, 1462.

¹⁵ (I), p. 755.

¹⁶ Rice, Phys. Rev. **34**, 1451 (1929).

$$\psi = \sum_n S_{dn} \psi_n' \exp(-2\pi i E_n' t / h) \quad (20)$$

where $S_{dn} = K/v_{cd}$. For values of r large compared to atomic sizes, we have from (12), (4), and (20)

$$\psi = \frac{\epsilon \Theta_c}{\pi v_{cd} r} \sum_n \frac{F_n' \exp(-2\pi i E_n' t / h)}{[1 + 4(E_n' - E_1)^2 / \omega^2]^{1/2}} \quad (21)$$

We shall now find the relation between the F_n' and the eigenfunctions $F_{c,s}$ of Eq. (18). The latter may be written in the following form for large r

$$F_{c,s} = \sin \{ \kappa(E_{c,s} - U_c - v_{ss})^{1/2} r + \zeta_s \} \quad (22)$$

where ζ_s is a phase constant. The condition that $F_{c,s} = 0$ at $r = r_1$ where r_1 is the largest value r can take (the system being in a box) requires

$$\sin \{ \kappa(E_{c,s} - U_c - v_{ss})^{1/2} r_1 + \zeta_s \} = 0. \quad (23)$$

But the quantum condition in the neighborhood of $r=0$ requires that ζ_s should be the same¹⁷ for all s . At any rate this will be practically true over a range of energies greater than the small breadth, w , of the broadened discrete state. It would always be exactly true if U_c were constant for small r , as well as large, (i.e. if (22) actually held for small r), and the smallest value r could take were 0. Now since F_n' obeys the equation (15) we have for large r

$$F_n' = \sin \{ \kappa(E_n' - U_c - v_{ss})^{1/2} r + \zeta_n' \} \quad (24)$$

F_n' must be 0 at $r = r_1$ so

$$\sin \{ \kappa(E_n' - U_c - v_{ss})^{1/2} r_1 + \zeta_n' \} = 0 \quad (25)$$

Eq. (25) will obviously be satisfied if

$$\zeta_n' = \zeta_s + \kappa(E_{c,n} - U_c - v_{ss})^{1/2} r_1 - \kappa(E_n' - U_c - v_{ss})^{1/2} r_1 \quad (26)$$

(see Eq. (23) and see also just before Eq. (19) for definition of $E_{c,n}$). Now as the difference between the quantities $(E_{c,n} - U_c - v_{ss})^{1/2}$ and $(E_n' - U_c - v_{ss})^{1/2}$ is very small¹⁸ we may write it as $\frac{1}{2}(E_{c,n} - E_n')$ $(E_{c,n} - U_c - v_{ss})^{-1/2}$ or, by (19) as $\frac{1}{2}(\beta + \epsilon/2) (E_{c,n} - U_c - v_{ss})^{-1/2}$. Now $\epsilon = 2\pi\kappa^{-1}(E_{c,n} - U_c - v_{ss})^{1/2} r_1^{-1}$. So we see that

$$\begin{aligned} \zeta_n' &= \zeta_s + \pi\beta/\epsilon + \pi/2 = \zeta_s + \pi/2 + \tan^{-1} \{ (E_n' - E_1)\epsilon/\pi v_{cd}^2 \} \\ &= \zeta_s + \pi/2 + \tan^{-1} \{ 2(E_n' - E_1)/w \} \end{aligned} \quad (27)$$

by (3) and remembering that $w = 2\pi v_{cd}^2/\epsilon$. We thus get an expression for ζ_n' which can be used in evaluating F_n' . Now

$$\sin \{ x + \tan^{-1} y \} = (\sin x + y \cos x) (1 + y^2)^{-1/2}.$$

¹⁷ Or differ only by multiples of π . We can choose that they should be all the same.

¹⁸ It may be made as small as we please by making r_1 large.

Using this formula we get from (24), (27), and (21)

$$\psi = \frac{\epsilon\Theta}{\pi v_{cd}r} \sum_n \frac{[\sin\{\kappa(E_n' - U_c - v_{cs})^{1/2}r + \zeta_s + \pi/2\} + [2(E_n' - E_1)/w]\cos\{\kappa(E_n' - U_c - v_{cs})^{1/2}r + \zeta_s + \pi/2\}]\exp(-2\pi i E_n t/\hbar)}{1 + 4(E_n' - E_1)^2/w^2}.$$

The sum over n can be converted to an integral with respect to E_n' , and then, except for the factor $1/r$, which merely means that here we have taken all three dimensions of space into account, and so have a spherical wave, the part which involves r has exactly the same form as Eq. (23) of the preceding paper. We thus have a wave of dissociating particles of exactly the same type as before, with exponential decrement with time bearing the same relation to the width of the discrete state, in fact the same in all details. There is thus a complete analogy in results between these two different types of decompositions. Also the part of the wave for small r can be handled as in the preceding paper, since for small r the eigenfunctions will not vary appreciably over a small range of energies.

I wish to express my thanks to Professor Heisenberg for his interest in this work, and helpful discussion.

CONCERNING THE ABSORPTION METHOD OF INVESTIGATING
 β -PARTICLES OF HIGH ENERGY: THE MAXIMUM
ENERGY OF THE PRIMARY β -PARTICLES OF
MESOTHORIUM 2.

BY N. FEATHER*

PHYSICAL LABORATORY, JOHNS HOPKINS UNIVERSITY, BALTIMORE

(Received April 30, 1930)

ABSTRACT

For the primary β -particles of radium C, radium E and mesothorium 2 the maximum effective mass range, R , has been determined in paper and aluminum by the method of Chalmers. In the two former cases the maximum energy of the particles, E , is known, and these results and earlier data lead to the relation

$$R = 0.511E - 0.091$$

for $E > 0.7$. Here R is measured in grams/cm² and E in millions of electron volts. For mesothorium 2, $R = 0.955 \pm 0.015$ gm/cm², so that the maximum energy of the particles is $2.05 \pm 0.03 \times 10^6$ electron volts. Reasons are advanced for employing the empirical relation above quoted rather than results obtained with particles of a single velocity, as in the experiments of Varder and Madgwick, in the interpretation of absorption measurements made upon primary β -particles.

INTRODUCTION

THE earliest recognition of the emission of two distinct types of corpuscular radiation from radioactive material followed immediately upon the adoption of absorption methods of investigation; continuously throughout the development of the subject these methods have been applied afresh in the study of the radiations from the β -ray bodies. Beyond a general qualitative analysis, however, they provide little information which admits of easy interpretation. We now know, for example, that exponential absorption reflects no fundamental property of the different natural radiations—and, in consequence, exponential absorption coefficients have lost much of their significance. Moreover most of the early work was directed toward their determination.

And yet, despite this indefiniteness, absorption measurements do provide, simply and without ambiguity, the maximum effective range, in the medium employed, of the particles submitted to analysis. Now it is of considerable interest to determine the maximum energy appearing as kinetic energy in each of the cases of β -particle disintegration and it is evident that absorption measurements make this determination possible when the necessary data relating effective range with the energy of the particle are available. Such data in fact exist, and already the method has been applied to the β -ray bodies of the active deposit of thorium by Chalmers¹ and to those of the active

* Fellow of Trinity College, Cambridge; Associate in Physics, Johns Hopkins University.

¹ Chalmers, Proc. Camb. Phil. Soc. 25, 331 (1929).

deposit of actinium by Sargent.² But the data in question, upon which the interpretation of these experiments depends, in themselves are ambiguous: the ranges in aluminum given by Madgwick³ are more than 10 percent greater than the corresponding ranges as determined by Varder.⁴

Eddy⁵ has recently made a more detailed study of the absorption of β -particles of somewhat less energy than those with which we are here chiefly concerned and has concluded that the discrepancies between the results of Varder and Madgwick are to a large extent due to the different arrangements of ionization chamber which these authors employed. This conclusion, coupled with the fact that the conditions obtaining in absorption measurements on the complete natural radiations are quite different from those effective in the two investigations under discussion, makes a review of the precise relevance of the data of Varder and Madgwick to the present problem of considerable interest. The results of each investigator show that the effective range is a linear function of the energy of the particle for values of the energy greater than 0.65 million electron volts, or formally

$$R = aE + b \quad (1)$$

for $E > 0.65$ (million electron volts). Varder's data for aluminum are best represented by $a = 0.469$, $b = -0.071$, R being expressed in grams/cm²; Madgwick's figures by $a = 0.552$, $b = -0.097$. It is to be expected that a similar relation must apply to the conditions of experiment in the primary β -particle case also, but it should be pointed out that the relation in question no longer connects the effective range with the energy for particles initially homogeneous in velocity, but rather it relates the maximum effective range with the maximum energy when particles of continuously varying energy are present. It is very probable that this circumstance makes the determination of the effective range more independent of the conditions than it appears to be in the case of particles of a single velocity,⁶ but obviously it cannot result otherwise than that the maximum effective range which is measured should be determined by the highest energy particles present in the beam. Nevertheless there is no simple reason for believing this range to be precisely the same as the effective range determined by extrapolation from the absorption curve taken under any arbitrary conditions with β -particles of that unique limiting velocity. For the purposes of interpretation of experiments performed upon the full natural β -radiation from different substances we ought in preference to employ a calibration curve determined under closely comparable conditions. Such a curve may be obtained by applying the absorption method to the determination of the maximum effective range of the β -particles from bodies which have already been studied in greater detail by the method of magnetic spectroscopy.

⁴ Varder, Phil. Mag. 29, 725 (1915).

⁵ Eddy, Proc. Camb. Phil. Soc. 25, 50 (1929).

⁶ A necessary condition for the truth of this statement is that the continuous spectrum of velocities should have a sharply defined upper limit. This seems to be the case: cf. Chalmers, reference 1, p. 337, Gurney, reference 9, p. 549.

The experiments of Chalmers¹ and Gurney⁷ provide the first point on such a curve. Chalmers fixed the maximum effective range of the β -particles of thorium C at 0.98 gm/cm² of aluminum whilst Gurney showed that the maximum energy of the particles was 2.18×10^6 electron volts. The first portion of the present work is devoted to the determination of the maximum effective range of the radium E β -particles and of those of radium C. The limiting energies to which these ranges correspond are known from the measurements of Madgwick,⁸ and Gurney,⁹ respectively. Then two more points are added to the curve and the most probable values of the constants a and b of Eq. (1) may be determined.

The second part of the work consists in a similar absorption experiment upon the primary β -particles of mesothorium 2 and the newly determined range-energy relation makes possible its interpretation.

GENERAL EXPERIMENTAL ARRANGEMENT

The β -ray electroscope used in all the measurements consisted of a gold leaf system suspended in the usual manner at the center of a cubical aluminum case of 11 cm edge and 3 mm thickness of wall. In the base of the electroscope a hole 7.5 cm square was closed with aluminum foil weighing 6.5 mg/cm². The electroscope was supported on a wooden stand with a space of 24 cm between its base and the surface of the bench. A wooden slide could be inserted in various positions below the base of the instrument. This slide carried both the active material and the absorbing foils. The former was placed at the bottom of a shallow cylindrical hole (depth 1.1 cm, diameter 3.2 cm) cut in the slide and the latter, in the form of sheets 5 cm square, were placed upon the slide so as to cover the hole symmetrically. In most cases the slide was inserted in the highest position, and in these circumstances the source was about 3.5 cm below the base of the electroscope. In all the experiments the decay of the source and the varying density of the air in the electroscope were corrected for by making frequent measurements under standard conditions of absorption. In general the mean of ten independent observations was obtained for each point plotted on an absorption curve. Adopting this routine it was not found necessary to employ a magnetic field to separate β - and γ -ray effects, even in the case of radium C where the latter effect is very pronounced, and indeed it is the writer's opinion that the avoidance of such a method is much to be preferred whenever that is possible, for it is difficult to estimate the effect of the stray magnetic field on the γ -ray ionization in the electroscope in any of the simpler experimental arrangements that have been used.

EXPERIMENTAL RESULTS. PART I

Radium E. Madgwick⁸ has determined the upper limit of the continuous spectrum of the β -particles of radium E as 1.07×10^6 electron volts energy. This is the datum with which our range measurements are to be combined.

⁷ Gurney, Proc. Roy. Soc. 112A, 380 (1926).

⁸ Madgwick, Proc. Camb. Phil. Soc. 23, 982 (1927).

⁹ Gurney, Proc. Roy. Soc. 109A, 540 (1925).

Absorption methods have, in fact, already been applied to the determination of the range in this case. In 1912 Gray¹⁰ first pointed out¹¹ the phenomenon of an end point to the β -particle absorption with a source of radium E. His measurements lead to an effective mass range between 0.45 and 0.49 gm/cm² of paper. Douglas¹² extended the measurements to other absorbing media and gave 0.474 and 0.460 gm/cm² for the effective ranges in paper and aluminum respectively. But the sources employed were weak and the logarithmic method of extrapolation was used to fix the range. It was thought worthwhile to repeat the determinations¹³ with a stronger source employing the method of simple extrapolation of Chalmers. This method has been adopted as standard throughout.

The results are shown in Fig. 1. They refer to a source of radium D, E and F in equilibrium¹⁴ deposited by evaporation on a small platinum dish. The

Fig. 1. Radium E.

weight of deposit, more than 1 cm² in extent, was a few milligrams only. Unwhitened paper was used as absorber and the maximum effective mass range in this medium may be taken as 0.475 ± 0.005 gm/cm².

A simple experiment was also made upon the radiation unabsorbed by this thickness of material. The source was covered with sheets of paper repre-

¹⁰ Gray, Proc. Roy. Soc. 87A, 487 (1912); Trans. Roy. Soc. Canada 16 III, 125 (1922).

¹¹ The end point is clearly shown in absorption curves published by Schmidt in 1907 (Phys. Zeits. 8, 362 (1907)).

¹² Douglas, Trans. Roy. Soc. Canada, 16 III, 113 (1922).

¹³ Absorption measurements by Aston (Proc. Camb. Phil. Soc. 23, 935, (1927)) and by Fournier and Guillot (Comptes rendus 189, 1079 (1929)) also have reference to a region including the β -particle end point but, being concerned chiefly with the weak γ -radiation, permit of no accurate range values being drawn from them.

¹⁴ The writer wishes to thank Dr. C. F. Burnam of the Kelly Hospital, Baltimore, for a supply of old radon tubes from which this material was extracted.

senting (together with the air gap and the base of the electroscope) 0.499 gm/cm^2 of absorber. Aluminum foils were then added and the further progress of the absorption followed. The curve *B*, Fig. 1, exhibits these results, the logarithm of the corrected ionization being plotted against the foil thickness. Curve *A* represents the parallel case where the absorption was in paper throughout. A mass absorption coefficient of $2.3 \text{ cm}^2/\text{gm}$ is a sufficiently good approximation here; the initial absorption in aluminum, however, is roughly five times as great, for equal mass of absorber. This is what we should expect if the absorption were chiefly photoelectric, and the numerical values also suggest that the effective radiation is for the most part the very soft component, probably the *LX*-radiation of radium D, for which a mass absorption coefficient of $16.5 \text{ cm}^2/\text{gm}$ in aluminum is accepted as correct.¹⁵ The smaller value ($11.3 \text{ cm}^2/\text{gm}$) found with the present arrangement is to be attributed largely to the fact that the first 0.5 gm/cm^2 of paper has already reduced this soft component to about a quarter of its original intensity, so that the influence of the less intense though harder components is no longer negligible. It is of interest to record that the last point on the curve *B*, representing the smallest ionization current involved in this series of measurements, yet represents a current about forty times as great as the natural leak of the electroscope effective at the time.

Radium C. The primary β -particles of this body comprise a continuous spectrum of energies having a sharp upper limit at 3.15×10^6 electron volts (Gurney⁹). On the other hand no data have hitherto been available concerning the maximum effective range of these particles as determined in the present type of experiment. The problem here presented is considerably more difficult than in the case of radium E, on account of the very great intensity of the γ -radiation from radium C and of the rapid decay of this body. The latter difficulty may be overcome by using a radon tube as a β -particle source, although this procedure increases the γ -ray effect, by adding the γ -rays of radium B to those of its subsequent product. Moreover the radiation thus added is in general much less penetrating than the latter, and it is the softer components of the radiation which constitute the greater source of error. An attempt was made to minimise this effect in the arrangement finally adopted.

A small glass bulb, about 3 mm in diameter, originally containing about 800 equivalent milligrams of radon was employed as the source of β -particles at the stage when its activity had fallen to a few thousandths of its initial value.¹⁶ In this way the points of Fig. 2 were obtained. The absorbing material consisted of aluminum to the extent of 1.012 gm/cm^2 placed directly over the source, with sheets of paper for the remainder. By using the aluminum it was hoped to cut down the softer components of the γ -rays to reasonable proportions whilst the use of paper for the rest of the absorption was governed by considerations of ease of manipulation and of the sharper type of absorption

¹⁵ Rutherford and Richardson, *Phil. Mag.* **26**, 324 (1913). Curie and Fournier, *Comptes rendus* **176**, 1301 (1923).

¹⁶ For this material also the writer is indebted to Dr. Burnam.

limit thereby obtained. Moreover Chalmers failed to find any appreciable difference between the mass ranges of the thorium C β -particles in paper and aluminum. The equivalence of these materials in this respect has been assumed in the present experiments. The walls of the radon tube were not negligibly thin and an estimate of their thickness was made in two ways, by direct weighing, and by a subsequent absorption experiment after the lapse of a few weeks, when the radium E β -particles were responsible for the greater proportion of the ionisation as measured through small thicknesses.¹⁷ The difference

Fig. 2. Radium C.

between the apparent maximum effective range of these particles as determined with this source and in the direct experiments on radium E described above was attributed to absorption in the glass walls of the bulb. Both methods suggested an equivalent thickness of glass of 0.03 gm/cm^2 . So corrected the maximum effective mass range of the primary β -particles of radium C in aluminum or paper may be given as $1.54 \pm 0.02 \text{ gm/cm}^2$, as indicated in the figure.

The range-energy relation. The data which are to be employed in constructing our calibration curve are given in Table I.

TABLE I. Data used in constructing calibration curve.

Source of β particles	Maximum energy electron volts $\times 10^{-6}$	Maximum effective mass range gm/cm ²
RaE	1.07	0.475
ThC	2.18	0.98
RaC	3.15	1.54

¹⁷ The final decay of the emanation originally contained in the bulb is responsible for the production of about 0.3 equivalent milligrams of radium D, E, and F.

Within experimental error this material is consistent with a linear relation such as that given by Eq. (1) and is best represented by the straight line

$$R = 0.511E - 0.091 \quad (2)$$

which, by analogy with the relations of Varder and Madgwick, may probably be regarded as valid for values of E greater than 0.7 (million electron volts). It may be remarked that the present straight line occupies a position intermediate between those of Varder and Madgwick—and it may be pointed out that the results of Eddy occupy a similar position in the region of smaller energies where the curve is no longer linear. But the intention of any very close comparison between the present results and results having reference to particles of a single velocity has already been disclaimed, so that no primary importance is attached to this apparent agreement. Moreover, not only was the work of Eddy concerned with particles of a single velocity, but it was carried out by the method of electrical counting, providing a further reason for caution in its comparison with the results of ionization measurements.

EXPERIMENTAL RESULTS. PART II

Mesothorium 2. The β -particles of mesothorium 2 have been studied by Yovanovitch and d'Espine¹⁸ by the direct deviation method of magnetic spectroscopy. These authors suggest that the high energy limit of the continuous spectrum occurs in the region of 1.6 million electron volts energy. It is not unreasonable to suppose, from a knowledge of the general characteristics of the method, however, that this represents merely a lower limit to the maximum energy of the particles.¹⁹

The difficulties in the way of absorption measurements with mesothorium 2 are similar to those obtaining with radium C: there are γ -rays of considerable intensity and the pure substance is of fairly rapid decay. The broad scheme of the experiments, therefore, was first to determine an absorption curve in full detail with a source of mesothorium 1 and 2 in equilibrium and then to make confirmatory tests with a small number of selected thicknesses of absorber and a source of pure mesothorium 2, in order to be certain that the main features of the former curve, in the region of the β -particle end point at least, were due to the latter body alone.

A solution of mesothorium 1, freed from radiothorium by repeated precipitation with iron, and from a large fraction of the ammonium chloride which accumulates as a result of such operations, was allowed to stand so that the thorium X should decay. Being neutralized the solution was electrolysed with platinum anode and silver cathode at a temperature of about 90°C.²⁰

¹⁸ Yovanovitch and d'Espine, *J. de Physique*, **8**, 276 (1927).

¹⁹ For a constant value of the field the dispersion decreases rapidly as the energy of the particles increases, and this, together with the peculiarities of photographic registration, must necessarily introduce considerable distortion. Both in the case of the primary β -particles of radium C and for those of radium E this method has given too low a value for the maximum energy (2.74×10^6 electron volts in the former case and 0.94×10^6 in the latter).

²⁰ Meitner, *Phys. Zeits.*, **12**, 1097 (1911).

Mesothorium 1 and 2 were obtained together, the latter in about 90 percent of its equilibrium amount. The silver plate (about 2 cm² in area), carrying the deposit on one surface only, was enclosed in an airtight container to prevent the diffusion of emanation. A thin sheet of mica was employed for the upper face of the vessel which fitted neatly in the whole cut in the electroscope slide already described. Since originally the mesothorium was extracted directly from monazite, radium was known to be present as "impurity." But the duration of the previous heat treatment of the solution, and of the electrolysis, was such that immediately after its preparation the β -particle source could be regarded as free from all contamination except by radium element itself. Provided, therefore, that measurements were carried out within the

Fig. 3. Mesothorium 2.

first 24 hours after the source was prepared they were unlikely to be seriously affected by the growing β -particle activity arising from the active deposit of radium.

The results of measurements with this source are shown in Fig. 3, the last measurement being completed 22 1/2 hours after the source was obtained on the plate. As in the experiment on radium C roughly the first two-thirds of the absorption was in aluminum—a thickness of 0.646 gm/cm² of this metal being succeeded by sheets of paper. In an attempt to detect any possible effect of the gradual building up of radium C in the source during the period of observation measurements were made in the following order, namely through

44, 40, , 0,
 11, 15, , 27,
 2, 6, , 42,
 29, 25, , 13

sheets of paper, in turn. This sequence was, of course, interrupted periodically to permit of measurements with a standard absorber in place. It will be seen from the figure that no such effect as was sought was observed.²¹ In this way the β -particle end point was fixed at 0.955 ± 0.015 gm/cm² and it only remained to confirm its identification with the maximum effective mass range of the primary β -particles of mesothorium 2 by an independent experiment.

A source of mesothorium 2 was prepared in the usual manner by precipitation with a trace of iron from a solution containing mesothorium 1 and 2 in equilibrium. Three thicknesses of absorber, corresponding respectively to the first and last points in Fig. 3 and to the point nearest the absorption discontinuity, were chosen and two sets of measurements made, separated in time by about 3 1/2 hours. Table II contains the results.

TABLE II. Results

Thickness of absorber gm/cm ²	Relative ionizations	
	(1)	(2)
0.660	1.000	1.000
0.952	0.867	0.870
1.241	0.825	0.824

The decay of activity, corresponding to a half period of 6.4 hours, showed that the source was sufficiently pure for the test to be conclusive, and the figures given, when compared with the values 1.000, 0.868, 0.812 read directly from the curve, establish the identity which was in question. The exact agreement in the second instance is probably fortuitous but it is obvious first of all that no appreciable amount of unrecognized radioactive impurity was present in the original source, and secondly that any γ -rays emitted by mesothorium 1 were of little or no consequence in the measurements made with that source.

Inserting the value 0.955 gm/cm² for R in Eq. (2) we have $E = 2.05$ million electron volts and consequently, as the result of these experiments, may adopt this as the most probable value for the maximum energy of the primary β -particles of mesothorium 2. As was pointed out earlier in the discussion, a value considerably in excess of that given by Yovanovitch and d'Espine was almost to be expected.

Finally, in addition to acknowledgements already made, the writer wishes to record his appreciation of help received from the Rumford Fund of the American Academy of Arts and Sciences, a grant from which made possible the purchase of the mesothorium employed in these researches.

²¹ Further measurements were made on the source at three different absorptions within the range of the figure after 4 and 10 days, respectively. Also a rough absorption curve extending over this range was determined for a source of radium B+C in equilibrium. All the measurements could be explained simply by assuming that 8.7 percent of the ionization through 0.66 gm/cm² of aluminum at the end of 4 days, and 17.0 percent at the end of 10 days, was due to the β and γ -rays of radium B+C which had grown in the interim.

THE MOTION OF ELECTRONS IN CARBON MONOXIDE

By H. B. WAHLIN

DEPARTMENT OF PHYSICS, UNIVERSITY OF WISCONSIN

(Received May 5, 1930)

ABSTRACT

With the same data as were presented in an earlier paper it is shown that K. T. Compton's theory of electron mobilities holds within the limits of experimental error for high pressures and low fields, provided it is assumed that the energy loss of the electrons on impact with the molecules is greater than that due to momentum transfer.

The electron mean free path in CO has been calculated and, when the electrons are in thermal equilibrium with the gas, is 0.069 cm at a pressure of 1 mm.

I

IN AN earlier paper¹ it was shown that the mobility of electrons in CO can be represented as a function of the field strength and the pressure by an equation of the form

$$u = \frac{a}{P(B + x/p)^{1/2}}$$

with a high degree of accuracy. It is only for low fields that a systematic deviation from this equation appears.

Later, K. T. Compton² showed that from theoretical considerations, the mobility should be given by

$$u = \frac{0.815e\lambda}{m^{1/2}[\alpha T + (\alpha^2 T^2 + 1.76\lambda^2 e^2 x^2/f)^{1/2}]^{1/2}} \quad (1)$$

That this equation is applicable to the mobility of electrons in H₂ and He (at least for low fields and high pressures) has been shown by the writer.³

It was in order to test the validity of the Compton equation when applied to CO that the calculations submitted herewith were undertaken. The data are the same as were used in the earlier paper.

The method used in obtaining the data was the Rutherford alternating potential one for determining mobilities and has been described in detail earlier.

The Compton equation may be written in the form

$$u = \frac{a}{[1 + (1 + Bx^2)^{1/2}]^{1/2}}$$

¹ H. B. Wahlin, Phys. Rev. **21**, 517 (1923).

² K. T. Compton, Phys. Rev. **22**, 333 (1923).

³ H. B. Wahlin, Phys. Rev. **27**, 558 (1926).

If the electron is moving under the action of a sine wave alternating field the velocity in the direction of the field at any instant is, according to this equation,

$$\frac{dy}{dt} = \frac{aX \sin 2\pi nt}{[1 + (1 + BX^2 \sin^2 2\pi nt)^{1/2}]^{1/2}}$$

Imposing the condition that during one half cycle of the alternating field the electrons shall travel a distance d (the distance between the plates in the Rutherford method) we get on reducing the elliptic integral obtained and solving for n

$$n = \frac{a(2r)^{1/2}}{\pi d(B)^{1/2}} 2[E(k, \phi) - F(k, \phi)] \quad (2)$$

where $r = (BX^2 + 1)^{1/2}$, $k = \left(\frac{r+1}{2r}\right)^{1/2}$, $\phi = \sin^{-1}\left(\frac{r-1}{r+1}\right)^{1/2}$

and X is the peak value of the field corresponding to the voltage intercept of the mobility curves.

This equation may be verified directly with the data at hand.

Placing $A = 16,800$ and $B = 0.005$ it is seen that at a pressure of 722 mm good agreement between the experimental results and the theoretical curve

Fig. 1.

calculated from Eq. (2) is obtained. (Fig. 1). Here the points are experimental and show the relation between the frequency and the effective value of the field.

Fig. 2 shows the comparison between theory and experiment for a pressure of 500 mm. Here A and B have been corrected for the change in λ with pressure, assuming that λ varies inversely as the pressure.

At a pressure of 250 mm the agreement is good for low fields (Fig. 3). In fields above 35 volts/cm a systematic deviation appears—*viz.* the mobility

decreases more rapidly with field strength than is to be expected on the basis of the theory. This deviation is best ascribed to the beginning of the Ramsauer effect.

Fig. 2.

Fig. 3.

A comparison of theory and experiment may also be made as follows. If it is assumed that the mobility is independent of the field strength, it is possible to calculate the mobility from the relation

$$k = \pi n d^2 / 2^{1/2} V$$

where n is the frequency, d the distance between the plates, and V the r.m.s. value of the alternating voltage of the intercept of the mobility curves.

The value calculated from this equation for the case of electrons will be an average mobility defined so that the average velocity with a mobility k shall be the same as the average velocity determined from Compton's equation. This may be written

$$\int_0^d dy = \int_0^{1/2n} kX \sin 2\pi n t dt = \int_0^{1/2n} \frac{aX \sin 2\pi n t dt}{[1 + (1 + BX^2 \sin^2 2nt)^{1/2}]^{1/2}}$$

Integrating and solving for k we get

$$k = \frac{a(2r)^{1/2}}{X(B)^{1/2}} [2E(k, \phi) - F(k, \phi)].$$

Here r , k , ϕ and X have the same significance as in Eq. 2 above.

Fig. 4 shows the relation between the theoretical and experimental values of k at a pressure of 722 mm. In plotting the curve the same values of A and B were used as in the calculation of n .

Fig. 4.

II

The limiting mobility for zero field will be given by $u = A/2^{1/2}$. Substituting the known value of A in this equation, the limiting mobility found is 11,900 cm/sec/volt/cm, at a pressure of 722 mm.

From this value of u the electron free path may be calculated using the theoretical relation $u = 0.75e\lambda/m\bar{c}$. The value thus calculated, placing $\bar{c} = 1.065 \times 10^7$ cm/sec (the thermal electron velocity at room temperature), is 0.069 cm at a pressure of 1 mm.

This value is 1.75 times the value calculated from the kinetic theory molecular free path, assuming the electron free path to be $4(2)^{1/2}$ the molecular one. It is also 1.68 times the electron free path in H_2 , whereas the kinetic theory prediction is that it should be less. It seems impossible therefore to apply molecular free path data to the calculation of electron free paths. This is also borne out by the results on N_2^4 in which it was found that the electron free path is 2.55 times the predicted value.

III

The value of B used in the calculations above is much smaller than the value calculated on the assumption that the impacts of the electrons with the molecules are elastic. For this case the expression for B becomes

$$B = \frac{1.76\lambda^2 e^2 M}{2\alpha^2 T^2 m}$$

assuming $f = 2m/M$ where m is the electronic and M the molecular mass. This expression gives

$$B = 0.278$$

whereas the value found above is 0.005.

On the basis of Compton's theory one must conclude one of two things: Either the electrons do not reach their terminal thermal energy under the action of a sine wave field, or the fraction of its energy that an electron loses on impact with a CO molecule is greater than it would be if the loss were due to momentum transfer only. In the case of N_2 and H_2 referred to above, it was shown that any error due to a non-terminal state is negligible, and it seems reasonable to conclude that this will also be the case for CO. The second alternative is therefore the more probable.

THE MAGNETIC SUSCEPTIBILITY OF GASES

I. PRESSURE DEPENDENCE

BY FRANCIS BITTER*

NORMAN BRIDGE LABORATORY OF PHYSICS, PASADENA, CALIFORNIA

(Received April 28, 1930)

ABSTRACT

A method is described for measuring the magnetic susceptibility of gases which has certain advantages over those used by previous observers. With such an apparatus, it is found that the volume susceptibility of CO_2 , N_2 and H_2 is proportional to the pressure. Deviations from proportionality of the type observed by Glaser are found in the above gases upon introducing water vapor as an impurity in amounts probably less than a few hundredths of a percent.

IN ATTEMPTING to interpret the results of magnetic observations on matter, it is difficult to determine what effects are due to the molecules themselves, and what due to their interaction with each other. Because of this, results obtained with gases may be interpreted with most confidence, since in this case, isolated molecules without interaction are most nearly approximated. The fundamental quantity to be observed is K , the volume susceptibility, which measures the average induced moment per cc. Classical mechanics and quantum theory agree in predicting

$$K = \left(\frac{a}{T} + b \right) \frac{p}{T} \quad (1)$$

or

$$K = cp. \quad (2)$$

a is a positive constant which is zero if there is no permanent magnetic moment in the molecule, and b is a negative¹ constant which measures the distribution of electric charge in the molecule. The experiments described below were undertaken to check Eq. (2). In a future communication I hope to take up the absolute values of the constants a and b , and their interpretation for various gases.

The proportionality between the volume susceptibility and the pressure must be established before any interpretation of the constants a and b can be undertaken as it is equivalent to the statement that the molecules in a gas do behave as isolated units with only thermal interactions to establish thermodynamic equilibrium. The first attempt to verify Eq. (2) experimentally was made by Glaser^{2,3,4} who found that it held only for O_2 and atomic

* National Research Fellow.

¹ b may, for polyatomic molecules, be positive, though no such case has actually been observed or even suggested. See, for instance, J. H. Van Vleck, *Phys. Rev.* **31**, 597 (1928).

diamagnetic gases, but that for CO_2 , CO , N_2 and H_2 certain characteristic deviations occurred. Subsequently, Lehrer,⁵ Hammar,⁶ and Vaidyanathan^{7,8} repeated this work, and found no anomalies of the type reported by Glaser. Hammar in a further paper⁹ suggested that the effect observed by Glaser might be due to the absorption of water vapor on the test body by means of which measurements are carried out, as he once found the effect, but made it disappear again by renewing the P_2O_5 in his cleaning train. Further Buchner¹⁰ showed that small temperature differences, if present, in the various parts of Glaser's measuring apparatus, might account for the observed phenomenon. Thereupon, Glaser in a brilliant series of papers^{11,12,13} succeeded in showing that by introducing small amounts (1%) of O_2 in CO_2 , he could produce a mixture which satisfied Eq. (2), but that with greater concentrations of O_2 anomalies reappeared; that in all probability adsorbed water vapor on his test body could not produce the effects observed; and that thermal disturbances were not present in his apparatus in a sufficient degree to influence his observations. From these results he deduces, and this is the weak point in his arguments, that other observers *had* O_2 as an impurity in their gases in just sufficient amounts (1% for CO_2) to hide the anomaly.

According to these papers, the relevant factors are small impurities of O_2 and H_2O . For the sake of completeness, let us add molecular orientation, which was first considered by Glaser himself, and two further ones whose influence has been tacitly neglected: excited states and ions. Molecular orientation in fields of the order of magnitude of those at present in use is not understandable¹⁴ on the basis of our present conception of the laws governing the behavior of molecules in a magnetic field, and may therefore be dismissed until the other possibilities are definitely disposed of. The presence of any radiation in the apparatus other than black-body radiation corresponding to the temperature of the gas under observation would destroy thermodynamic equilibrium and invalidate Eq. (2). As a matter of fact, excess of incoming radiation would produce an effect of the type observed by Glaser, though as nearly as one can calculate, it should be much smaller. Exact computations are impossible, as the electrical constitution of excited states is unknown. Actual observation on N_2 under various conditions of illumination ranging from almost complete darkness to very intense illumination of the gas between the pole pieces of the magnet gave no effect of the order of magnitude of that observed by Glaser. Further, the presence of 2 mg of radium within a few cm of the test body (see diagram of the apparatus in Fig. 1) gave no

change in the deflections of the order of magnitude of those to be expected if the Glaser effect is to be explained on the basis of the anomalous behavior of ions which are, of course, always present unless very elaborate precautions are taken.

Experimentally, then, the problem reduces itself to the determination of the effect of small amounts of impurities. To settle this question definitely for all possible impurities in varying amounts in all the gases on which observations have been made would require a very long investigation. In the following, I have gone only part way. The results obtained experimentally are that,

(1) CO_2 , N_2 and H_2 in which certainly not more than traces of H_2O and O_2 are present obey Eq. (2).

(2) A mixture of CO_2 and about 11% O_2 when dried as efficiently as possible, obeys Eq. (2).

(3) CO_2 , N_2 and H_2 , when contaminated by small amounts of H_2O (probably less than a few hundredths of a percent) do not obey Eq. (2), but give deviations of the type observed by Glaser.

The proof of these statements is contained in the rest of this report. Assuming their correctness, the present state of our knowledge concerning the applicability of Eq. (2) is summed up on the following statements.

Both linearity and departure from linearity have been observed in pressure susceptibility curves on samples CO_2 , N_2 and H_2 considered pure by the observers. The one observer, Glaser, who consistently obtains departure from linearity finds that linearity can be produced in CO_2 by critical amounts of O_2 impurity. He assumes that a similar effect exists for N_2 and H_2 and assumes that the samples used by other observers are contaminated with just this critical amount of impurity. Presumably, this critical amount of impurity would vary from gas to gas. The above assumption is possibly applicable to some observations, but it is certainly very improbable that it applies to all. It is certainly not applicable to the observations reported in this paper, since spectroscopic evidence is given that the purifying train removed all observable traces of O_2 from N_2 . Further, since the purifying train removed O_2 from N_2 satisfactorily, it probably did so equally well for H_2 and CO_2 . Further, since a mixture consisting of CO_2 and 11% of O_2 showed linearity, it is impossible to contend that this linearity was due to a 1% O_2 contamination. This much of the evidence seems straightforward, and disposes of the assumption that linearity in all observations is due to a critical O_2 impurity. The interpretation of the remainder of the evidence, that the addition of water vapor to the above gases gives anomalous effects, is not so clear. It shows merely that Glaser's results may be due to water vapor. But it is also conceivable that other substances might have a similar effect, and it is quite possible though highly improbable, that Glaser's results are due to some still undetermined and unsuspected cause. Taking the evidence all in all, however the following conclusions seem most plausible: that dry gases and gas mixtures obey Eq. (2); and that Glaser's anomalies are due to the presence of water vapor in his measuring apparatus.

It should be noticed that the mechanism by which H_2O influences the magnetic behavior of gases is by no means specified; it need not be adsorption in the test body, and in the light of Glaser's¹² work probably is not. It is, however, known that small amounts of H_2O do produce anomalous effects in gases. (For instance, ion mobilities¹⁵). This might suggest a clustering of gas molecules around H_2O molecules. Further the absence of any anomaly in argon and neon in Glaser's apparatus might be explained by assuming that these gases because of their chemical inertness do not cluster around H_2O molecules. However, such assumptions need experimental verification, and further discussion at present is useless. One more fact should, however, be observed, and that is that Glaser's arrangements for drying his gases are, as nearly as one can tell from his publications, extremely good, especially in his purifying train for H_2 , where the last unit is a liquid air trap containing charcoal! The only way in which any vapor could possibly contaminate this H_2 is if it were introduced in transferring the gas from the cleaning train to the apparatus (a step which is not described in his papers) or from the walls and ground joints of the apparatus itself.¹⁶ The latter is probably the only possibility, as in order to explain the fact that Glaser can repeat his results over and over again, a constant source of impurities would have to be assumed.

DESCRIPTION OF THE EXPERIMENTS

The method used in the measurements described below is essentially that employed by Glaser,² Hammar⁴ and Vaidyanathan.⁷ It consists in measuring the torque exerted by a gas on a solid body suspended in an inhomogeneous magnetic field. This solid body, called the test body, was constructed as shown in Fig. 1*a* and *b*. It is entirely of Pyrex glass with fused joints. At the bottom of a glass rod is a cylindrical vessel divided radially into four equal chambers. Two of these, *A*, had small holes in them to permit the surrounding gas to enter. The other two, *B*, could be sealed off. In this particular set of experiments, they were first exhausted, and sealed at *C'*. Then *C'* was dipped into liquid air, and they were sealed off at *C*. Above this test body was a small glass rod *D* so mounted that it could be either moved vertically or rotated horizontally around the stem of the test body. A small spring of tungsten wire was attached to hold it in place in any given position. If the test body with a vacuum in all four quadrants, is suspended between the pole-pieces of a magnet, it will be in equilibrium in some position which is adjustable by moving *D*. Actually *D* was moved and the suspension twisted until the test body would hang as nearly as possible with the dividing walls parallel and perpendicular to the line joining the pole pieces, both when the

¹⁵ H. Erikson, *Phys. Rev.* **34**, 635 (1929).

¹⁶ In one of his papers,¹² Glaser performed two experiments to show that water vapor does not enter his apparatus at this point. One consisted in showing that P_2O_5 was not attacked in a tube sealed to his system near the measuring apparatus; the other consisted in showing that a glass rod which changed its resistance when water vapor was adsorbed on its surface, did not do so in the course of a series of measurements. One can only say that these measurements are not quantitative and until one knows how little water vapor can be detected, no inference can be drawn.

magnet was on and off. If now, with the field on, a gas is admitted to the chambers *A*, the test body will evidently be deflected in such a way that *A* will approach the pole-pieces if the gas is paramagnetic, or recede from them if it is diamagnetic. The advantage of this test body over that used by Glaser is that it is made entirely of diamagnetic glass, and consequently, the

Fig. 2. Diagram of apparatus.

Fig. 1a. and 1b. Diagram of test body.

magnetic forces acting on it are practically independent of the temperature. The advantage over Hammer's test body lies in its symmetry, so that the magnetic forces acting on it do not have to be compensated by a large twist of the supporting fiber. In this way, the zero position (position of rest in a vacuum) is made practically independent of the field strength and of

the temperature. M is a mirror by means of which changes in position are read off on a scale 3 meters away. The suspension consisted of two small quartz hooks with a fiber drawn out between them. The test body hangs in the chamber shown in Fig. 2. The lower part is a Dewar flask. Liquid air or other condensed gases may be admitted at G into a chamber surrounded by a vacuum. In the present investigation, the chamber G contained air at room temperature. The inner chamber in which the test body was suspended had four openings; E , for admitting gases was fused to the purifying train; W , where a large plane window was sealed on with picein; and the lid, sealed at L and N with picein. N was introduced to lower and raise the test body, as the method of drawing the fiber made it impossible to predetermine its length to more than approximately 1 cm. To the lid were fused the glass tubes V terminating in a spiral of small thin tubing containing a platinum wire used as a resistance thermometer with terminals at F . H is a glass collar drawn in perspective which, when the test

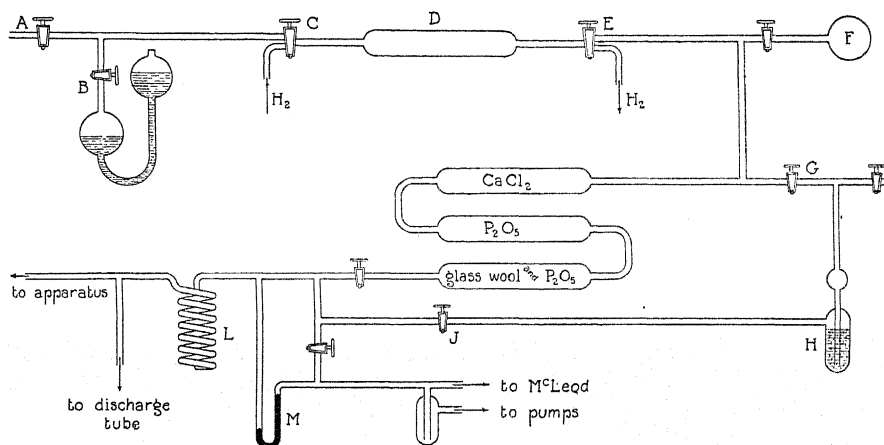

Fig. 3. Diagram of cleaning train.

body was in place, came just below R , Fig. 1*a*, so that if in lowering the system into its container the fiber should break, the test body would be caught by H instead of dropping to the bottom of the container.

For the preliminary experiments the purifying train was very simple, consisting of a small quartz furnace, containing copper wire, a tube containing CaCl_2 and finally a liquid air trap. With this apparatus, the effect of light and γ -rays was investigated, and found to have no influence on the shape of the pressure susceptibility curves, as mentioned above. The gases used were taken from steel cylinders under pressure. The first measurements were made on CO_2 and the curves in Fig. 4 obtained. The liquid air trap was, of course, not in operation. The system was so slow in coming to rest that before proceeding with the measurements, a small damping coil of copper wire was attached to the rod D , Fig. 1a. This greatly improved the accuracy with which readings could be made. The next measurements were made with N_2 , and the curves in Fig. 5 repeated several times, alternately

with and without liquid air. These experiments indicated that the critical factor was purification and that probably the water vapor given off by the CaCl_2 ¹⁷ (which has a partial pressure of about 0.3 mm) was responsible for the departures of the observations from linearity, since the introduction

Fig. 4. Pressure susceptibility curve of undried CO_2 .

of a liquid air trap gave readings along a straight line. Consequently, the cleaning train was rebuilt with a view to carefully checking the effect of impurities. The system built is shown in Fig. 3. The tank containing the gas to be measured is connected to the system at *A*. *B* is a gasometer containing

Fig. 5. Pressure susceptibility curves. \square and \circ N_2 .

pump oil, and was a great convenience in admitting the gases. *D* is a quartz tube 60 cm long and 2.5 cm in diameter filled with copper wire. At either end the tube was fused to short pieces of smaller tubing and these sealed with

¹⁷ This CaCl_2 was in the system while adjustments were being made, and had already taken up a good deal of water. The partial pressure of 0.3 mm is given in A. Goetz, *Physik und Technik des Hochvakuum*, p. 114, Second Edition.

sealing wax to the two way stopcocks *C* and *E*. The tube *D* was first covered with asbestos, then wound with chromel resistance wire in such a way that the near end from the point of view of gas entering the system could be kept red hot, while the far end did not glow at all. *F* is a bulb containing O_2 for measurements on gases mixed with O_2 . From this point, there were two approaches to the measuring apparatus. One went through a wash bottle *H* containing an 85% mixture of H_2SO_4 and H_2O whose specific gravity was 1.775. Such a mixture has according to the Landolt Bernstein Tables a vapor pressure of 0.15 mm. This path could be isolated from the system by means of the stopcocks *G* and *J*, and these were not opened until the first measurements with dry gases were finished. The other path went through three drying tubes, each about 1 meter long and 2–3 cm in diameter. The first contained $CaCl_2$, the second P_2O_5 , and the third P_2O_5 spread on glass wool. At this point the two paths joined again and were connected through a large stopcock to the pumps, a McLeod gauge, a mercury manometer, and to the apparatus through a glass spiral containing approximately 2 meters of glass tubing which could be immersed in liquid air. Immediately before the measuring apparatus a small discharge tube with a quartz window was fused to the system, so that a photograph of the spectrum of every gas could be taken immediately after a measurement. The procedure in filling a gas was to pump out the whole apparatus from *E* on, except for the measurements with dry gases, in which the wash-bottle *H* was not evacuated. In about 10 minutes the pressure could be reduced to 10^{-3} mm. The oil in the gasometer was sucked up to the stopcock *B*, which was then closed. The gas to be measured was then blown through the apparatus from *A* and out at *E*. Then the furnace *D* was heated and H_2 flushed over the copper to activate it. Then more gas was flushed through from *A* to remove the H_2 . Then *E* was closed and *B* opened until the gasometer was full, when the stopcock *A* was closed. Then by opening *E*, gas could be let into the measuring apparatus from the gasometer. In this way the system could be filled without applying a vacuum to the reducing valve on the gas tank. Before beginning measurements the apparatus was filled and evacuated two or three times. The magnet was operated by a bank of storage batteries, giving 21 amperes and the current kept constant to about 0.01%. The coils were immersed in transformer oil which was cooled with water circulation, so that with the above current, the magnet was at a temperature only a few degrees above room temperature.

With this equipment the experiments were resumed. The first gas examined was CO_2 . The results of three runs are shown in Fig. 6. The gas went through the drying tubes at the rate of about 2 liters an hour. The spiral *L* was at room temperature. Although the points are somewhat scattered about the line drawn in the figure, there can be little doubt that they lie along a straight line. All measurements on CO_2 were complicated by the fact that in spite of the damping, the test body would continue to swing over a range of a few tenths of a millimeter for some time, usually about 1/2 hour, sometimes longer, and these swings were not perfectly regular. The

effect was especially large at atmospheric pressure. Apparently the swinging would die down and then suddenly start up again. This effect was observed only with CO_2 , not with a vacuum, or air, or O_2 or N_2 or H_2 in the apparatus. The observed points on Fig. 6 at atmospheric pressure are indicated by a line, as no single definite deflection could be obtained. Further, the zero

Fig. 6. Pressure susceptibility curve of dried CO_2 .

position of the apparatus did change between runs, as observed by Glaser in his papers. The cause of this zero-shift has not been determined. I am of the opinion that it is due to the changes in adsorbed layers on the test body, and hope eventually to build an apparatus that can be baked out to

Fig. 7. N_2 band spectrum in varying degrees of purity.

test this point. The next measurements were made on N_2 with and without a liquid air trap, and three runs gave points lying on a straight line at least as closely as the points in Fig. 5. The spectroscopic photographs for N_2 proved to be the only useful ones. With CO_2 and H_2 , small impurities of O_2 and H_2O did not show. The spectrograph used was a small one made by Hilger with a quartz prism for use in the ultraviolet. In Fig. 7, are repro-

ductions of sample photographs. All three photographs were given the same exposure, 30 secs, with the same current and were taken with a gas pressure of about 3 cm in the discharge tube.

The first photograph was taken with N_2 passed over the hot copper, $CaCl_2$, P_2O_5 and the liquid air trap. In the second, the liquid air trap was removed. In the third, the liquid air trap was replaced but the furnace which heated the copper turned off. In the first picture, the NO bands are entirely absent. In the second, they begin to appear. This means that the water vapor which has passed all three drying tubes is sufficient, on dissociation, to produce a detectable amount of NO. The NO bands in the third photograph are due entirely to the O_2 present in the gas, as it comes from the tank, all water having been absorbed¹⁸ in the liquid air trap. A gas analysis showed that the N_2 in the tank contained only 0.6% of O_2 .

Fig. 8. Pressure susceptibility curves of H_2 with varying amounts of water vapor.

The next measurements were made on H_2 dried over P_2O_5 , but not with liquid air. This gave a very small Glaser effect. Upon the introduction of liquid air, however, a further run gave a perfectly straight line. The interpretation of this seems very straightforward; namely, that in spite of preliminary flushings over the copper in the furnace, this was not completely reduced, and that therefore, the H_2 entering the drying tubes contained more water vapor than any of the gases previously used; if this is so, it follows that a drying train, in all 3 meters in length, left sufficient amounts of water vapor in the gas to be detectable. It is also interesting to note that the one gas in

¹⁸ With longer exposure times the NO bands would appear even on photographs of N_2 as pure as I could make it. That this was due to the heating of the electrodes could be shown by taking two photographs of 30 secs duration each immediately after each other. The second showed NO bands, while the first did not. This sets a lower limit to the amount of water vapor detectable, but this is surely very small, as P_2O_5 has a vapor pressure of 10^{-4} mm and ice at liquid air temperatures 10^{-7} mm. See Goetz.¹⁷

which Hammar observed a Glaser effect was H_2 , which, for the reasons given above, probably contained more water vapor than either N_2 or CO_2 . The view that the H_2 leaving the furnace was very wet is further substantiated by the next measurements. The liquid air was removed and the gas admitted to the apparatus via the wash bottle *H*. The first runs gave very large Glaser effects, as in the lower curve in Fig. 8, but after considerable flushing, it was possible to repeat several times the curve in Fig. 8, which showed an intermediate Glaser effect. If the gases were saturated in the wash bottle, this corresponds to a water vapor pressure of .15 mm.

The results obtained so far seemed fairly conclusive, except for CO_2 , where it might conceivably be contended that the straight line in Fig. 6 is due to just that amount of O_2 (1%) impurity which according to Glaser destroys the anomaly. The first argument against such a view is that the furnace certainly purified N_2 so that nothing like 1% of O_2 was left as an impurity, and that consequently, there is every reason to believe that it

Fig. 9. Pressure susceptibility curve of the mixture 89% CO_2 + 11% O_2 .

did the same for CO_2 . The problem can, however, be attacked from another angle. According to Glaser,¹¹ the paramagnetic mixture of CO_2 plus about 11% O_2 should definitely show an anomaly at low pressures. This was tried with the gas dried in the train described above, and the observations indicated no such effect. The results are plotted in Fig. 9. The concentration of O_2 in this experiment was calculated on the basis of the relative deflections for the mixture and pure CO_2 . Deflection for CO_2 plus O_2 / Deflection for pure CO_2 = $+7.5 / -9.0 = -.83$. According to Glaser, an anomaly should certainly be observed for O_2 concentrations corresponding to values of the above ratio between $-.9$ and 0 . This effectively disposes of the argument that normal behavior of CO_2 is due to a 1% O_2 impurity, since such normal behavior is found in a mixture which certainly contains much more than 1% of O_2 .

In conclusion, I wish to take this opportunity of expressing my appreciation of the very beautiful work done by Mr. William Clancy in blowing the glass parts of the apparatus previously described.

LETTERS TO THE EDITOR

Prompt publication of brief reports of important discoveries in physics may be secured by addressing them to this department. Closing dates for this department are, for the first issue of the month, the twenty-eighth of the preceding month; for the second issue, the thirteenth of the month. The Board of Editors does not hold itself responsible for the opinions expressed by the correspondents.

Scattering of Alpha-Rays and High Speed Electrons in Radial Fields

Wentzel,¹ Sommerfeld,² and Mitchell,³ among others, have derived by the wave mechanics first approximation formulae for elastic scattering of alpha-rays and high speed electrons in spherically symmetrical fields. They all use Born's perturbation method and differ from each other only in their assumptions as to the potential fields that represent the scattering system. The fundamental expression, however, from which their particular scattering formulae may be derived, by the special assumptions as to the potential functions, may be written as:

$$c \quad \left| \frac{\psi_1}{\psi_0} \right| = \frac{K^2}{rEv} \int_0^\infty \rho V(\rho) \sin \rho u d\rho \quad (1)$$

where $|\psi_1/\psi_0|$ is the absolute value of the ratio of the amplitude of the scattered alpha-ray or electron wave at a large distance r from the scattering atom, to that of the incident wave, and is a function of the argument u . E is the energy of the particle, M its mass, and $K^2 = 8\pi^2 ME/h^2$; $u = 2K \sin \theta/2$ where θ is the angle of scattering. $V(\rho)$ is the potential energy of the particle when it is at a distance ρ from the center of the scattering system.

A Coulomb potential $V(\rho)$ should theoretically lead to the Rutherford scattering formula, but as it gives a divergent integral, Wentzel assumed that $V(\rho) = (A/\rho)^{-\alpha\rho}$. Sommerfeld made essentially the same assumption, though he justified it physically by deriving it from the wave mechanical model of a nucleus screened by its electrons concentrated in the K shell. Mitchell, supposed the electrons to be distributed as in the Thomas-Fermi statistical theory of the heavier atoms. These various assumptions

do lead to scattering formula which differ from the Rutherford formula only to the extent that the $V(\rho)$ assumed differ from the Coulomb value.

As experimentally it is definitely established that deviations from Rutherford's formula do occur, Sommerfeld,² Kirchner,⁴ and Mott⁵ have attributed these deviations to the electron distributions about the nuclei of the scattering atoms, and consequent deviations from the Coulomb potential. These authors have computed by Eq. (1) the scattering to be expected from certain types of potential function and have compared them with the observed scattering. But since we are after all more interested in a direct determination of the potential field and electron distribution within an atom than in merely checking observed with predicted scattering formulae according to assumed types of potential field, we propose to reverse the problem heretofore considered. Thus we propose to determine directly the potential field $V(\rho)$ and the electron distribution from the observed scattering.

This problem can be solved; in principle, by applying Fourier's reciprocal theorem to Eq. (1); we then obtain:

$$V(\rho) = \frac{2rE}{\pi K^2 \rho} \int_0^\infty v \left| \frac{\psi_1}{\psi_0} \right| \sin \rho u dv \quad (2)$$

The classical charge density σ is then given by:

¹ G. Wentzel, Zeits. f. Physik 40, 590 (1927).

² A. Sommerfeld, Ergänzungsband, p. 226.

³ A. C. G. Mitchell, J. of Franklin Institute.

⁴ F. Kirchner, Naturwiss. Jan. 24, 1930.

⁵ N. F. Mott, Nature, Dec. 28, 1929.

$$\sigma = \frac{-1}{4\pi\epsilon} \Delta^2 V = \frac{-rE}{2\pi^2 K^2 \epsilon \rho \partial} \frac{\partial^2}{\partial \rho^2} \int_0^\infty \left| \frac{\psi_1}{\psi_0} \right| \sin \rho u d\rho \quad (3)$$

where ϵ is the charge of the alpha-particle or electron.

Although physically u and hence $|\psi_1/\psi_0|$ is only defined for $0 \leq v \leq 2K$, the integration in (2) and (3) implies that the functional form of $|\psi_1/\psi_0|$ is to be used, as derived from the experimental curves. And even when the integration can only be carried out graphically, the region for $u > 2K$ may be safely neglected anyway except for very small y values of ρ , since K will always be at least of the order of 10^9 for any case to which the present approximation applies. In fact, the major difficulty in carrying out the integrations is for small values of u , for these give the largest contribution to the integrals, while at the same time the values of $|\psi_1/\psi_0|$ for small values of u will be the most uncertain since accurate scattering measurements at small angles are very difficult. Computations are now being made to test the possibility of making reasonable extrapolations and deriving reasonable distributions by equations (2) and (3).

We may point out, too, that Eq. (3) gives the net charge distribution, of both the nuclear positive charge and the enveloping electronic charge. Thus to the extent that the data can be obtained with accuracy and the integration carried out accurately, it will afford a means of studying the charge distribution of the nucleus as well as of the electrons. Heretofore, the nucleus has been considered as a point charge so that σ would have meaning only for $\rho > 0$ and then give the electron density only. From our present point of view we need make no such assumption,

but rather determine simultaneously the positive and negative charge distribution which gives the resultant scattering $|\psi_1/\psi_0|$. Of course, if σ turns out to be negative for all $\rho > 0$ it would be proof that the nucleus is essentially a point charge, but we do not have to assume this to begin with.

It is of interest to note that if we assume the Rutherford scattering formula: $|\psi_1/\psi_0| = A/v^2$, we immediately get from Eq. (2) the Coulomb potential, and avoid Wentzel's convergence difficulty. It is easily verified also that using Sommerfeld's formula: $|\psi_1/\psi_0| = A/v^2 + d^2$ we get his expression for $V(\rho)$.

Finally, it may be observed that our point of view of reversing the problem of scattering as heretofore considered, may also be applied to the interpretation of x-ray scattering intensities. In this problem, the structure factor, F , which determines the interference of the scattered rays and depends on the charge distribution of the scattering atom, may be expressed as:

$$F = \frac{\lambda}{4\pi \sin \epsilon} \int_0^\infty \frac{U(r)}{r} \sin \left| \frac{4\pi r \sin \theta}{\lambda} \right| dr \quad (4)$$

where $U(r)/4\pi r^2$ is the charge density, assumed to have spherical symmetry, at a distance r from the center of the scattering system, θ is the angle of reflection, and λ is the wave-length. An inversion of this integral will again give directly the charge distribution as an integral of the same type as (2) with the observable function, F , in the integrand.

Nuclear Electrons

It has been suggested by Heitler and Herzberg (Naturwissenschaften 17, 673, 1929) to explain the observations of Rasetti (Proc. Nat. Acad. Sci. 15, 515, 1929) on the Raman effect in N_2 that the electron in the nucleus loses its spin and its contribution to the statistics of the nucleus. If all the nuclear particles (electrons as well as protons) are effective in determining whether the nuclear spin factor makes the total Ψ function symmetrical or antisymmetrical in the nuclei, there is great difficulty (cf. R. S. Mulliken, Trans. Faraday Soc. 25, 644, 1929) in explaining the

fact that in the Raman spectrum of N_2 the transitions between the even rotational levels are the stronger, whereas for H_2 the Raman lines representing transitions between odd rotational levels are more intense. For both H_2 and N_2 have a $^1\Sigma$ normal state, built up out of two equal atoms in S states, each with an odd number of nuclear particles (1 for the H atom, 21 for the N atom). And therefore, since for both molecules $\Lambda = 0$, and since the electron configurations are in both cases composed of closed shells, making ΣL_r for the external electrons an even number, one would

expect the odd K levels to be the stronger levels, symmetrical in the nuclei.

If, however, only the nuclear protons have a spin, then the interchange of electrons in the two nuclei does not affect the symmetry of the Ψ function. Consequently the nuclear spin factor will make the total Ψ function either symmetrical or antisymmetrical in the nuclei, according as the number of protons is even or odd. But the stronger K levels should always be symmetrical in the nuclei with respect to the nuclear spin factor, and so a rule that Ψ must be symmetrical in the nuclei if the number of protons is even, antisymmetrical in the nuclei if the number of protons is odd, would require that the even K levels be stronger in N_2 (14 protons) and the odd K levels be stronger in H_2 (1 proton). There is then no contradiction with previous conclusions as to the electronic configuration of the normal state for N_2 and H_2 . Furthermore, there is now also agreement with the 2:1 alternating intensity ratio found in the N_2^+ bands, for this ratio requires a nuclear spin $= 1 \cdot h/2\pi$ for the N atom, which is to be interpreted as a parallel orientation of the spins of the two protons in excess of α -particle configurations. The nuclear spin $= 3/2 \cdot h/2\pi$ recently reported by Harvey and Jenkins (Phys. Rev. 35, 789, 1930) is, as they sug-

gest, additional evidence in support of the view that the spin of the electron is not effective in the nucleus.

In this connection it is interesting to recall that the radius of a non-rotating Lorentz electron of mass $8.994(10)^{-28}$ gm calculated on classical electromagnetic theory is $1.88(10)^{-13}$ cm, whereas that of a Lorentz electron with a spin of a half quantum which has a mean mass equal to the figure above is $3.98(10)^{-9}$ cm. On the other hand, a Lorentz proton of mass $1.661(10)^{-24}$ gm has a radius of $1.02(10)^{-16}$ cm if it has no rotation and a radius of $2.15(10)^{-12}$ cm if it is assumed to have a half quantum of spin. If the radius of the nucleus is of the order of magnitude of 10^{-12} cm as suggested by experiments on the scattering of α -rays, these figures indicate that the size of a spinning electron is too great to permit its inclusion in the nucleus. It may be for this reason that nuclear electrons have no spin. The dimensions of a spinning proton, on the other hand, are of the same order of magnitude as those of the nucleus.

Concerning the Existence of a New Term in Hg I

T. Takamine¹ and T. Suga have recently made an excellent photographic investigation of the near infrared spectrum of Hg. On their spectrograms they find two new series of lines given by $X-m^3S_1$ and $X-m^3D_3$ having a common final term of value 15299 cm^{-1} . They state that this new term is of the nature of a P term but that other evidences would certainly be necessary before its reality is established. It is the purpose of this note to present other evidence which supports their assumption.

All of the lines of longer wave-length—except two (outside of the region covered)—necessary to complete the two series appear on the writer's² records of this spectrum and were reported as unclassified lines. These two series with the writer's additions are tabulated below. The value of X is taken as

¹ T. Takamine and T. Suga, Sc. Pap. I. P. C. R., No. 232, 13, (1930).

² E. D. McAlister, Phys. Rev. 34, No. 8, Oct. 15 (1929).

15297 cm^{-1} since this gives a closer agreement between observed and calculated frequencies when the writer's additions are included. Fowler's term values are used. Takamine's lines are marked with a T.

Of particular interest is the first line (negative ν_{calc}) of this "sharp" series $\lambda = 15300\text{\AA}$ (λ_{vac} Paschen³) which is one of the strong lines in the infrared spectrum of Hg. Paschen⁴ attempted to use it as the first line of another series but this attempt failed to gain recognition. It does not fit into the once-ionized Hg scheme and appears much too strong in the arc spectrum to be a spark line. Hence this assignment of it to Takamine's series seems quite reasonable.

The deviations from the calculated values are somewhat larger than is desirable but the discrepancies are probably due to the difficulty of accurate wave-length measurements in this region. The intensity² (mm deflection) of the first three lines in the "sharp" series and of the second line in the "diffuse" series

are particularly convincing as to the correctness of the present assignment. The writer has inserted in the "diffuse" series a line $\lambda_{\text{air}} = 9243\text{\AA}$ appearing on Takamine's pictures which he did not include. This line appears as a sharp line on all of Takamine's pictures while most of the others in this series are diffuse or "washy." This must be why Takamine does not include it. However the photographic method undergoes an enormous change in sensitivity between this line and the others in this series, and also the other lines appear much sharper on his one hour exposure than they do on the 10 hour one. It thus seems likely that this line really belongs to the series.

Boundary Conditions in Wave Mechanics Reply to Criticism

Mr. Eckart's letter in the May 15th issue of the Physical Review about my paper of April 15th on the above subject seems to call for some reply. If the potential varies sufficiently gradually from the constant value zero to a constant value V' then there is no reflexion and if there is no reflexion for a particular wave-length there will be none for any shorter wave-length. My calculation showed that there may be no reflexion at the layers on the surfaces of metals because the thickness of these layers may be sufficient to allow the potential variation to be sufficiently gradual for this when $E > V'$. According to this the usual boundary conditions at a discontinuity may not be applicable to these layers. I therefore suggested new boundary conditions giving no reflexion when $E > V'$ which can therefore be used with these layers when they give no reflexion with $E > V'$.

I also suggested that these new boundary conditions may be correct for an actual discontinuity if such a thing can exist.

Mr. Eckart suggests that the absence of reflexion is due to the potential variation acting like an étalon with a spacing of one quarter-wave length. The distance in which the potential changes may be made any multiple or fraction of a wave-length, without reflexion, by suitably changing the constant β so that I do not think the action is really at all analogous to that of an étalon.

I quite agree with what Mr. Eckart says about the very limited generality of the solution of the wave equation which I obtained.

Ionization Potential of Carbon

The ionization potential of carbon was estimated as 11.2 volts by Fowler and Selwyn (Proc. Roy. Soc. A118, 34, 1928). The basis for this estimation was the C I spectrum which they arranged into series for the first time and a comparison of this spectrum, which was not extensive enough for accuracy, with that of the related spectra of N II and O III.

In my work on the helium continuous spectrum (Phys. Rev. 35, 1113, 1930) I had noticed that a series of lines shone brightly in the ultraviolet when the stopcock grease contaminated the helium. I followed up this observation by purposely introducing carbon monoxide into the helium with the result that the spectrum of C I has been greatly

extended in the vacuum region and some new features of this spectrum observed. In this note I shall deal only with a small phase of the data now on hand, namely that concerned with the ionization potential of carbon. The fuller treatment is reserved for the complete paper that will be published when the examination of these data is finished.

The most obvious feature of the new ultraviolet spectrum is that it contains three series of multiplets that converge to the same three-fold limit, the $^3P_{0,1,2}$ of the atom. These have been measured to eight members and form the basis of the present determination of the ionization potential of normal carbon. The series multiplets are not resolved after the first three members so one has to deal with diffuse lines for the higher terms. Fortunately, however, the middle series is much stronger than the other two. It stands out like a ridge in the mist and is easily measured. It is the middle series that has been used for the calculation of the terms and the ionization potential.

The following is a list of the "ridge" groups: $\lambda 1649.93$ (2), (uncertain if C I), 1277.53 (5)

seen as triplet in second order; 1193.17 (5), 1158.02 (4); 1139.80 (3); 1129.12 (2); 1122.32 (1); and 1117.68 (0). The series limit is $A = 90834 \text{ cm}^{-1}$ and the effective quantum numbers for the above lines are 1.905; 2.955; 3.952; 4.948; 5.949; 6.952; 7.955; and 8.970. It is seen that this is very nearly a Rydberg series. The values are not too smoothly arranged but are as good as the nature of these unresolved multiplets when superimposed on two other converging groups might be expected to yield.

Using the known values of the separations of the lowest 3P term of C I, and assuming that the above limit refers to its center of gravity, the term values have been calculated to be $^3P_2 = 90817.7$, $^3P_1 = 90845.2$ and $^3P_0 = 90860$. The metastable levels 1D and 1S listed by Fowler and Selwyn lie 1.179 volts and 2.593 volts respectively above the 3P_0 state, and the ionization potential of the carbon atom from the 3P_0 , lowest normal state, is 11.217 volts.

JOHN J. HOPFIELD

The Ultraviolet Light Theory of Aurorae and Magnetic Storms

The ultraviolet light theory of aurorae and magnetic storms¹ contained some unsettled points and some conclusions in disagreement with observation. The further development of the theory of the outer atmosphere² and the recognition of an effect hitherto unseen have now automatically removed the discrepancies. So that the theory, with no change in the original assumptions, begins to assume a more finished appearance. The new effect has emerged directly from the results of Page.³ Page showed, on the assumption of an earth with no excess charge, that the long free path ions in the upper atmosphere would drift westward. We now point out that the westward drift is hindered by collisions of the ions with the neutral molecules of the atmosphere which move approximately with the earth's rotation. As a result of the hindrance there is a displacement of positive ions to polar regions and negative ions to equatorial regions. This sets up an electric field which, together with the earth's magnetic

field, causes the high flying ions to move partially with the angular velocity of the earth. They descend into the 50° to 70° latitudes during the evening hours to cause aurorae and the diurnal variation phase of the world wide magnetic storms. With the new values of the electrical conductivity² of the upper atmosphere the diurnal variation phase is seen to be due to the gravitational magnetic drift currents set up by the polar ionic concentrations. Agreement is secured throughout with the observations. The second phase of the world wide magnetic storm is found to arise mainly from reactions in the atmosphere rather than to induced currents in the earth.

BOOK REVIEWS

Elementare Quantenmechanik. M. BORN AND P. JORDAN. Pp. 434. J. Springer, Berlin, 1930. Price bound RM 29.80.

This book appears in the "Struktur der Materie" series edited by Born and Franck as the second volume of the former's well-known "Vorlesungen über Atommechanik." Written by the founders of the matrix mechanics, it is the first book on the subject to give a systematic and thorough account of the formulation of quantum mechanics by matrix methods.

The guiding view-point is expressed in the preface: "We are convinced that the true connection of the classical and the new mechanics lies not so much in the formal similarity of the wave-mechanical differential equations and boundary value problems with the methods of classical mechanics of continua, as in the correspondence principle of Niels Bohr; we see in the new mechanics the rigorous working out of Bohr's program."

The authors have succeeded in giving an admirably clear account of the subject from this standpoint. After chapters devoted to mathematical methods and the basic ideas of quantum mechanics there is a valuable chapter devoted to theorems on angular momentum from the standpoint of invariance under the rotation group. The chapter on perturbation theory gives a full account of dispersion theory including natural optical activity and the Kerr and Faraday effects. The two remaining chapters are devoted to the statistical interpretation of quantum mechanics and the quantized electromagnetic wave approach to radiation theory.

The notation is unwieldy and shows perhaps the richest efflorescence of subscripts, superscripts and diacritical marks that has yet blossomed in any physical treatise. Can we hope to understand nature in terms of equations like

$$2 U_{\rho\rho}^{(k)(rr)} = - \sum_{l=1}^{k-1} \sum_{j,r} U_{\rho r}^{(l)+(r j)} U_{r\rho}^{(k-l)(j r)} .$$

The notation devised by Dirac for his forthcoming book is much simpler and it is to be hoped that it rather than that of this book, will be the one to find general acceptance.

The book is to be recommended as the most important that has thus far appeared on the subject. The word elementary in the title has to be taken more in the sense of fundamental and first principles, rather than simple, easily understood and suitable for a first introduction to the subject.

E. U. CONDON

ANALYTIC SUBJECT INDEX TO VOLUME 35

References marked (A) are to abstracts of papers presented at meetings of the American Physical Society, those marked with (L) refer to letters to the Editor.

Aberration of light

From terrestrial sources, N. Galli-Shohat—664(A)

Absorption of light

Hg vapor, resonance radiation, A. R. Thomas—1253

Lacquer films, ultraviolet, W. P. Dewey, D. C. Duncan—1423(A)

Lake water, ultraviolet, C. D. Hodgman—1423(A)

Liquids, near infrared, effect of pressure, J. R. Collins—1433(A)

Na vapor, 300–1300A, S. A. Korff, J. L. Nickerson—1433(A)

Na vapor in flames, C. D. Child—294(A)

Organic liquids, infrared, E. K. Plyler, T. Burdine—605; R. B. Barnes—662(A), 1524

Organic liquids, intensity and position of overtones, P. E. Shearin—973

$\text{SmCl}_2 \cdot 6\text{H}_2\text{O}$, comparison with reflection at high and low temperatures, S. Freed, F. H. Spedding—212(L)

Various bodies, $\lambda > 50\mu$, C. H. Cartwright—415

Vitamin A, characteristic, J. W. Woodrow, H. L. Cunningham—125(A)

Acoustics

Absorption and velocity of high frequency sound in oxygen, W. H. Pielemeier—1417(A)

Absorption and velocity of sound in gases, interferometer method, J. C. Hubbard—1442(A)

Analogue of Schroedinger wave equation, R. B. Lindsay—666(A)

Tone quality, influence of walls—D. C. Miller, J. R. Martin—1417(A)

Uncertainty principle, problems, G. W. Stewart—1441(A)

Velocity in liquids at audio-frequencies, L. G. Pooler—832

Velocity of ultrasonic waves, C. D. Reid—814

Aerodynamics (see also Hydrodynamics)

Airfoils of circular cross-section, L. J. Briggs, H. L. Dryden—1416(A)

Wind pressure on cylindrical stacks, H. L. Dryden, G. C. Hill—1416(A)

Afterglow

Air, production and characteristics, J. Kaplan—600

Nitrogen, R. Ruedy—125(A)

Alpha-particles

Recombination with electrons; measurements, A. H. Barnes—217; A. H. Barnes, B. Davis, H. L. Hull—1433(A); explanation, W. Band—1128(L); theory, E. C. G. Stueckelberg, P. M. Morse—116(L), 659(A)

Scattering in radial fields, M. Muskat—1583(L)

Scintillations, time distribution, from weak source, N. Feather—705

Anode spots

In Geissler tube, relation to absorption and emission of gases, C. H. Thomas, O. S. Duffendack—72

Arcs (see also Discharge of electricity in gases, Spark discharge)

A.c., between brass electrodes, extinction, T. E. Browne, Jr., F. C. Todd—1441(A)

A.c. restriking, F. C. Todd, T. E. Browne, Jr.—1441(A)

Temperature, from multiplet intensities, G. R. Harrison—133(A)

Vacuum, cathode characteristics, R. Tanberg—294(A), 1080

Vacuum, pole effect, temperature shift of spectra, F. T. Holmes—652(L)

Astrophysics

Anomalous rotation of sun, R. Gunn—635

Pulsating stars, electrodynamic damping, R. Gunn—107, 295(A)

Solar corona, theory, E. O. Hulburt—297(A), 1379

Atomic beams

Alkali metals, reflection from crystals, J. B. Taylor—375

Hydrogen, attempt to detect de Broglie waves, T. H. Johnson—1432(A)

Hydrogen, collisions in Hg vapor, radius of atom, E. G. Lunn, F. R. Bichowsky—563(L)

Hydrogen, diffraction by LiF crystal, T. H. Johnson—1444(A); 1299(L)

Hydrogen, reflection from calcite, A. J. Dempster—298(A), 1405(L)

Hydrogen, reflection from LiF crystals, T. H. Johnson—650(L), 658(A)

Hydrogen, scattering by Hg, A, O₂, I₂, E. G. Lunn, F. R. Bichowsky—671(A)

- Oxygen, as reducing agent, W. H. Rodebush, W. A. Nichols, Jr.—649(L)
- Reflection, specular, from crystals, A. Ellett—293(A)
- S, magnetic moment, E. J. Shaw, T. E. Phipps, W. H. Rodebush—1126(L)
- Zn, reflection from NaCl, H. A. Zahl—293(A)
- Atomic weights**
- H and He, R. T. Birge—1015(L)
- Packing fraction, periodicity, H. Olson—213(L)
- Atomization**
- Mechanism, R. A. Castlemen, Jr.—1014(L), 1416(A)
- Atmospheric electricity**
- Auroras and magnetic storms, theory, E. O. Hulburt—1587(L)
- Ionization in upper atmosphere, variation with longitude, E. O. Hulburt—240
- Potential gradient in lower atmosphere, variation, J. G. Brown—135(A)
- Space charge in lower atmosphere, J. G. Brown—135(A)
- Barkhausen effect**
- Propagation along wires, K. J. Sixtus, L. Tonks—1440(A)
- Size of discontinuities, R. M. Bozorth, J. F. Dillinger—733
- Beta-particles**
- From mesothorium 2, maximum energy, N. Feather—1559
- Biophysics**
- Excitation of nerves, theory, N. Rashevsky—1435(A)
- Flarimeter, for testing circulatory fitness, P. V. Wells—1418(A)
- Vitamin A, absorption of light, characteristic, J. W. Woodrow, H. L. Cunningham—125(A)
- Black body**

Thoriated tungsten, N. B. Reynolds—158
- Cosmic rays**
Analysis of observations, L. D. Weld—295(A)
Method of measuring energy by magnetic deflection, L. M. Mott-Smith—1125(L)
Method of study, M. A. Tuve—651(L)
Nature, L. F. Curtiss—1433(A)
- Crystals and crystal structure**
Ag sheet, cold rolled crystal orientation, C. B. Hollabaugh—1426(A)
Alloys containing precipitated crystals, C. S. Barrett—1425(A)
Alloys, magnetic, of high Pt content, microstructure, F. W. Constant—116(L)
Alum, radiation emitted under pressure in electric field, I. A. Balinkin—1443(A)
Bi, methods of forming, factors influencing orientation and perfection effect of magnetic field, A. Goetz—193
Calcite, grating space, C. D. Cooksey, D. Cooksey—564(L)
Colloidal crystals, x-ray diffraction bands, theory, C. C. Murdock—8
Cr-Ni alloys, variables, F. C. Blake, J. O. Lord—660(A)
Electron distribution, theory, P. M. Morse—1310
Fe, radial asterism, C. Nusbaum—1426(A)
Fe, very pure, x-ray study, O. L. Roberts—1426(A)
GdCl₃·6H₂O, line spectra, Paschen-Back effect, S. Freed, F. H. Spedding—1408(L)
Ice, grown from vapor, J. M. Adams—136(A)
Inhomogeneities, theory, R. H. Canfield—114(L); reply, F. Zwicky—283(L)
Mosaic crystals of elements, R. H. Canfield—671(A)
Possible symmetries, R. H. Canfield—660(A)
Stability of lattices, theory, R. H. Canfield—530
Unit lattice of interpenetrating lattices, example, F. C. Blake—660(A)
Zn, method of growth, E. P. T. Tyndall—868(L)
- Cybotactic State**
Alcohols, G. W. Stewart—296(A), 726
Liquids, organic, mixtures, A. W. Meyer—291(A)
Liquids, organic, temperature effect, E. W. Skinner—128(A)
Resumé of evidence, A. M. Taylor—668(A)
Triphenolmethane, G. W. Stewart—291(A)
Viscosity relations, R. L. Edwards, G. W. Stewart—291(A)

- Water, molecular association, G. W. Stewart—1426(A)
- Dielectric constant and properties**
Acetic acid vapor, C. T. Zahn—1047
Conducting media, J. Wyman, Jr.—623
CS₂ and NO, temperature variation, electric moments, C. H. Schwingel, J. W. Williams—855
CS₂ vapor, C. T. Zahn—848
Energy losses, effect of polar molecules, F. Hamburger, Jr.—657(A), 1119
H₂O and KCl solutions, high frequencies, F. H. Drake, G. W. Pierce, M. T. Dow—613
KCl solutions, A. Austin—1428(A)
Polarization, extension of Van Vleck's theory, C. T. Zahn—1056
Rochelle salt, temperature effect, C. B. Sawyer, C. H. Tower—269
Rubber, temperature and pressure variation, time lag, A. H. Scott—1429(A)
Tung oil, polarization and electric moment, A. A. Bless—1442(A)
- Diffraction of atoms** (see Atomic beams)
Diffraction of electrons (see Electrons, diffraction)
Diffraction of molecules (see Molecular beams)
Diffraction of radiation (see X-rays, diffraction)
Discharge of electricity in gases (see also Arc, Spark)
Anode spots, relation to absorption and emission of gases, C. H. Thomas, O. S. Duffendack—72
Cathode characteristics, R. Tanberg—294(A), 1080
Cathode heating by He⁺, Ne⁺, A⁺, C. C. Van Voorhis, K. T. Compton—1438(A)
Excitation processes in hollow cathode, R. A. Sawyer—1421(A)
H₂, high frequency, conductivity, C. J. Brasefield—1073; electron velocities—92, 122(A)
High frequency, characteristics, O. Stuhlman, Jr., M. D. Whitaker, M. L. Braun—1436(A)
H₂, striations, potential relations, J. Zeleny—699
Hg, positive column, T. J. Killian—1238
Ne, oscillations, G. W. Fox—1066
Ne, secondary electrons from Ni, W. Uytterhoeven, M. C. Harrington—1421(A)
Plasmoidal, high frequency oscillatory discharges, R. W. Wood—658(A), 673
Rare gases and Hg vapor, positive column, collisions of second kind, O. S. Duffendack, L. B. Headrick—1421(A)
Shot effect, abnormal, J. S. Donal, Jr.—1430(A)
Striations, temperature variation of striations, F. M. Sparks, C. T. Knipp—259, 297(A)
Striations and magnetic effect in electrodeless discharges, J. Tykocinski-Tykociner, J. Kunz—1436(A)
- Dispersion of light**
By symmetrical top-like molecules, theory, M. Muskat—1442(A), 1262
- Dissociation**
Diatomic molecules, by rotation, O. K. Rice—1538
H₂, by electron impact measurement, W. Bleakney, J. T. Tate—658(A), 1180; theory, E. U. Condon—658(A)
Predissociation of diatomic molecules, D. S. Villars, E. U. Condon—1028
- Dissociation, heat of** (see also Molecular structure and constants)
AgCl, from spectra, B. A. Brice—960
AlH, from spectra, D. S. Villars, E. U. Condon—1028
Cd₂, J. G. Winans, R. Rollefson—1436(A)
CO, from spectra, J. Kaplan—957
O₂, from spectra, J. Kaplan—436(L)
O₂, heat of formation, L. C. Copeland—1443(A)
- Double refraction**
Electrical, in gases, J. W. Beams, E. C. Stevenson—1440(A)
- Earth** (see Geophysics)
- Elasticity**
Metals, mass-weight ratio under strain, P. I. Wold—296(A)
Plastic deformation of ductile metals, A. Nadai—1418(A)
Shear vibrations in quartz, overtones, J. R. Harrison—1417(A)
Tensile stress and conductivity, in permalloy, L. W. McKeehan—657(A)
Torsion of rhombic prisms and cylinders, J. Kunz—1417(A)
Young's modulus for small stresses, D. K. Froman—120(A), 264
- Electrical conductivity and resistance**
Al, changes with working, G. E. Davis, G. Greenwood—1429(A)
Alloys, theory, L. W. Nordheim—1430(A)
Contact resistance, microphonic action, F. S. Goucher—1429(A)
Electrolytes, variation with frequencies, D. E. Richardson—297(A)
Permalloy, effect of stress and magnetic field, L. W. McKeehan—657(A)
- Electrical discharge in gases** (see Discharge of electricity in gases)
- Electric moment** (see Dielectric constant)
- Electrolytic phenomena**
E.m.f. location in photovoltaic cells W. N. Lowry—1270

- E.m.f. resistance, capacitance in photovoltaic cells, H. E. Hammond—998
 Polarization capacity and resistance temperature effect E. E. Zimmerman—543
 Resistance at various frequencies D. E. Richardson—297(A)
- Electromagnetic theory**
 Constitutive equations C. Kaplan F. D. Mur-naghan—763
 Interaction of field and matter J. R. Oppenheimer—461
 Magnetic poles F. W. Warburton—292(A)
- Electrons**
 Density distribution in equilibrium with hot body, A. T. Waterman—668(A)
 Distribution in atoms and molecules, from x-ray scattering: He, A. H. Compton—925, 1427(A); Cl, G. G. Harvey, G. E. M. Jauncey—1427(A); MgO, E. O. Wollan—127(A), 1019
 Equilibrium concentration in universe, L. S. Kassel—778
 Motion in crystals, theory, P. M. Morse—1310
 Nuclear, spin, L. Page, W. W. Watson—1584(L)
 Relation to protons, theory, J. R. Oppenheimer—562(L)
 Photoelectric (see **Photoelectric effect**)
 Recombination with alpha-particles: measurements, A. H. Barnes—217; A. H. Barnes, B. Davis, H. L. Hull—1433(A); explanation, W. Band—1128(L); theory, E. C. G. Stueckelberg, P. M. Morse—116(L), 659(A)
 Recombination with Hg^+ , search for critical potentials, A. M. Cravath—659(A)
 Scattering in radial fields, M. Muskat—1583(L)
 Valence, in diamond, M. L. Huggins, R. Parrish—136(A)
 Velocity, direct determination, T. R. Wilkins, J. A. Wood—657(A); C. T. Perry, E. L. Chaffee—1437(A)
- Electron, charge**
 Most probable value, R. A. Millikan—1433(A), 1231
- Electrons, diffraction**
 Crystals, quantum theory, P. M. Morse—1310
 Cu crystal, H. E. Farnsworth—1131(L); satellites—1432(A)
 Relation to Compton effect, J. Kunz—129(A)
- Electrons in gases**
 Absorption coefficients, collision diameters: Cd and Zn vapors, R. B. Brode—134(A), 504; H_2 , He, A, Ne, N_2 , CO, C. E. Normand, R. B. Brode—1438(A), 1217
 Energy losses: H_2 , analysis of ions, W. Bleakney, J. T. Tate—658(A), 1180; He, Ne, ionization efficiencies, P. T. Smith, J. T. Tate—1438(A); Hg vapor, C. W. Foard—293(A), 1187; Hg vapor, analysis of ions, W. Bleakney—123(A), 139; K vapor, ionization efficiencies, J. Kuns, A. Hummel—123(A)
 Mobility and velocity: in CO, H. B. Wahlin—122(A), 1568; in H_2 , high frequency discharges, C. J. Brasefield—92, 122(A)
 Scattering, angular distribution: H and H_2 , G. P. Harnwell—285(L); He, A, H_2 , A. L. Hughes, J. H. McMillen—1438(A)
- Electrons in metals**
 Alloys, resistance, theory, L. W. Nordheim—1430(A)
 Field currents, temperature dependence, N. A. de Bruyne—172
- Electrons, photoelectric (see Photoelectric effect)**
Electrons, scattered (see Electrons in gases)
- Electrons, secondary**
 From Au, Ag, Al when bombarded by 16–40 Kv cathode rays, P. B. Wagner—98
 From contaminated surfaces, P. L. Copeland—293(A), 982
 From Ni, by impact of metastable atoms and positive ions, W. Uytterhoeven, M. C. Harrington—124(A), 438(L), 1421(A)
- Electrons, thermionic (see Thermionic emission of electrons)**
- Electro-optical effects**
 Modification of light waves by electrical oscillations on Kerr cell, L. H. Stauffer—1440(A)
- Element 87**
 Presence in pollucite and lepidolite, F. Allison, E. J. Murphy—285(L)
- Emulsions**
 Particle size, effect of pH , I. C. Weeks—668(A)
- End losses**
 Effect on characteristics of filaments, I. Langmuir, S. MacLane, K. Blodgett—478
- Faraday effect**
 Lag, method of chemical analysis, F. Allison, E. J. Murphy—124(A); search for element 87, F. Allison, E. J. Murphy—285(L)
- Ferromagnetism**
 Origin, magnetic and silicon steel, J. C. Stearns—1, 292(A)
- Field currents**
 Temperature dependence, N. A. de Bruyne—172
- Fine structure (see also Hyperfine structure)**
 BeF bands, F. A. Jenkins—315
 PbO bands, A. Christy, S. Bloomenthal—46
 Mo $K\beta$ doublet, S. K. Allison, J. H. Williams—135(A), 149
- Flarimeter**
 For testing circulatory fitness, P. V. Wells—1418(A)

Fluorescence

- C₆H₆, spectrum, F. Almasy, C. V. Shapiro—1422(A)
 Cs, third principal series line, C. Boeckner—664(A)
 Iodine, infrared, by Hg arc, F. W. Loomis—662(A)
 Sensitized, polarization, A. C. G. Mitchell—1422(A)
 X-rays, efficiency, A. H. Compton—127(A)

Gases

- Equation of state, H. J. Brennen—129(A)
 Persistence of molecular velocities, second order reactions, L. S. Kassel—261

Geiger-counters

- Multiple coincidences, M. A. Tuve—651(L)

Gelation temperature

- Starch, method of determination, E. C. McCracken—1423(A)

Geophysics (see also Atmospheric electricity)

- Composition of earth interior, A. A. Bless—1436(A)
 Earth currents, transient, and earthquake, R. Hamer—656(A)
 Ice ages, CO₂ theory, H. B. Maris—1016(L)
 Ozone concentration in atmosphere, R. Ruedy—295(A)
 Zodiacal light, theory, relation to magnetic storms, E. O. Hulburt—295(A), 663(A), 1098

Gravitation

- Mass-weight ratio of metals under strain, P. I. Wold—296(A)

Heat conductivity (see Thermal conductivity)**Heat of Dissociation (see Dissociation, heat of)****Huyghens principle**

- Applicability, G. E. Uhlenbeck—1439(A)

Hydrodynamics

- Distribution of non-reacting fluids in gravitational field, M. Muskat—1415(A), 1384
 Shatter oscillations in liquids, nature and theory, E. H. Kennard—428
 Thermal convection, R. W. Babcock—1008
 Variable flow in pipes, theory, H. Bateman—177

Hyperfine structure

- Effect on polarization of resonance radiation, A. Ellett—588
 Error in literature, S. Goudsmit—436(L)
 Mn I, observations and theory, H. E. White, R. Ritschl—208(L), 1146
 Mn, predictions, S. Goudsmit—440(L)
 Paschen-Back effect, S. Goudsmit, R. F. Bacher—129(A)
 Relations between separations, theory, S. Goudsmit, R. F. Bacher—126(A)
 Relation to nuclear spin, theory, H. E. White—441, 664(A)

Intensities in spectra

- Cd, voltage relations, D. Colson—294(A)
 Cr I, Cr II, multiplets, C. E. Hesthal—126(A)
 HCl, vibration-rotation bands, J. L. Dunham—1347
 He, continuous, maxima, J. M. Dewey—155
 He, variation with voltage, J. Razek, P. J. Mulder—1423(A), 1442(A)
 Hg, electrodeless discharge, O. P. Hart, O. Stuhlman, Jr.—1437(A)
 Hg λ 2537, variation with potential, F. C. Osten-sen—286(L)
 In Schumann region, vacuum spectrograph, G. R. Harrison—1443(A)
 Li₂, isotope effect, A. Harvey, F. A. Jenkins—789
 Multiplets, temperatures of arc, G. R. Harrison—133(A)
 Ne, multiplets, measurements, H. N. Swenson—126(A)
 Super-multiplet lines, theory, J. H. Bartlett, Jr.—229
 Ti I, measurements, O. U. Vonwiller—802

Interference

- Method of measuring distance, S. H. Chamberlain—663(A)

Interferometer

- Recording, C. W. Chamberlain—663(A)

Ionization by Impact

- H₂, by electrons, analysis of ions, W. Bleakney, J. T. Tate—658(A), 1180
 H₂, by electrons, theory, E. U. Condon—658(A)
 He, by K⁺ ions, Richard M. Sutton, J. C. Mouzon—694
 He, Ne by electrons, efficiency 0–5000 volts, P. T. Smith, J. T. Tate—1438(A)
 Hg, by electrons, efficiency of production of Hg⁺, Hg²⁺, Hg³⁺, Hg⁴⁺, Hg⁵⁺, W. Bleakney—123(A); 139
 K vapor, by electrons, efficiency, J. Kunz, A. Hummel—123(A)

Ionization by radiation (see Photoionization)**Ions**

- Accommodation coefficient, He⁺, N⁺, A⁺, on Mo surface, C. C. Van Voorhis, K. T. Compton—1438(A)
 Diffraction, H⁺ by crystals, A. J. Dempster—298(A), 1405(L)
 Motion in gases, excitation of spectra, Hg⁺ in N₂, H. D. Smyth, E. G. F. Arnott—126(A)
 Motion in gases, ionization, K⁺ in He, R. M. Sutton, J. C. Mouzon—694
 Motion in gases, neutralization, retardation, scattering, R. B. Kennard—1129(L); Cs⁺, Li⁺ in H₂ and He, J. S. Thompson—123(A), 1196; Li⁺ in Hg vapor, I. W. Cox—123(A)

- Recombination coefficient, air and oxygen, O. Luhr—1394
- Recombination with electrons, Hg^+ , A. M. Cravath—659(A)
- Reflection; H^+ from crystals, A. J. Dempster—298(A), 1405(L); Li^+ from metals, R. B. Sawyer 124(A), 1090
- Thermionic emission (see **Thermionic emission of positives**)
- Velocity, direct determination, T. R. Wilkins, J. A. Wood—657(A)
- Ions, mobility**
- In Cl_2 and Cl_2 -air mixtures, L. B. Loeb—137(A), 184
- In moist and dry air—J. Zeleny—1441(A)
- Isotopes**
- Ag and Cl, from AgCl band spectra, B. A. Brice—960
- C_{18} , from band spectra, A. S. King, R. T. Birge—133(A)
- Li, from band spectra, A. Harvey, F. A. Jenkins—789
- Metals, magneto-optical effect, F. Allison, E. J. Murphy—124(A)
- N_{18} , from band spectra, S. M. Naude—130(A)
- O_{17} , disintegrative synthesis, W. D. Harkins, A. E. Schuh—130(A); origin, S. C. Lind—1408
- Pb, effect in PbO bands, S. Bloomenthal—34
- Regularities in nuclei, H. A. Barton—408; in radioactive nuclei, H. C. Urey, H. Johnston—869(L)
- Vibrational shift in band spectra, R. T. Birge—133(A)
- Joule-Thomson coefficient**
- Air, J. R. Roebuck—121(A)
- Real gases, simple equation, J. A. Beattie—643
- Kerr effect**
- Alternating fields, modulation of light wave, L. H. Stauffer—1440(A)
- In gases, pressure variation, J. W. Beams, E. C. Stevenson—1440(A)
- X-ray study of molecular orientation, R. L. McFarlan—211(L), 1426(A), 1469
- Kinetic theory of gases**
- Equation of state, H. J. Brennan—129(A)
- Molecular velocities, direct measure, I. F. Zartman—134(A)
- Persistence of velocities, second order gas reactions, L. S. Kassel—261
- Light waves**
- Modification by electrical oscillation on Kerr cell, L. H. Stauffer—1440(A)
- Huyghen's principle, applicability, G. E. Uhlenbeck—1439(A)
- Luminescence**
- Chemiluminescence of Na, J. W. Woodrow, R. M. Bowie—1423(A)
- Magnetic fields**
- High frequency, intensity measurements, R. H. Mortimore—753
- Magnetic storms (see Geophysics)**
- Magnetic properties**
- Barkhausen effect, propagation along wires, K. J. Sixtus, L. Tonks—1440(A); size of discontinuities, R. M. Bozorth, J. F. Dillinger—733
- Bi, influence of magnetic field on crystal formation, A. Goetz—193
- Co, thin films, E. P. T. Tyndall, W. W. Wertzbaugher—292(A)
- Ferromagnetism, search for origin, J. C. Stearns—1, 292(A)
- Moment of Li nucleus, S. Goudsmit, L. A. Young 1418(A)
- Moment of sulphur molecule, E. J. Shaw, T. E. Phipps, W. H. Rodebush—1126(L)
- Permalloy, effect of stress on resistance in magnetic field, L. W. McKeehan—657(A)
- Rb, susceptibility, C. T. Lane—977
- Steel, temperature changes accompanying magnetization, W. B. Ellwood—1440(A)
- Susceptibility of gases, pressure dependence, Francis Bitter—1572
- Magneto-optical effects**
- Faraday effect, lag, search for element 87, F. Allison, E. J. Murphy—285(L)
- Method of chemical analysis, F. Allison, E. J. Murphy—124(A)
- Magnetostriction**
- Measurements by heterodyne method, A. B. Bryan, C. W. Heaps—298(A)
- Mathematics**
- Least squares, application, W. E. Deming—665(A)
- Matter**
- Electrons and protons, theory; J. R. Oppenheimer—562(L)
- Equilibrium with radiation in universe, L. S. Kassel—778
- Interaction with field, J. R. Oppenheimer—461

Recombination

- Alpha-particles and electrons, measurements, A. H. Barnes—217; A. H. Barnes, B. Davis, H. L. Hull—1433(A); explanation, W. Band—1128(L); theory, E. C. G. Stueckelberg, P. M. Morse—116(L), 659(A)
- Ions and electrons, Hg^+ , A. M. Cravath—659(A)
- Ions and ions, air and oxygen, O. Luhr—1394

Rectifiers

- Characteristics, R. Ruedy—129(A)
- Contact, cupric sulphide-magnesium junctions, M. Bergstein, J. F. Rinke, C. M. Gutheil—1425(A)

Reflection of corpuscles

- Alkali metal atoms, from crystals, J. B. Taylor—375

Atoms, from crystals, A. Ellett—293(A)

H atoms, attempt to detect de Broglie waves, T. H. Johnson—1432(A)

H atoms from LiF crystal, T. H. Johnson—1299(L), 1444(A)

H^+ , by crystals, A. J. Dempster—298(A), 1405(L)

Li^+ from metal surfaces, R. B. Sawyer—124(A), 1090

Molecules, diffraction by crystals, O. Stern—298(A)

Zn atoms from NaCl, H. A. Zahl—293(A)

Reflection of light

$SmCl_3 \cdot 6H_2O$ comparison with absorption at high and low temperatures, S. Freed, F. H. Spedding—212(L)

Refractive index

H_2O and KCl solution at high frequencies, F. H. Drake, G. W. Pierce, M. T. Dow—613

Au, for $C K\alpha$ x-rays, E. Dershem—128(A)

Relativity

Aberration of light from terrestrial sources, N. Galli-Shohat—664(A)

Field and matter, interaction, J. R. Oppenheimer—461

General, energy-momentum principle, R. C. Tolman—875; entropy principle—896; weight of thermal equilibrium—904

Michelson-Morley experiment, suggested explanation, N. Galli-Shohat—1418(A)

Relation to aether drift, W. F. G. Swann—127(A), 336

Transformation of oscillation to travelling wave, de Broglie's postulate, V. Karapetoff—127(A)

Unified field theory and wave mechanics, W. Band—1015(L)

Unified field theory, Schwarzschild's solution, M. Salkover—I 209(L), II 214(L), reply, M. S. Vallarta—435(L)

Unified physical field, W. Band—115(L)

Resolving power

Calcite, for x-rays, S. K. Allison, J. H. Williams—1476

Crystal grating, limits, B. Davis—209(A)

Resonance radiation

Cs, third principal series line, quenching, C. Boeckner—664(A)

Hg, absorption in Hg vapor, A. R. Thomas—1253

Polarization, effect of hyperfine structure, A. Ellett—588

Scattering of light (see also Raman effect)

In Na vapor, S. A. Korff—435(L)

Schottky effect (see also Photoelectric effect, Thermionic emission)

Thoriated tungsten, N. B. Reynolds—158

Sedimentation

Equilibria of colloidal particles, N. Johnston, L. G. Howell—274

Shatter oscillations

Nature and theory, E. H. Kennard—428

Shot effect

Abnormal, in gas discharge, J. S. Donal, Jr.—1430(A)

Of positive ions, effect on space charge limited electron current, L. P. Smith—1430(A)

Oxide-coated filaments, H. N. Kozanowski—1430(A)

Snow flakes

Origin, J. M. Adams—113(L)

Solar physics

Anomalous rotation of sun, R. Gunn—635

Spark discharge

Early stages, time of appearance of spectra, temperature, ion concentration, E. O. Lawrence, F. G. Dunnington—134(A), 396

Initial stages, time lag in characteristics, J. W. Beams, J. C. Street—658(A)

Time differences in appearance of spectrum lines, J. W. Beams—24

Time lags at overvoltages, J. C. Street—1437(A)

Specific heats

Gases, variation with pressure, E. J. Workman—667(A)

Solid organic compounds from Raman spectra, D. H. Andrews, J. C. Southard—670(A)

Spectra, atomic

Alkali atoms, Stark effect and electron spin, theory, V. Rojansky—782

C I, ionization potential, J. J. Hopfield—1586(L)

Cd, voltage-intensity relations, D. Colson—294(A)

Co II, analysis, J. H. Findlay—1420(A)

Complex spectra, method of calculating, W. V. Houston—136(A)

Cr I, Cr II, intensities in multiplets, C. E. Hesthal—126(A)

Cs, resonance and quenching of third principal series line, C. Boeckner—664(A)

Excitation, in hollow cathode, R. A. Sawyer—1421(A)

GdCl₂·6H₂O, line spectra from solid, S. Freed, F. H. Spedding—1408(L)

H, variation with pressure and capacitance, E. O. Hulburt—1420(A)

He, H, N, O, 600–1100 Å, J. J. Hopfield—1133(L)

He, continuous, intensity maxima, J. M. Dewey—155

He, intensities, J. Razek, P. J. Mulder—1423(A)

He, intensity-voltage relations, P. J. Mulder, J. Razek—1442(A)

Hg, average lives of 2^3P-2^3S triplet, R. H. Randall, H. W. Webb—665(A)

Hg, intensity potential relations for $\lambda 2537$, F. C. Ostensen—286(L)

Hg $2^3P_{012}-2^3S_1$, mean lives, R. H. Randall, H. W. Webb—665(A), 1161

Hg, relative intensities in electrodeless discharge, O. P. Hart, O. Stuhlman, Jr.—1437(A)

Hg I, new term, E. D. McAlister—1585(L)

Hyperfine structure and nuclear spin, H. E. White—441, 664(A)

Hyperfine structure, error in literature, S. Goudsmit—436(L)

Hyperfine structure, Paschen-Back effect, S. Goudsmit, R. F. Bacher—129(A)

Hyperfine structure, relations between separations, S. Goudsmit, R. F. Bacher—126(A)

In II, measurements and classification, R. J. Lang—126(A)

In spark discharge, time of appearance of lines, J. W. Beams—24

Interval ratios, rule for *sp*, *sd*, *sf*, configurations, E. U. Condon, G. H. Shortley—1419(A), 1342

Li, magnetic moment of nucleus, S. Goudsmit, L. A. Young—1418(A)

Lu, regularities, W. F. Meggers, B. F. Scribner—1420(A)

Mn, hyperfine structure, H. E. White, R. Ritschl—208(L)

Mn I, hyperfine structure, H. E. White, R. Ritschl—1146

Mn, prediction of hyperfine structure, S. Goudsmit—440(L)

Multiplets, extension of Houston's and Slater's relations, S. Goudsmit—1325

Multiplets, intensities, temperature of arcs, G. R. Harrison—133(A)

Na III, Mg IV, Mg V, for ultraviolet, new levels, irregular doublet law, J. E. Mack, R. A. Sawyer—229, 661(A)

Ne, intensities, H. N. Swenson—126(A)

Pd, surplus level, A. G. Shenstone—1420(A)

Rare earths, origin of line absorption spectra, O. Laporte—130(A)

Resonance separations in p^5s and d^5s configurations, O. Laporte, D. R. Inglis—1337

Ru I, analysis, W. F. Meggers, A. G. Shenstone—868(L)

Rydberg formula, generalization, R. M. Langer—649(L)

Sb III, Sn II, classification, R. J. Lang—445, 664(A)

SmCl₃·6H₂O, reflection and absorption, S. Freed, F. H. Spedding—212(L)

Spark discharge, time of appearance of lines, E. O. Lawrence, F. G. Dunnington—134(A), 396

- Stark effect near series limit, J. Dewey—1439(A)
 Super-multiplet lines, intensities, J. H. Bartlett, Jr.—229
 Temperature shift and pole effect in vacuum arc, F. T. Holmes—652(L)
 Tl I, intensity measurements, O. U. Vonwiller—802
 Tl II, extinction and analysis, S. Smith—235
Spectra, molecular (see also **Raman effect**)
 Acetylene, ethylene, 6800-9200A, R. M. Badger—1433(A)
 AgCl, analysis, B. A. Brice—960
 Air, afterglow, J. Kaplan—600
 BeF, wave-lengths, analysis, molecular constants, F. A. Jenkins—315
 CaH, red bands, Zeeman effect, W. W. Watson, W. Bender—1440(A), 1513
 Cd₂, heat of dissociation, J. G. Winans, R. Rollefson—1436(A)
 C₆H₆ fluorescence, F. Almasy, C. V. Shapiro—1422(A)
 C₆H₆, electronic transitions, C. V. Shapiro, R. C. Gibbs, J. R. Johnson—1422(A)
 C₆H₆, emission 2500-3000A, J. B. Austin, I. A. Black—452
 CO, comet tail bands, emitter, L. R. Maxwell—665(A)
 CO, fourth positive bands, new measurements and classification, R. S. Estey—309
 CO, fourth positive bands, wave-lengths, L. B. Headrick, G. W. Fox—1033
 CO, new band system, J. Kaplan—1298(L)
 Cyclohexane, vibration doublets, J. W. Ellis—437(L)
 Excited radicals in compounds, constancy of vibration frequencies, C. P. Snow—563(L)
 H₂ absorption 600-1100A, J. J. Hopfield—1133(L)
 H₂, (B-A) bands, resonance, H. H. Hyman—1419(A)
 HCl, vibration-rotation bands, intensities, J. L. Dunham—1347
 Hg band at 2540, origin, R. Rollefson—1177
 Iodine, fluorescence, infrared, by Hg arc, F. W. Loomis—662(A)
 Isotope shift, R. T. Birge—133(A)
 Li₂, blue-green absorption, A. Harvey, F. A. Jenkins—132(A), 789
 MgH, λ 2511 band, Zeeman effect, G. M. Almy, F. H. Crawford, E. L. Hill—124(A)
 MgO, blue-green, analysis, P. N. Ghosh, P. C. Mahanti, B. C. Mukkerjee—1491
 N₂, afterglow, R. Ruedy—125(A)
 N₂, excited by positive ion impact, H. D. Smyth, E. G. F. Arnott—126(A)
 NH₃, absorption in visible, R. M. Badger—1038
 NH₃, evidence of two molecular types, J. W. Ellis—595
 OH bands, Zeeman effect, G. M. Almy—1495
 O₂, atmospheric new absorption band, H. D. Babcock—125(A)
 Organic liquids, absorption, infrared, E. K. Plyler, T. Burdine—605
 Organic liquids, C-H vibration, Raman effect, R. B. Barnes—662(A)
 Organic liquids, intensity and position of overtones, P. E. Shearin—973
 PbO, fine structure analysis, A. Christy, S. Bloomenthal—46
 PbO, quantum analysis and isotope effect, S. Bloomenthal—34
 Predissociation from high rotational states, D. S. Villars, E. U. Condon—1028
 SmCl₃·6H₂O, reflection and absorption, S. Freed, F. H. Spedding—212(L)
Spectra, reflection
 SmCl₃·6H₂O, comparison with absorption, S. Freed, F. H. Spedding—212(L)
Spectrograph, Spectrometer
 Infrared, resolving power, R. B. Barnes, A. H. Pfund—1434(A)
 Vacuum, for intensity measurements in Schumann region, G. R. Harrison—1443(A)
 X-ray, two-crystal, F. K. Richtmyer, S. W. Barnes, E. Ramberg—1428(A)
 X-ray, multiple crystals, J. DuMond, H. Kirkpatrick—136(A); adjustments and tests, H. Kirkpatrick, J. DuMond—136(A)
 X-ray, vacuum, C. E. Howe—1428(A)
Stark effect
 Alkali atoms, electron spin, theory, V. Rojansky—782
 Hydrogen atom, theory, F. G. Slack 1170
 Near series limit, J. Dewey—1439(A)
Stars (see **Astrophysics**)
Sun (see **Astrophysics**)
Surface tension
 Glass, molten, W. B. Pietenpol, H. H. Scott—296(A)
 Retention of liquids in assemblages of homogeneous spheres, W. O. Smith, P. D. Foote, P. F. Busang—1416(A)
Susceptibility, magnetic (see **Magnetic properties**)
Thermal conductivity
 Solution of general equation for certain cases, R. L. Peek, Jr.—554
Thermal convection
 In fluids, R. W. Babcock—1008
Thermal expansion
 Carbonyl, measurements, P. Hidnert—120(A)

- Cu-Ni-Sn alloy, P. Hidnert, W. T. Sweeney—667(A)
- Pb, measurement, P. Hidnert, W. T. Sweeney—296(A)
- Thermal radiation**
Of glass for $\lambda > 50\mu$, C. H. Cartwright—415
- Thermionic emission of electrons**
Composite surfaces, work function, effect of fields, W. B. Nottingham—1128(L); ion-grid theory, J. A. Becker, 1431(A)
Electron density distribution in equilibrium with hot body, A. T. Waterman—668(A)
From various filaments, effect of end losses, I. Langmuir, S. MacLane, K. B. Blodgett—478
Oxide-coated filaments, characteristics, E. F. Lowry—668(A), role of base metal, E. F. Lowry—121(A), 1367; shot effect, H. N. Kozanski—1430(A)
Pt-coated glass filaments, characteristics, A. K. Brewer—1360
Relation to surface heat of charging, K. F. Herzfeld—248
Shot effect, abnormal, in Ne gas, J. S. Donal, Jr.—1430(A)
Thoriated tungsten, variation with extent of thoriation, W. H. Brattain—1431(A); contact e.m.f., Schottky effect, N. B. Reynolds,—158
Work function, space charge interpretation, R. S. Bartlett—669(A)
- Thermionic emission of positives**
From thoriated tungsten, H. B. Wahlin—653(L)
From W and Mo, characteristics, L. P. Smith—381
Shot effect, effect on space charge limited electron currents, L. P. Smith—1430(A)
- Thermodynamics**
Dalton-Gibbs law, test, L. J. Gillespie—1435(A)
Entropy in general relativity, R. C. Tolman—896
Equation of state for gases, H. J. Brennen—129(A)
Excitation of nerves, theory, N. Rashevsky—1435(A)
Homogeneous coordinates, uses, H. J. Brennan—294(A)
Joule-Thomson effect, theory, J. A. Beattie—643; measurements with air, J. R. Roebuck—121(A)
Mixtures of real gases, theory, J. A. Beattie—1435(A)
Nernst heat theorem, H. J. Brennen—121(A)
Simultaneous irreversible processes, L. Onsager—666(A)
Systems with several equilibria, N. Rashevsky—666(A)
Third law, W. H. Rodebush—210(L)
- Thermoelectric properties**
Bi crystals, Peltier and Thomson effects, H. D. Fagan, T. R. D. Collins—421
- Thermoregulator**
For low temperatures, R. B. Scott, F. G. Brickwedde—670(A)
Photoelectric, F. G. Brickwedde, R. B. Scott—670(A)
Thomson effect in Zn crystals, L. A. Ware—667(A), 989
- Thomson effect** (see **Thermoelectric properties**)
- Transitions, radiative**
Probability, theory, J. R. Oppenheimer—939
- Ultrasonic waves**
Velocity measurements, C. D. Reid—814
- Uncertainty principle**
In acoustics, G. W. Stewart—1441(A)
Formulation and classical interpretation, H. P. Robertson—667(A)
- Vacuum tubes**
For high-voltages, M. A. Tuve, G. Breit, L. R. Hafstad—66; M. A. Tuve, L. R. Hafstad, O. Dahl—1406(L)
Grid-glow tube relays, D. D. Knowles, S. P. Sashoff—1431(A)
- Valence**
Valence electrons in diamond, location, M. L. Huggins, R. Parrish—136(A)
- Viscosity**
Dependence on molecular space arrangement, R. L. Edwards, G. W. Stewart—291(A)
Of compressed gases, J. H. Boyd, Jr.—1284
- Voltmeter**
Vacuum tube, improvements, R. H. Mortimore—753
- Wave equation**
Huyghens principle, G. E. Uhlenbeck—1439(A)
- Work function** (see **Thermionic emission**)
- X-rays, absorption**
Au, for $K\alpha$, E. Dershem—128(A)
Temperature independence, J. A. Bearden—1443(A), 1463
- X-rays, diffraction, reflection and scattering** (see also **Compton effect**)
Alcohols, molecular association, G. W. Stewart—296(A), 726
Alcohols, relation to viscosity, R. L. Edwards, G. W. Stewart—291(A)
Calcite, glancing angle for $AgK\alpha$, C. D. Cooksey, D. Cooksey—564(L)
Compton effect, position and width of modified line, F. L. Nutting—661(A)
Crystals of colloidal size, form of bands, theory, C. C. Murdock—8
Diamond, Valence electrons, M. L. Huggins, R. Parrish—136(A)
Fe crystal, magnetized and unmagnetized, J. C. Stearns—1, 292(A)

- Fe, Ni, Cu atoms, R. W. G. Wyckoff—215(L)
 Glass, C. $K\alpha$ line, J. Thibaud—1452
 He, distribution of electrons, A. H. Compton—1427(A)
 Liquids, effect of electric field, R. L. McFarlan—211(L), 1426(A), 1469
 Liquids, organic mixtures, A. W. Meyer—291(A)
 Liquids, organic, temperature effect, E. W. Skinner—128(A)
 Magnetite and silicon steel, magnetized and unmagnetized, J. C. Stearns—1
 MgO, electron distribution, E. O. Wollan—1019
 NaCl, electron distribution in Cl, G. G. Harvey, G. E. M. Jauncey—1427(A)
 NaCl, temperature effect, W. D. Claus—1427(A)
 Ni, O, in NiO, R. W. G. Wyckoff—583
 Quartz, C $K\alpha$, E. Dershem, M. Schein—292(A)
 Spectra, N. S. Gingrich—1444(A)
 Spectroscopic analysis, J. A. Bearden—1427(A)
 Theory, relation to electron distribution in atoms, A. H. Compton—925, 1427(A)
 Triphenylmethane, G. W. Stewart—291(A)
 Water, molecular association, G. W. Stewart—1426(A)
- X-rays, emission**
 Efficiency, W. W. Nicholas—128(A)
 From three-element tube, A. Bramley—869 (L)
 Mechanism, W. Band—1129(L)
- X-rays, fluorescence**
 Efficiency, A. H. Compton—127(A)
- X-rays, photoelectric effect**
 Relation to J phenomenon, T. H. Osgood—1407(L)
 Space distribution of K and L electrons, C. D. Anderson—1139
- X-rays, photographic effect**
 Theory, A. P. H. Trivelli—662(A)
- X-rays, polarization**
 From thin Al anticathode, B. Dasannacharya—129(A)
- X-rays, refraction**
 Au, for $K\alpha$, E. Dershem—128(A)
- X-rays, spectra and Spectroscopy**
 Absolute measure of wave-lengths, J. M. Cork—128(A)
 Ag $L\alpha$ satellites, excitation potential, S. W. Barnes, F. K. Richtmyer—661(A)
 By double crystal, N. S. Gingrich—1444(A)
 Ca, Cr, Mn, Co, Ni, Cu, Zn, K absorption, fine structure, B. Kievit, Jr., G. A. Lindsay—292(A)
 Cu, Mo, Ag K lines, structure, J. Valasek—291(A)
 Effect of nuclear spin on term values, theory, G. Breit—1447
 Instrument for high-voltage, F. Sillers, Jr.—1428(A)
 $K\alpha$ satellites of Ni I As, F. K. Richtmyer, E. Ramberg—661(A)
 Limiting resolving power of crystal grating, B. Davis—209(L)
 L series, Ca to Zn, measurements, C. E. Howe—717
 Mo $K\alpha$, natural width, S. K. Allison, J. H. Williams—1476
 Mo $K\beta$ doublet, separation and fine structure, S. K. Allison, J. H. Williams—135(A), 149
 Mo L series, wave-lengths by ruled grating, J. M. Cork—1456
 Scattered x-rays, N. S. Gingrich—1444(A)
 Spectrograph and radiograph, F. Sillers, Jr.—1428(A)
 Spectrograph, multiple crystal, J. DuMond, H. Kirkpatrick 136(A); adjustments and tests, H. Kirkpatrick, J. DuMond—136(A)
 Spectrograph, vacuum, C. E. Howe—1428(A)
 Spectrometer, two-crystal, F. K. Richtmyer, S. W. Barnes, E. Ramberg—1428(A)
- Young's modulus**
 Under small stresses, D. K. Frohman—120(A), 264
- Zeeman effect**
 CaH bands, W. W. Watson, W. Bender—1440(A), 1513
 Hyperfine structure, Paschen-Back effect, S. Goudsmit, R. F. Bacher—129(A)
 $GdCl_3 \cdot 6H_2O$, line spectra of solid, Paschen-Back effect, S. Freed, F. H. Spedding—1408 (L)
 MgH $\lambda 5211$ band, G. M. Almy, F. H. Crawford, E. L. Hill—124(A)
 OH bands, G. M. Almy—1495
- Zodiacal light**
 Theory, E. O. Hulburt—295(A), 663(A), 1098
